Figure 1. Image of male (top) and female (bottom) *Atlanticoncha ochracea* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

The Tidewater Mucket (*Atlanticoncha ochracea*) was reassigned into the genus *Atlanticoncha* in Smith et al. (2020). The Freshwater Mussel Conservation Society recognized this name change in the 2023 Freshwater Mussel Name List. The scientific name was changed from Leptodea ochracea as it appeared in the 2015 SWAP.

The Tidewater Mucket is usually small but can reach up to about 4 inches in length (Bogan and Alderman 2004, 2008). The shell is elliptical to ovate with a rounded anterior margin and an evenly rounded ventral margin. The posterior ridge is well developed and ends in a blunt point about halfway up from the base (Figure 1). The species is sexually dimorphic. Shells of males are more elliptical with the posterior margin somewhat pointed; shells of females are more ovate with a truncated posterior margin. The outer surface of the shell is a dull and yellowish/grayish/greenish- or brownish-olive, sometimes with fine grayish or greenish rays. The inner surface of the shell is white to reddish pink.

The Tidewater Mucket is fairly distinct; however, it can sometimes be confused with Lampsilis cariosa, especially when handling live specimens. The Yellow Lampmussel has a waxier periostracum and does not get thin rays on the entirety of the shell. The Tidewater Mucket is also an overall thinner shelled species and internally has thin and elongated pseudocardinal teeth. Atlanticoncha ochracea pseudocardinal teeth are situated far forwards of the umbo versus almost directly under the umbo in L. cariosa.

Status

The Tidewater Mucket is currently assigned a global ranking of vulnerable to apparently secure (G3/G4) (NatureServe 2024). This mussel is ranked as critically imperiled (S1) in some of its northern ranges but ranked imperiled (S2) in North Carolina and vulnerable (S3) in Georgia (NatureServe 2024). It is currently ranked imperiled to vulnerable (S2S3) in South Carolina.

POPULATION SIZE AND DISTRIBUTION

The Tidewater Mucket is found in coastal rivers, lakes, ponds, and shallow-moving sections of rivers from Nova Scotia to the Savannah River in Georgia. Historically, it has been found in the Waccamaw and Savannah Rivers in South Carolina (Bogan and Alderman 2004, 2008). In 2004 it was found in the Pee Dee River in North Carolina just above the South Carolina State Line and in the lower Little Pee

Dee River in South Carolina (Figure 2). We have a total of 19 reported observations of the species from 2004-2019. Targeted surveys in the coastal plains with suitable habitat are needed for this species.

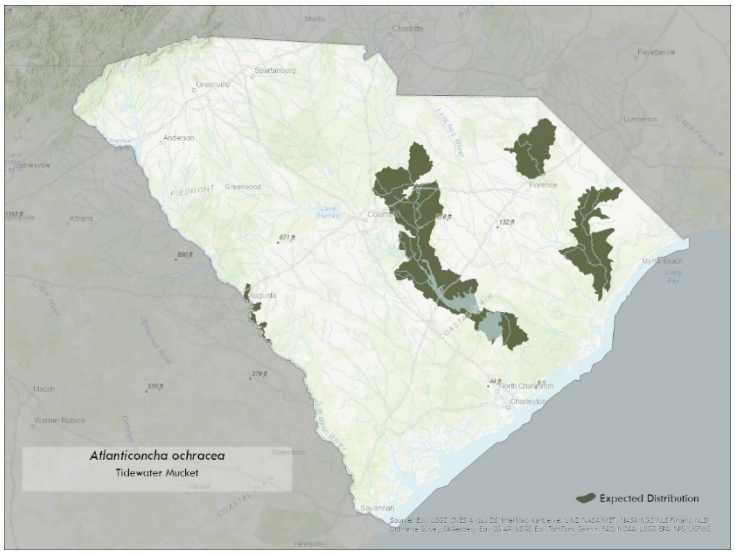

Figure 2. Expected distribution of *Atlanticoncha ochracea* based on reported observations at a HUC 10 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Tidewater Mucket tends to be found on the lower coastal plain, often in water with tidal influence, but always in freshwater. It has been typically found in pristine rivers.

Tidewater Mucket are presumed long-term brooders, spawning in the fall and releasing glochidia the following spring (Nedeau et al. 2000). Reported host fishes in laboratory conditions include Banded Killifish, White Perch, and Yellow Perch (Kneeland 2006; Wick 2006). In 2008, Kneeland and Rhymer confirmed glochidia of A. ochracea on all three host species mentioned previously in wild populations with White Perch being most heavily infested with glochidia.

CHALLENGES

Like other freshwater mussels, this species is sensitive to channel modification, agriculture and urban pollution, sedimentation, and saltwater intrusion. Additionally, A. ochracea uses a semi-anadromous species of fish as its host, the white perch, (Kneeland 2006, 2008). White perch that are not locked by reservoirs migrate from estuaries to freshwater to spawn. This movement inland allows the Tidewater Mucket to maintain native ranges. Channel modifications and fragmented habitats directly impact the only method of dispersal by the species.

Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the Tidewater Mucket currently.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to document the extent of distribution and population size and range of the Tidewater Mucket.
- Explore the need to upgrade the listing of the Tidewater Mucket in South Carolina,

based on survey results.
- Determine habitats that are critical for this species in South Carolina.
- Perform host fish trials to determine natural hosts for native populations.
- Conserve populations of host fish to insure reproduction of the Tidewater Mucket in the wild.
- Protect critical habitats for the Tidewater Mucket from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Tidewater Mucket.
- Encourage responsible land use planning.
- Determine the effects of saltwater intrusion.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Tidewater Mucket to various point and non-point sources of pollution and land use impacts.
- Conduct a thorough search of museum records for the Tidewater Mucket and determine if there are any additional historical records for this species.
- Conserve populations of host fish to insure reproduction of the Tidewater Mucket in the wild.
- Develop a restoration plan that considers the need for augmentation or reintroduction.
- Consider species needs when participating in the environmental permit review process.

MEASURES OF SUCCESS

- Completion of targeted surveys in areas of historic occupancy and similar habitat types.
- Work to reduce or halt further disturbance to the habitat and natural hydrology of occupied rivers.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Comprehensive, range-wide genetic analysis of the species.
- Completion of thorough, standardized surveys in presumed range and habitat of the species.
- Determination of host fishes used for reproduction of the Tidewater Mucket.
- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Tidewater Mucket.
- Determine the effects of channel modification, such as dams, on the Tidewater Mucket.
- Determination of environmental and toxicological tolerances and endpoints.

Carolina Slabshell

Elliptio congaraea
(Lea 1831)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Morgan Kern and Ericah Beason (SCDNR)

Figure 1. Images of *Elliptio congaraea* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

The Carolina Slabshell belongs to one of the largest genera in the Unionidae family in North America with 31 species recognized in North America, Canada, and Mexico as of 2023 (FMCS 2023). The overlapping morphological variations between species and limited comprehensive genetic and morphological analysis make it difficult to tease apart valid *Elliptio* species and their ranges. Large synonymies of Elliptio species without adequate, range-wide genetic confirmation also make conservation recommendations difficult.

Oftentimes, *Elliptio* species in South Carolina fall under 3 "groups" that are characterized by generalizations of overall morphological traits. These groups are not based on comprehensive genetic and morphological research, but years of observation of morphological traits and are simply a means to aid in the understanding of morphological types seen through the *Elliptio* genus. A working list of the *Elliptio* of South Carolina can be found in Bogan and Alderman (2008).

The three groups are the lanceolata, the complanata, and icterina. The lanceolates group is comprised of species that have a greater length to heigh ratio than the complanates and include species such as *Elliptio angustata*, *Elliptio producta,* and *Elliptio folliculata*. The complanates group is comprised of species that are rather rectangular to subrhomboidal in shell outline and usually compressed; species in this group include those such as *Elliptio complanata*, *Elliptio roanokensis*, *E. fraterna*, *E. congaraea,* and *Elliptio hopetonensis*. Lastly, species in the icterina group are typically smaller in overall size, inflated, and have a waxy, dark exterior with a prominent posterior ridge; species in this group recognized to occur in South Carolina include *Elliptio icterina* and species that were synonymized by Johnson (1970).

The Carolina Slabshell, like other species of *Elliptio,* has taxonomic difficulties and challenges have been ongoing with *E. congaraea, E. waccamawensis, E. complanata* and *E. fraterna*. In (2017), Williams et al. consider *E. congaraea* a valid taxa and *E. waccamawensis* a synonym for *E. congaraea* with supporting molecular evidence from McCarty et al (2016). The results of the genetic analysis did not provide enough evidence to separate individuals between the lake form once called Waccamaw Spike and the river morphologies found downstream. Williams et al. (2017) recognizes the common name Carolina Slabshell and not Carolina Elephantear as the species appears in the 2015 SWAP. There are ongoing concerns with *E. congaraea* and whether it is distinct from *E. fraterna* and *E. complanata,* but comprehensive genetic analysis has not occurred.

The shell of the Carolina Slabshell (Figure 1) has two described morphologies. The river morphology is more compressed with an umbo or beak that is slightly elevated above the hinge line with sculpturing of parallel undulations or wrinkles on the posterior slope. The pseudocardinal and lateral teeth are present. The umbo or

beak cavity is not deep. The posterior ridge is high and angled. The outer surface of the shell is greenish-yellow or tawny and is usually rayed. The shape of the shell is rhomboid. The inner surface of the shell is purplish (Bogan and Alderman 2004, 2008). The lake morphology is inflated with a prominent umbo or beak and angular posterior ridge. The ventral margin is straight. The pseudocardinal and lateral teeth are present. The shell is elliptical in shape. The outer surface of the shell is light to dark brown and smooth; the inner surface is white to bluish (Bogan and Alderman 2004, 2008).

Status

NatureServe (2024) currently identifies the species having a global ranking of vulnerable (G3). In North Carolina and Georgia, the species is ranked vulnerable (S3) and in South Carolina, the species is ranked apparently secure (S4).

POPULATION SIZE AND DISTRIBUTION

This species ranges from the Ogeechee Basin in Georgia to the Chowan River Basin in Virginia (Bogan and Alderman 2004, 2008). Carolina Slabshell is found in most river basins in South Carolina and can be recovered in low to moderate numbers at sites it is present (Figure 2).

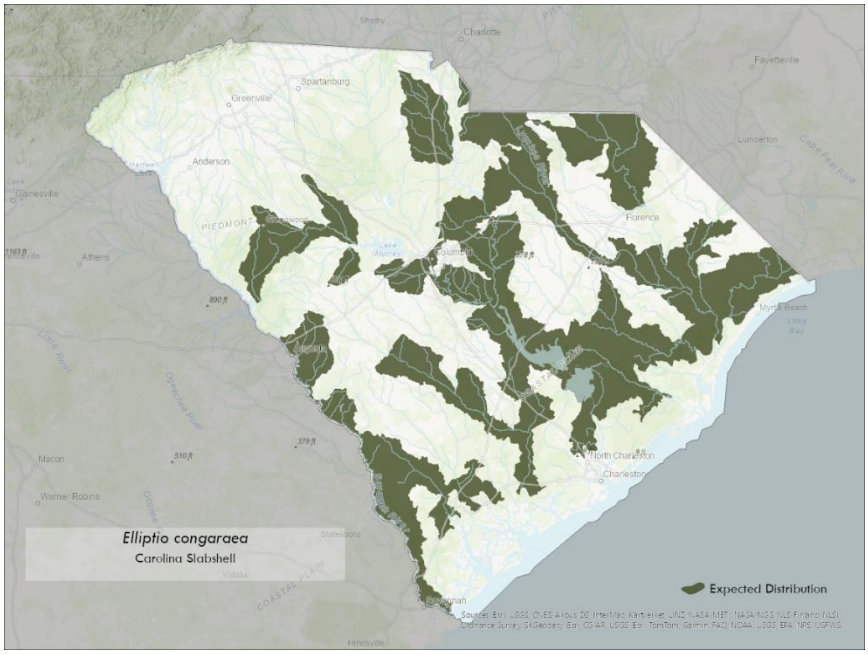

Figure 2. Expected distribution of *Elliptio congaraea* based on reported observations at a HUC 10 watershed level and designated ecoregion.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Carolina Slabshell species is found in a variety of habitats, including rivers, lakes, and small streams. Johnson (1970) notes the species in sandy substrates in swift water of medium sized rivers to smaller creeks. This species can be found in many substrates, preferring sandy substrate (Bogan and Alderman 2008). The Carolina Slabshell (*Elliptio congaraea*) does not tolerate silt substrates and prefers slow-moving velocities, hydrology that is often lost due to impoundments and stream channelization (Pandolfo et al. 2016).

Gravid females have been observed brooding from May to July in Lake Waccamaw (Bogan and Alderman 2008). The host fish(es) for this species are unknown.

CHALLENGES

There is still much taxonomic uncertainty in the *Elliptio* genus which exhibits highly variable shell morphology. While the *Elliptio* genus is largely recognized as monophyletic, many species designations within the genus have yet to be tested and are based only on morphology. While the relationship of Carolina Slabshell and the formerly recognized Waccamaw Spike has been evaluated, the relationship of the species to the rest of the genus remains unclear (Williams et al. 2017). Classifications in this genus will require genetic testing that includes representative specimens of all *Elliptio* species from across their ranges.

Little is known about the reproductive and brooding behaviors of *E. congaraea,* and wild host fish(es) are unknown.

Like other freshwater mussels, the Carolina Slabshell is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The host fish(es) for the Carolina Slabshell are unknown, but like other freshwater mussels, the Carolina Slabshell must have adequate access to species-specific hosts and relies on host fish(es) for reproduction and distribution. Maintaining stream connectivity for host fish(es) is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are currently no significant conservation accomplishments specifically for the Carolina Slabshell.

CONSERVATION RECOMMENDATIONS

- Continue monitoring populations of Carolina Slabshell in South Carolina.
- Conduct genetic analyses to determine the relationship between the Carolina Slabshell and other species in the genus *Elliptio*.
- Perform host fish trials to determine natural hosts for native populations.
- Conserve populations of host fish to insure propagation of the Carolina Slabshell in the wild.
- Protect critical habitats for the Carolina Slabshell from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Carolina Slabshell.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Determine the life history of the Carolina Slabshell including time of spawning and brooding.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

- Determine the effects of channel modification, such as dams, on the Carolina Slabshell.
- Determine the environmental and toxicological tolerances and endpoints.

MEASUREMENTS OF SUCCESS

- Completion of targeted surveys where historic occupancy or suitable habitat for host fish.
- Collection of genetic swabs of Carolina Slabshell to ensure successful identification of species range and distribution.
- Development of a list of habitats where populations of Carolina Slabshell exist in South Carolina.
- Determining or confirming host species of Carolina Slabshell in South Carolina.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determination of the effects of channel modification, such as dams, on the Carolina Slabshell.
- Determination of environmental and toxicological tolerances and endpoints.
- Determination of life history of the Carolina Slabshell including time of spawning and brooding.

Pod Lance

Elliptio folliculata (Lea, 1838)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason (SCDNR)

Figure 1. Image of *Elliptio folliculata* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

The Pod Lance belongs to one of the largest genera in the Unionidae family in North America with 31 species recognized in North America, Canada, and Mexico as of 2023 (FMCS 2023). The overlapping morphological variations between species and limited comprehensive genetic and morphological analysis make it difficult to tease apart valid *Elliptio* species and their ranges. Large synonymies of Elliptio species without adequate, range-wide genetic confirmation also make conservation recommendations difficult.

Oftentimes, *Elliptio* species in South Carolina fall under 3 “groups” that are characterized by generalizations of overall morphological traits. These groups are not based on comprehensive genetic and morphological research, but years of observation of morphological traits and are simply a means to aid in the understanding of morphological types seen through the *Elliptio* genus. A working list of the *Elliptio* of South Carolina can be found in Bogan and Alderman (2008).

The three groups are the lanceolata, the complanata, and icterina. The lanceolates group is comprised of species that have a greater length to heigh ratio than the complanates and include species such as *Elliptio angustata*, *Elliptio producta,* and *Elliptio folliculata*. The complanates group is comprised of species that are rather rectangular to subrhomboidal in shell outline and usually compressed; species in this group include those such as *Elliptio complanata*, *Elliptio roanokensis*, *E. fraterna*, *E. congaraea*, and *Elliptio hopetonensis*. Lastly, species in the icterina group are typically smaller in overall size, inflated, and have a waxy, dark exterior with a prominent posterior ridge; species in this group recognized to occur in South Carolina include *Elliptio icterina* and species that were synonymized by Johnson (1970).

The Pod Lance, like other species of *Elliptio*, has taxonomic difficulties and challenges have been ongoing with *E. lanceolata*, *E. angustata*, *E. fisheriana*, and *E. folliculata*. In (1970), Johnson considered *E. folliculata* a synonym of *E. lanceolata*, but Turgeon et al. (1998) consider *E. folliculata* a valid taxon distinct from *E. lanceolata*. A master’s thesis by Lohmeyer (2020)

found a high degree of haplotype sharing between *E. ahenea*, *E. angustata*, *E. producta*, *E. shepardiana,* and *E. folliculata* in the southern Atlantic slope (St. John River Drainage, FL to Neuse drainage, NC) and support synonymizing of the above species with *E. angustata* but this research has not been peer reviewed or published. Although the species is currently recognized as valid and distinct, future research may reveal synonymy with another lanceolate *Elliptio*.

The Pod Lance's shell is narrow and uninflated, resembling a straight-edged razor (Figure 1). The dorsal and ventral margins are parallel to one another. The outer surface of the shell is rough; the inner surface varies from bluish to pink (Bogan and Alderman 2004, 2008). The shell can vary in color from pale yellowish brown to dark brown, almost black. The umbo is at or below the hinge; a posterior wing may be present.

Like other freshwater mussels, *E. folliculata* can be confused with other *Elliptio* species such as *Elliptio angustata* and *Elliptio producta*, especially when alive or young. Animals of *Elliptio folliculata* are far more compressed and have a greater length to height ratio than *E. angustata* or *E. producta*; *E. folliculata* dorsal and ventral margins are parallel.

Status

NatureServe (2024) identifies the Pod Lance as having a ranking of imperiled to vulnerable globally (G2/G3). In North Carolina and Georgia, the species is ranked as imperiled (S2) and in South Carolina the species is ranked as critically imperiled to vulnerable (S1S3).

POPULATION SIZE AND DISTRIBUTION

The Pod Lance ranges from the Ogeechee River in Georgia to the Waccamaw and Cape Fear Basins in North Carolina. The Pod Lance has been reported in all the major river basins in South Carolina (Bogan and Alderman 2004, 2008). This species is found alongside other lanceolate *Elliptio* species and stands out due to its extremely compressed shell and blade-like appearance. It is not found often in South Carolina and when it is found, it is found in relatively low abundance (Figure 2).

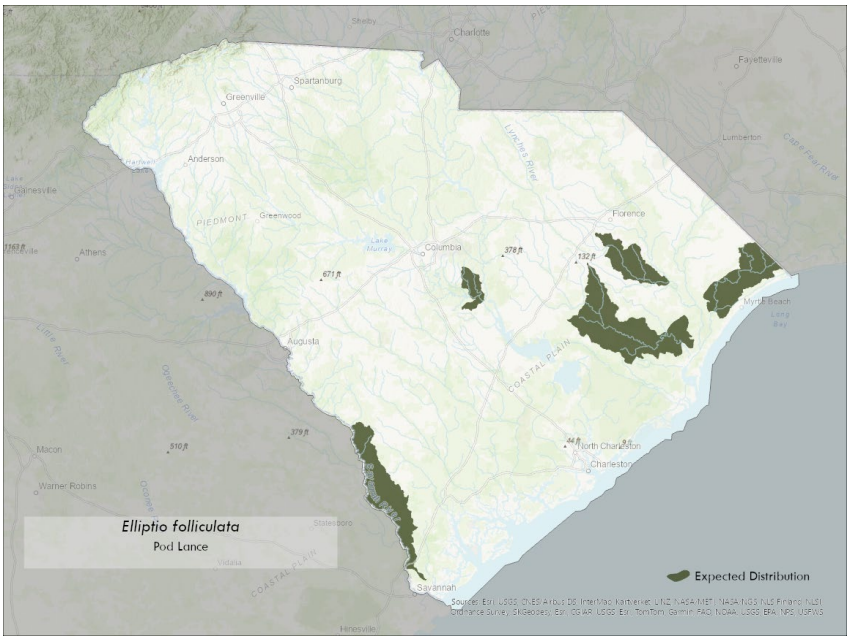

Figure 2. Expected distribution of *Elliptio folliculata* based on reported observations at a HUC 10 watershed level and designated ecoregions.

Like other *Elliptio* species, it is likely that overlapping morphology has skewed population distribution data. In South Carolina, the Pod Lance has been reported across the Pee Dee and Savannah watersheds in the coastal plain. There is one reported observation of the species in the Congaree River (Santee watershed), but it is noted that the species identification is in question and cannot be confirmed. In the Savannah watershed, the species has only been reported in the main stem Savannah River.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Pod Lance has been found on sandy or clay substrates in water generally greater than 1 m (3.3 ft.) in depth. It has been found in both rapidly flowing rivers as well as slow flowing areas (Bogan and Alderman 2004, 2008). Like other *Elliptio* species, research for the Pod Lance is minimal. There are no known host fishes.

CHALLENGES

The greatest challenge with the Pod Lance is the uncertainty of taxonomy and the validity of the species against other lanceolate *Elliptio* species across the southern Atlantic slope. Like other species in the genus, comprehensive, range-wide genetic analysis is needed. Determining population ranges in South Carolina is also difficult due to a high likelihood of misidentifications. There are no known host fishes for the Pod Lance, but the species may use an anadromous fish like other species of *Elliptio*. Little is known about the reproductive and brooding behaviors of *E. folliculata,* and wild host fish(es) are unknown.

Like other freshwater mussels, the Pod Lance is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The host fish(es) for the Pod Lance are unknown, but like other freshwater mussels, the Pod Lance must have adequate access to species-specific hosts and relies on host fish(es) for reproduction and distribution. Maintaining stream connectivity for host fish(es) is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the Pod Lance currently.

CONSERVATION RECOMMENDATIONS

- Conduct genetic analyses across the range of the Pod Lance to determine its relationship with other lanceolate *Elliptio* species.
- Conduct surveys, especially deep water, to determine the current range and status of the Pod Lance.
- Explore the need to list the Pod Lance within South Carolina based on survey results.
- Protect critical habitats for the Pod Lance from future development and further habitat degradation by following Best Management Practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Pod Lance.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Pod Lance to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Resolving taxonomic questions regarding the relationship between the Pod Lance and other *Elliptio* species.
- Determination of host fish species in laboratory and wild.
- Determination of environmental and toxicological tolerances and endpoints.
- Determination of habitat preferences.
- Determination of species range in South Carolina and target deep water habitats.

DESCRIPTION

Taxonomy and Basic Description

The shell of the Brother Spike (Figure 1 and 2) is elongate, rather thin, and subrhomboid; the anterior end is regularly rounded, the posterior end blunt, the ventral margin is mostly straight, and the dorsal margin straight or slightly curved. There is a well-developed posterior dorsal ridge that becomes double near the posterior margin. The posterior slope is covered with corrugations, or ridges that extend from near the umbo to the posterior margin. The outer surface of the shell is smooth and shiny, reddish-brown to yellowish, often with fine green rays that become obscured with age. The inner surface varies from white to pink, salmon, and purple. Bogan and Alderman (2004, 2008) note the Brother Spike reaching 65 mm (2.6 in.) in length; however, Johnson (1970) plated *Unio fraternus* from the Chattahoochee River in Georgia being 69 mm in length.

Like other animals in the *Elliptio* genus, there are taxonomic challenges. In 1970, Johnson lumped many taxa under a single name, but current genetic research suggests some synonymized species are valid. Johnson (1970) considered *E. mcmichaeli* a synonym of E. fraterna but Fuller and Bereza (1975) and Brim Box and Williams (2000) consider *E. fraterna* and *E. mcmichaeli* distinct species. Comprehensive, range-wide genetic analysis is needed to determine the validity of *E. fraterna* as a distinct species.

Like other native freshwater mussels, the Brother Spike can be confused with other species such as *Elliptio congaraea* and *Elliptio complanata*, especially when living. The Brother Spike closely resembles the Carolina Slabshell but the Brother Spike is consistently much thinner and more compressed (Johnson 1970). The Brother Spike could also be confused with the Eastern Elliptio; however, the Eastern Elliptio does not have corrugations on the posterior slope like the Brother Spike.

Status

The Brother Spike is listed as a state endangered species in South Carolina and is declining in abundance and distribution. NatureServe (2024) notes the species as having a global ranking of critically imperiled (S1). In Alabama, it has a ranking of presumed extirpated (SX), and in North Carolina, Florida, and Georgia, it has a ranking of critically imperiled (S1) (NatureServe 2024). In South Carolina it has a ranking of critically imperiled (S1?). The Brother Spike was included on a list of 374 species being petitioned for consideration as candidates for federal protection (USFWS 2011); however, a finding has not been made.

POPULATION SIZE AND DISTRIBUTION

This species appears to be endemic to the Savannah River Basin and occupies two disjunct river systems, the Savannah, draining to the Atlantic, and the Apalachicola, draining to the Gulf of Mexico. The animal is rare wherever it is found. There is at least one historic occurrence from the Chattahoochee River but may be extirpated from the river now. Specimens have been reported from the Chattahoochee, Flint, Apalachicola, and Savannah rivers. Britton and Fuller (1979) noted that *Elliptio fraterna* was naturally rare in the Savannah River system and reported observations suggest that the species is rare in all inhabited systems.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Not much is known about the habitat preferences of the Brother Spike, but Johnson (1970) reported the species to inhabit sand bars in swift flowing sections of streams and rivers (Johnson 1970). In (1979), Britton and Fuller document the species as only being found on sand bars. The species may be a deep-water species, but confirmation is needed (NatureServe 2024).

There are no known host fish for the species and no life history research has been completed.

CHALLENGES

Specific challenges are difficult to determine due to the lack of data associated with the species. Due to the rarity of occurrences, it is likely that populations of Brother Spike are being impacted by decreased reproduction and genetic variation due to fragmented occurrences and disjointed populations. The Brother Spike is presumed to be a deep-water mussel and if accurate, damming, dredging, low water levels, and water withdrawal would pose direct threats to the presumed habitats. Additionally, sedimentation and shifts in substrates due to development and sedimentation are likely to directly interfere with the Brother Spike as it seems to prefer sand bars. Additionally, like other freshwater mussels, the Brother Spike faces challenges due to anthropogenic pollutants, poor land management, channel modification, and clearing of riparian buffers. Changes to the habitat that do not directly affect the mussels may affect their host fishes and without adequate access to species-specific hosts, reproduction cannot occur.

CONSERVATION ACCOMPLISHMENTS

The Brother Spike has been listed as an endangered species in South Carolina.

CONSERVATION RECOMMENDATIONS

- Conduct genetic analyses to determine the relationship between the Brother Spike and other *Elliptio* species.
- Conduct targeted, comprehensive surveys to determine the current range and status of the Brother Spike.
- If populations are found, research is needed to determine the habitat preferences and host fishes needed for reproduction of the Brother Spike.
- Protect critical habitats for the Brother Spike from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Brother Spike.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Brother Spike to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Resolving taxonomic questions regarding the relationship between the Brother Spike and other *Elliptio* species.
- Completion of targeted, comprehensive surveys.
- Persistence of any identified populations and an increase in population size.
- Determination of host fishes.
- Determination of ecological and toxicological endpoints.

Altamaha Slabshell

Elliptio hopetonensis (Lea, 1838)

Contributor (2024): Ericah Beason (SCDNR)

Figure 1. Image of *Elliptio hopetonensis* courtesy of the North Carolina State Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan. The NCSM catalog number of the specimen photographed is 46026.2.

Taxonomy and Basic Description

The Altamaha Slabshell belongs to one of the largest genera in the Unionidae family in North America with 31 species recognized in North America, Canada, and Mexico as of 2023 (FMCS 2023). The overlapping morphological variations between species and limited comprehensive genetic analysis make it difficult to tease apart valid *Elliptio* species and their ranges. Large synonymies of Elliptio species without adequate, range-wide genetic confirmation also make conservation recommendations difficult.

Oftentimes, *Elliptio* species in South Carolina fall under 3 “groups” that are characterized by generalizations of overall morphological traits. These groups are not based on comprehensive genetic and morphological research, but years of observation of morphological traits and are simply a means to aid in the understanding of morphological types seen through the *Elliptio* genus.

The three groups are the lanceolata, the complanata, and icterina. The lanceolates group is comprised of species that have a greater length to heigh ratio than the complanates and include species such as *Elliptio angustata*, *Elliptio producta,* and *Elliptio folliculata*. The complanates group is comprised of species that are rather rectangular in shell outline and usually compressed, species in this group include those such as *Elliptio complanata*, *Elliptio roanokensis*, and *Elliptio hopetonensis*. *Elliptio hopetonensis* is in the complanates group because it has a rather rectangular shell appearance, but animals may get inflated in soft substrates. Lastly, species in the icterina group are typically smaller in overall size, inflated, and have a waxy, dark exterior with a prominent posterior ridge; species in this group recognized to occur in South Carolina include *Elliptio icterina* and species that were synonymized by Johnson (1970).

The Altamaha Slabshell is somewhat oblong, compressed to inflated, with somewhat thick valves (Figure 1). The umbo is scarcely prominent and undulated at the tip. The posterior is broad and bi-angulated. The outer surface of the shell is smooth, except near shell margins, and varies in color from greenish with yellow hues in younger individuals to deep brown in older individuals. Narrow green rays may be present but darken with age. The inner surface of the shell is noted as purple and iridescent (Lea 1838). The lateral teeth are long and curved.

Because of the varying degree of morphological overlap in the *Elliptio* genus, the Altamaha Slabshell can be easily confused with several species, especially when alive. Animals of *Elliptio hopetonensis* can easily be misidentified with some animals of *Elliptio complanata* and *Elliptio roanokensis*. *Elliptio hoptonensis* is mostly identified by its large bi-angulated posterior, that extends into somewhat of a wing at the dorsal margin. It also has a very noticeable posterior ridge.

A study trying to determine if glochidia could aid in or be used for identification of *Elliptio* species described the glochidia as depressed and subelliptical with a length of 206 ± 5.8 µm (197-215µm), a height of 226 ± 3.9 µm (222-231µm), and a hinge length of 137 + 5.0 µm (130-145 µm) (O'brien et al. 2003). They describe the anterior and posterior margins as equal and more rounded towards the ventral margin (O'brien et al. 2003). Additionally, they describe a broad flange, covered in vertical rows of microstylets, extending from the ventral margin (O'brien et al. 2003). Lastly, the dorsal margin is long and straight with the hinge ligament located closer to the posterior margin; the surface of the valve is covered with loose-looped exterior valve sculpturing (O'brien et al. 2003).

Status

NatureServe (2024) currently identifies the global ranking for this species as apparently secure (G4). The Altamaha Slabshell is ranked as apparently secure (G4) in Georgia and not ranked (SU) in South Carolina due to insufficient data on the species.

POPULATION SIZE AND DISTRIBUTION

The Altamaha Slabshell is endemic to Georgia and historically only found in the Altamaha River system where it remains one of the most common native mussels collected. Additional surveys placed the species in the Ogeechee and Savannah River systems as of 2009 (NatureServe 2024). Until 2024, South Carolina did not recognize the species having occupancy in the state, despite having a reported observation of the species by Tim Savidge in the Savannah River in 2006 and in Turkey Creek in 2013 which was presumed to be a misidentification due to the observation being outside of

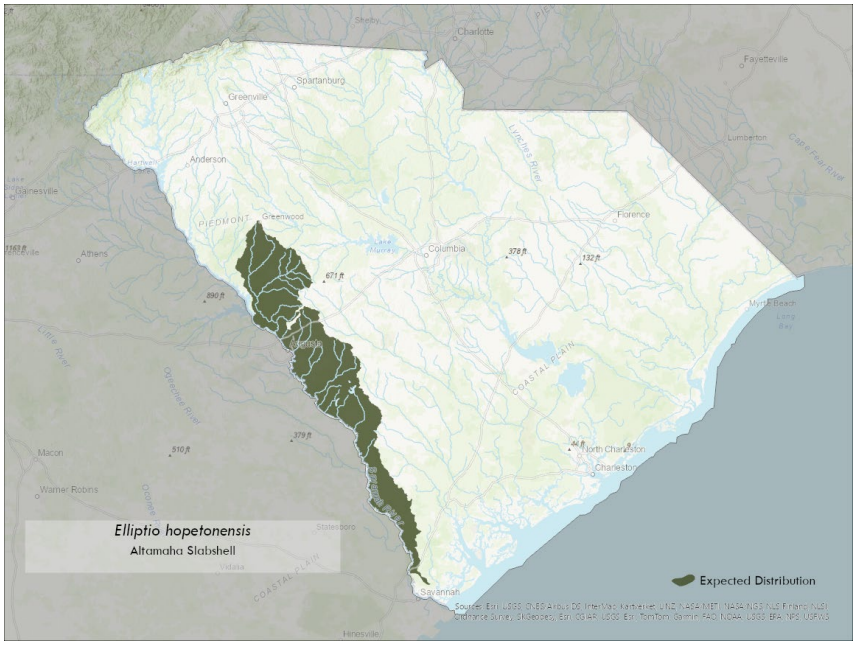

Figure 2. Expected distribution of *Elliptio hopetonensis* based on reported observations at a HUC 8 watershed level and designated ecoregion.

its recognized range (Figure 2). Targeted sampling in the Savannah River and associated tributaries is needed to determine the range of *E. hopetonensis* in South Carolina.

In 2024, SCDNR and partners in Georgia sampled a historic site in the Savannah River and documented live individuals of *E. hopetonensis*, which is the first reported observation of *E. hopetonensis* by South Carolina state entities. Although individuals of the species have been identified, genetic analysis is needed to confirm if indeed, *E. hopetonensis* is a distinct species.

Animals have been reported mostly in Georgia, including the Ocmulgee River drainage, Little Ocmulgee River tributary, Oconee River, Ohoopee River, Altamaha River drainage; however, it has also been documented in the Savannah River and potentially Turkey Creek in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Johnson (1970) and Heard (1975) note the species being found in sand, mud, and sandy mud and Heard (1975) note them in moderate to slack current. The individuals found in the Savannah River in 2024 were found in stable, sandy mud with clay mixed throughout.

Genetic analysis conducted on *E. hopetonensis* in upper, more urbanized, and lower reaches of the Altamaha, which are separated by some discontinuities in appropriate habitat, showed no significant structure of mitochondrial data suggesting that uniform management may be beneficial across the range of the species (Small et al. 2012).

A laboratory trial identified Eastern Mosquitofish (*Gambusia holbrooki*) and Bluegill (*Lepomis macrochirus*) as potential hosts, but no metamorphosis success was reported (O'brein et al. 2003). An additional study identified Bluegill, Fathead Minnow (*Pimephales promelas*), and Largemouth Bass (*Micropterus salmoides*) as hosts, but reported very low (<5%) metamorphosis success on all tested species (Johnson et al. 2012). Host fish interactions in the wild are unknown but the species may use an anadromous fish like other species of *Elliptio*.

O'brein et al. (2003) reported finding gravid females in the Altamaha River in April and Johnson et al. (2012) reported finding gravid females in June.

CHALLENGES

Taxonomy of this species as well as other *Elliptio* species in South Carolina need comprehensive, range-wide genetic analysis to determine which species are valid and to be recognized in the state.

As it has only been documented in South Carolina recently, little is known about the habitat preferences, abundance, and population range of the Altamaha Slabshell in South Carolina. The Altamaha Slabshell can easily be misidentified with other *Elliptio* species which make determination of the species range difficult. The Altamaha Slabshell appears rare in South Carolina, likely only occurring in the Savannah River, but little work has been done to survey the Savannah River and non-wadeable habitat in the larger Savannah Basin where this species can be

found. Little is known about the reproductive and brooding behaviors of *E. hopetonensis* and wild host fishes are unknown.

Like other freshwater mussels, the Altamaha Slabshell is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The natural host fishes for the Altamaha Slabshell are unknown, but like other freshwater mussels, the Altamaha Slabshell must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

Listing the mussel on the 2025 South Carolina State Wildlife Action Plan.

CONSERVATION RECOMMENDATIONS

- Conduct targeted surveys in the Savannah River and tributaries to determine the range of the species in South Carolina.
- Determine the validity of the species alongside overlapping morphologies of *Elliptios.*
- Explore the need to list the Altamaha Slabshell within South Carolina.
- Determine adequate host fishes for the Altamaha Slabshell.
- Study interactions of laboratory host fishes in the wild.
- Protect critical habitats for the Altamaha Slabshell from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Altamaha Slabshell.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Research the reproductive and brooding behavior of the species.

- Conduct further research to determine the degree of sensitivity of the Altamaha Slabshell to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Completion of thorough, standardized surveys in presumed range and habitat of the species.
- Determination of host fishes used for reproduction of the Altamaha Slabshell.
- Determination of life history of the Altamaha Slabshell including time of spawning and brooding.
- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Altamaha Slabshell.
- Comprehensive, range-wide genetic analysis of the species alongside other overlapping *Elliptio* mussels.
- Determine the effects of channel modification, such as dams, on the Altamaha Slabshell.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determination of environmental and toxicological tolerances and endpoints.

Figure 1. Image of *Elliptio producta* photographed by Briana Carico, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

The Atlantic Spike belongs to one of the largest genera in the Unionidae family in North America with 31 species recognized in North America, Canada, and Mexico as of 2023 (FMCS 2023). The overlapping morphological variations between species and limited comprehensive genetic and morphological analysis make it difficult to tease apart valid *Elliptio* species and their ranges. Large synonymies of Elliptio species without adequate, range-wide genetic confirmation also make conservation recommendations difficult.

Oftentimes, *Elliptio* species in South Carolina fall under 3 “groups” that are characterized by generalizations of overall morphological traits. These groups are not based on comprehensive genetic and morphological research, but years of observation of morphological traits and are simply a means to aid in the understanding of morphological types seen through the *Elliptio* genus. A working list of the *Elliptio* of South Carolina can be found in Bogan and Alderman (2008).

The three groups are the lanceolata, the complanata, and icterina. The lanceolates group is comprised of species that have a greater length to heigh ratio than the complanates and include species such as *Elliptio angustata*, *Elliptio producta,* and *Elliptio folliculata*. The complanates group is comprised of species that are rather rectangular to subrhomboidal in shell outline and usually compressed; species in this group include those such as *Elliptio complanata*, *Elliptio roanokensis*, *E. fraterna*, *E. congaraea*, and *Elliptio hopetonensis*. Lastly, species in the icterina group are typically smaller in overall size, inflated, and have a waxy, dark exterior with a prominent posterior ridge; species in this group recognized to occur in South Carolina include *Elliptio icterina* and species that were synonymized by Johnson (1970).

The Atlantic Spike, like other species of *Elliptio*, has taxonomic difficulties and challenges have been ongoing with *E. lanceolata*, *E. angustata*, *E. fisheriana*, and *E. folliculata*. In (1970), Johnson considered *E. producta* a synonym of *E. lanceolata*, but Williams et al. (2017) consider *E. producta* a valid taxon distinct from *E. lanceolata*. A master’s thesis by Lohmeyer (2020)

found a high degree of haplotype sharing between *E. ahenea*, *E. angustata*, *E. producta*, *E. shepardiana,* and *E. folliculata* in the southern Atlantic slope (St. John River Drainage, FL to Neuse drainage, NC) and support synonymizing of the above species with *E. angustata* but this research has not been peer reviewed or published.

Although the species is currently recognized as valid and distinct, personal communication with biologists in agencies across the southern Atlantic slope drainage found that agencies tend to synonymize *E. angustata* and *E. producta* and refer to them as either *E. angustata* or *E. producta* and this varies across agencies in the same state and across states. For example, currently, The South Carolina Department of Natural Resources recognizes both taxa based on the Freshwater Mollusk Conservation Society (2023) names list but some independent agencies that sample within South Carolina only recognize *E. angustata* while others only recognize *E. producta*. The synonymy comes from the overwhelming overlap in the morphological characteristics of the two species and the morphological differences between lentic and lotic animals. Because of this, it is difficult to determine short- and long-term trends of the population.

The shell of the Atlantic Spike (Figure 1) is somewhat compressed and solid with a maximum length of nearly 140 mm (5.6 inches). The anterior margin is rounded and the posterior margin roundly pointed, with a low posterior ridge. The outer surface of the shell is slightly shiny, dark reddish-brown or greenish-brown in color. The inner surface may be purple (Bogan and Alderman 2004, 2008). The ventral margin sweeps upwards towards the posterior of the shell and the posterior point is typically at or above the midline of the shell.

Like other freshwater mussels, *E. producta* can be confused with other *Elliptio* species such as *Elliptio angustata* and *Elliptio folliculata*, especially when alive or young. *Elliptio producta* can be distinguished from *E. angustata* because of ventral margin sweeping up towards the midline. Animals of *E. angustata* have a posterior point towards the ventral margin, not the midline of the shell. Animals of *Elliptio folliculata* are far more compressed and have a greater length to height ratio than *E. angustata* or *E. producta*; *E. folliculata* umbo are at or below the hinge.

Status

NatureServe (2024) shows the Atlantic Spike of having a global ranking of vulnerable (G3). The species is ranked as imperiled (S2) in Pennsylvania, imperiled to vulnerable (S2S3) in Maryland, vulnerable (S3) in South Carolina, and not ranked in North Carolina or Georgia.

POPULATION SIZE AND DISTRIBUTION

The Atlantic Spike ranges from the Savannah River in Georgia to the Potomac River Basin in Maryland and Pennsylvania. Because of the overlapping morphology and the commonality of lanceolate *Elliptios* when compared to higher conservation priority species, minimal research has been completed on *E. producta* populations. In South Carolina, the species has been found across the state, but most reported observations have been in the Santee and Savannah watersheds in the piedmont regions (Figure 2).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Johnson (1970) noted that the species was found in streams or rivers with sandy, rocky, and/or muddy bottoms in sections where the current is not too rapid. Observational collections have been made in most substrate types and in different lentic and lotic environments. Like other freshwater mussels, *Elliptio producta* need stable habitat and adequate access to host fishes.

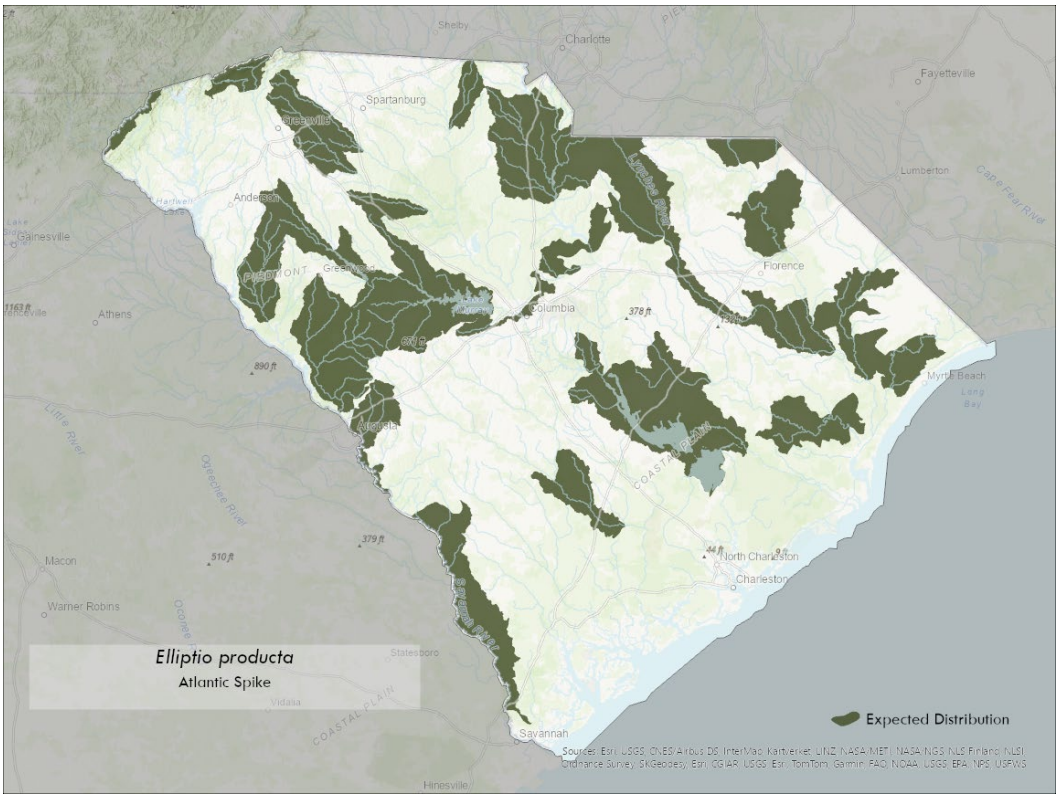

Figure 2. Expected distribution of *Elliptio producta* based on reported observations at a HUC 10 watershed level and designated ecoregion.

There are no known host fishes for the Atlantic Spike.

CHALLENGES

The greatest challenge with the Atlantic Spike is the uncertainty of taxonomy and the validity of the species against other lanceolate *Elliptio* species across the southern Atlantic slope. Like other species in the genus, comprehensive, range-wide genetic analysis is needed. There are no known host fishes for the Atlantic Spike, but the species may use an anadromous fish species like other species of *Elliptio*.

Like other freshwater mussels, the Atlantic Spike is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The host fish(es) for the Atlantic Spike are unknown, but like other freshwater mussels, the Atlantic Spike must have adequate access to species-specific hosts and relies on host fish(es) for reproduction and distribution. Maintaining stream connectivity for host fish(es) is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments for the Atlantic Spike currently.

CONSERVATION RECOMMENDATIONS

- Conduct comprehensive, range-wide genetic analyses of the Atlantic Spike to determine its relationship with other lanceolate species of *Elliptio*.
- Explore the need to list the Atlantic Spike within South Carolina based on survey results.
- Protect critical habitats for the Atlantic Spike from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Conduct surveys to determine habitat preferences of the species.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Atlantic Spike.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Atlantic Spike to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Resolving taxonomic questions regarding the relationship between the Atlantic Spike and other *Elliptio* species.
- Determination of host fish species in laboratory and wild.
- Determination of environmental and toxicological tolerances and endpoints.
- Determination of habitat preferences.
- Determination of life history of the Atlantic Spike including time of spawning and brooding.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.

DESCRIPTION

Taxonomy and Basic Description

The Roanoke Slabshell belongs to one of the largest genera in the Unionidae family in North America with 31 species recognized in North America, Canada, and Mexico as of 2023 (FMCS 2023). The overlapping morphological variations between species and limited comprehensive genetic and morphological analysis make it difficult to tease apart valid *Elliptio* species and their ranges. Large synonymies of Elliptio species without adequate, range-wide genetic confirmation also make conservation recommendations difficult.

Oftentimes, *Elliptio* species in South Carolina fall under 3 “groups” that are characterized by generalizations of overall morphological traits. These groups are not based on comprehensive genetic and morphological research, but years of observation of morphological traits and are simply a means to aid in the understanding of morphological types seen through the *Elliptio* genus. A working list of the *Elliptio* of South Carolina can be found in Bogan and Alderman (2008).

The three groups are the lanceolata, the complanata, and icterina. The lanceolates group is comprised of species that have a greater length to heigh ratio than the complanates and include species such as *Elliptio angustata*, *Elliptio producta,* and *Elliptio folliculata*. The complanates group is comprised of species that are rather rectangular to subrhomboidal in shell outline and usually compressed except for *E. hopetonensis*; species in this group include those such as *Elliptio complanata*, *Elliptio roanokensis*, *E. fraterna*, *E. congaraea*, and *Elliptio hopetonensis*. Lastly, species in the icterina group are typically smaller in overall size, inflated, and have a waxy, dark exterior with a prominent posterior ridge; species in this group recognized to occur in South Carolina include *Elliptio icterina* and species that were synonymized by Johnson (1970).

The Roanoke Slabshell, like other species of *Elliptio*, has taxonomic difficulties and challenges have been ongoing with *E. roanokensis, E. judithae,* and *E. complanata*. In (1970), Johnson considered *E. roanokensis* a synonym of *E. complanata*, but Williams et al. (2017) consider E. roanokensis a valid taxa and *E. judithae* a synonym for *E. roanokensis*. Clark (1986) described *E. judithae* from the Neuse River but North Carolina only recognized *E. roanokensis* in the Neuse, Tar, Roanoke, Cape Fearm and Yadkin-Pee Dee drainages. *Elliptio judithae* is not a recognized species as of the (2019) Freshwater Mollusk Conservation Society names list.

The Roanoke Slabshell is a thin, rectangular, thick shelled mussel that can grow to a length of greater than 150 mm (6 inches) (Bogan and Alderman 2004, 2008). The posterior ridge of the Roanoke Slabshell varies from well-defined to uniformly round. The outer surface of the shell is smooth, except near shell margins, and is generally yellowish/reddish-brown. The color of the Roanoke Slabshell darkens with age; narrow greenish rays are often present but are less distinct in larger individuals. The inner surface of the shell is usually purple.

Like other freshwater mussels, the Roanoke Slabshell can be confused with other *Elliptio* species such as *Elliptio complanata*, especially when alive or young. The Roanoke Slabshell can be distinguished from the Eastern Elliptio due to the thick, rectangular, compressed shell of the Roanoke Slabshell. The Roanoke Slabshell also gets larger than the Eastern Elliptio.

Status

NatureServe (2024) currently identifies the global ranking for this species as vulnerable (G3). The Roanoke Slabshell is ranked imperiled in Georgia and Virginia (S2), imperiled to vulnerable in South Carolina (S2S3), and vulnerable in North Carolina (S3).

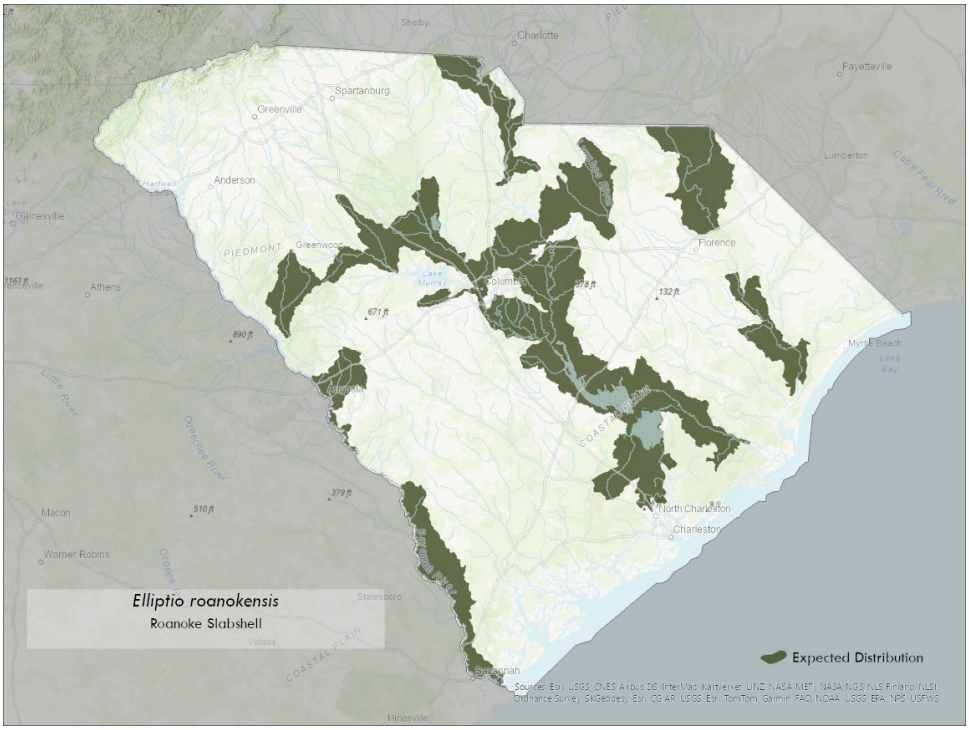

Figure 2. Expected distribution of *Elliptio roanokensis* based on reported observations at a HUC 10 watershed level and designated ecoregion.

POPULATION SIZE AND DISTRIBUTION

Walter (1954) considered the range of the Roanoke Slabshell to be from the Connecticut River in Massachusetts to the Altamaha River in Georgia.

The species is currently recognized in Georgia, South Carolina, North Carolina, and Virginia. In South Carolina, it is found in the main stem of the Pee Dee River and in the Catawba, Congaree, and Savannah River drainages (Figure 2). In South Carolina, the Roanoke Slabshell is relatively common in several sites in the Pee Dee, Savannah and Congaree Rivers.

NatureServe (2024) identifies the Roanoke and Chowan populations as nearly extirpated and the Tar, Neuse, Cape Fear, Savannah, and Pee Dee populations as significantly reduced; however, there have been no definitive population studies conducted for the species. The Catena Group (2006) notes collecting individuals from the Great Pee Dee River, but collections are dominated by large, older individuals suggesting low recruitment of the species.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Roanoke Slabshell is found in large rivers but can occasionally be found in small creeks. The Catena Croup (2006) notes the species being found in deep run habitats dominated by coarse sand/pea gravel with swift flow in the Pee Dee River drainage. Through modeling, Pandolfo et al. (2016) found *E. roanokensis* suited to coarse gravel habitats with deeper and swifter waters. The Roanoke Slabshell may be able to tolerate large variations in flow levels and higher water temperatures, making it able to survive in some locations near dams and hydroelectric plants, but specific endpoints and tolerances are unknown. The species has experienced large die-offs when the plants generate extremely low flows and cause levels of oxygen to drop (Taxonomic Expertise Committee 2004).

The Roanoke Slabshell, like the Eastern Elliptio, is capable of at least 2 broods during one season and the brood cycle may be as short as 18 days (Price and Eads 2011). Brooding *E. roanokensis* were collected from late March to late June and water temperatures were 14.5°C when *E. roanokensis* were collected already gravid (Price and Eads 2011).

Laboratory trials found Blueback Herring, Gizzard Shad, and White Perch served as hosts for the Roanoke Slabshell; encystment lasted 10-16 days (Eads et al. 2015). Price and Eads (2011) found that brooding periods of Roanoke Slabshell are associated with temperatures of 14-18°C, and Eads et al. (2015) suggests that the timing of Blueback Herring and American Shad spawning makes them the most likely natural hosts. Additional work by Wardell and Eads found American Shad to be a confirmed host in laboratory trials (Eads person. Comm. 2024).

CHALLENGES

Like other *Elliptio*, there are taxonomic challenges that need to be sorted through comprehensive, range-wide genetic analysis.

The Roanoke Slabshell, like many freshwater mussel species, is vulnerable to water fluctuations caused by channel modifications such as dams. Not only do the dams directly affect the Roanoke Slabshell by altering flow and habitat, but they act as a barrier for host fishes which is the only means of dispersal for the Roanoke Slabshell. Dams create physically isolated mussel populations in the same river reach and without fish passage, upstream populations could be extirpated due to the lack of anadromous fish, the hosts needed for Roanoke Slabshell

reproduction. Juveniles are rarely found above dams that prohibit fish passage, but Roanoke Slabshell mussels often return to these areas following efforts to facilitate fish passage.

Additionally, shifts in substrates due to development and sedimentation are likely to directly interfere with the Roanoke Slabshell as it seems to prefer coarse gravel. The Roanoke Slabshell, and many other mussels, face challenges due to anthropogenic pollutants, poor land management, channel modification, and clearing of riparian buffers. Changes to the habitat that do not directly affect the mussels may affect their host fishes and without adequate access to species-specific hosts, reproduction cannot occur.

CONSERVATION ACCOMPLISHMENTS

The brooding season of *E. roanokensis* has been studied in the Broad River (Price and Eads 2011).

CONSERVATION RECOMMENDATIONS

- Comprehensive, range-wide genetic analysis.
- Explore the need to list the Roanoke Slabshell within South Carolina.
- Closely monitor Roanoke Slabshell populations near dams for changes in population density.
- Work with other state agencies (DHEC) to determine appropriate minimum flows to protect the Roanoke Slabshell.
- Recommend minimum flows during the FERC relicensing process.
- Facilitate the travel of anadromous fishes by keeping rivers and streams free of artificial obstructions or by using fish ladders at dams.
- Monitor areas upstream of fish ladders or locations where obstructions have been removed to determine if the Roanoke Slabshell has extended its range upstream.
- Protect critical habitats for the Roanoke Slabshell from future development and further habitat degradation by following Best Management Practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Roanoke Slabshell.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Roanoke Slabshell to various point and non-point sources of pollution and land use impacts.
- Verify wild host fishes.

MEASURES OF SUCCESS

- Persistence of identified populations of the Roanoke Slabshell.

- Increases in populations or population size of Roanoke Slabshell.
- Achieving minimum flows from dams.
- Achieving fish passage through in-stream obstacles and dams.
- Determination of ecological and toxicological tolerances and endpoints.
- Verification of host fishes in the wild.

Atlantic Pigtoe

Fusconaia masoni

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason (SCDNR)

Figure 1. Image of *Fusconaia masoni* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan. The NCMNS catalog number of the specimen photographed is 12275.

DESCRIPTION

Taxonomy and Basic Description

The shell of the Atlantic Pigtoe is subrhomboidal in shape, but individuals from headwater areas are more elongate. There is a distinct posterior ridge. The outer surface of the shell is yellow to dark brown and parchment like, while the inner surface is iridescent blue to salmon, white, or orange. Its small shell is generally less than 50 mm (2.2 in.) in length (Bogan and Alderman 2004, 2008).

The Atlantic Pigtoe, like many other native freshwater mussels, can easily be confused with other species such as *Elliptio congaraea*, especially when alive. The Atlantic Pigtoe mussel does not get as large as the Carolina Slabshell and is more triangular in appearance than the Carolina Slabshell. The Carolina Slabshell also usually has noticeable plications on the posterior slope.

Status

The Atlantic Pigtoe is a state endangered species in South Carolina. NatureServe (2024) currently identifies the Atlantic Pigtoe as having a global status of critically imperiled (G1). It is listed as possibly extirpated (SH) in South Carolina and ranked as critically imperiled (S1) in Georgia. In North Carolina it is ranked vulnerable (S3) and in Virginia it is ranked as imperiled (S2). In November 2021, the Atlantic Pigtoe was federally listed as threatened. Additionally, roughly 563 river miles (906 river kilometers) were designated and fall within 17 units of critical habitat (USFWS 2021).

POPULATION SIZE AND DISTRIBUTION

This species originally ranged from the James River Basin in Virginia to the Ogeechee River basin in Georgia, but its range has been steadily declining. In South Carolina, it was once found in the Savannah River drainage, but had not been collected in the State for over 100 years (Bogan and Alderman 2004, 2008). It is difficult to determine the timing of the decline, since few surveys were conducted for the Atlantic Pigtoe throughout the 1900s. This species was probably historically widespread in South Carolina; it is currently found in the Pee Dee River and Goose Creek in North Carolina. There are only historical records or shell material of the species in South Carolina, and it is possible that this species has been extirpated from the state.

Remnant populations could still exist in the state but targeted, comprehensive surveys in historical and suitable habitat are needed.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The preferred habitat of the Atlantic Pigtoe is coarse sand and gravel at the downstream edge of riffles. It is less common in sand, cobble, and mixtures of sand, silt, and detritus (Bogan and Alderman 2004, 2008). The Atlantic Pigtoe requires fast-flowing, well oxygenated streams and is typically found in medium to large rivers. Pandolfo et al. (2016) found through modeling that *V. constricta* and *F. masoni* had similar suitable habitat including moderately penetrable gravels and cobble with boulders and woody debris providing most suitable cover for the species; it was noted that *F. masoni* suitable habitat was slightly deeper and faster flowing that *V. constricta*.

The Atlantic Pigtoe mussel is a short-term brooder, brooding larvae (glochidia) for roughly 30-60 days before releasing them and fecundity can vary greatly (Rash and Neeves 2005). The Atlantic Pigtoe does not do well with environmental and water quality changes which make studying life history difficult. It has been noted that brooding females will abort glochidia due to environmental changes and transport and glochidia are not viable after 24 hours, making laboratory trials difficult (Black 2001). Brooding Atlantic Pigtoe mussels have been collected from mid-May and early-June (Wolf 2012). Conglutinates are semi-buoyant, pinkish, and average ~5mm in length (Wolf 2012)

Laboratory trials show transformation of juveniles on Bluegill, Shield Darters, Whitefin Shiner, and Satinfin Shiner but transformation success for all species was low (Watters and O'Dee 1997; O'Dee and Watters 2000; Rash and Neeves 2005). Higher transformation success was seen with Longnose Dace, Creek Chub, and Rosefin Shiner (Wolf and Emrick 2011). It is likely that the Atlantic Pigtoe utilizes the feeding behavior of minnows to reproduce and further research into host fish interactions in the wild are needed.

CHALLENGES

The Atlantic Pigtoe is a species of mussel that is vulnerable to local extirpation and without conservation measures, will be vulnerable to extinction. Data collection from 2005-2019 indicate only 7 viable populations of the species in Virginia and North Carolina, presumably occupying only 40% of its historic range (USFWS 2021). Only 3 of the 7 viable populations have documented multiple occurrences from 2005-2019.

With small, fragmented populations, successful wild reproduction is of concern; but due to the life history of the species, assisted propagation of the species is also a challenge. The Atlantic Pigtoe is a short-term brooder and only broods for a period of roughly 30-60 days before expelling larvae. This short window of time makes laboratory propagation of the species more difficult than species that have a longer window of larvae viability.

The Atlantic Pigtoe seems to be extremely vulnerable to changes in water quality, in-stream substrate, and habitat connectivity (USFWS 2021). Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture,

and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

One of the healthiest, most viable populations of this species was recently lost in Virginia and the populations in North Carolina are not doing well (Taxonomic Expertise Committee 2004). A recent study determined that the glochidia (larvae) of the Atlantic Pigtoe are extremely sensitive to pollution. Levels of ammonia far below USEPA criteria maximum concentrations caused the death of glochidia (Augspurger et al. 2003).

CONSERVATION ACCOMPLISHMENTS

In November 2021, the Atlantic Pigtoe was federally listed as threatened and roughly 563 river miles (906 river kilometers) were designated and fall within 17 units of critical habitat (USFWS 2021). The species is listed as state endangered in South Carolina.

CONSERVATION RECOMMENDATIONS

- Conduct targeted, comprehensive surveys in historical and suitable habitats to see if remnant populations are in South Carolina.
- If South Carolina populations are rediscovered, protect land near these populations and upstream from where they are found should be protected through land acquisition and conservation easements.
- If populations are rediscovered, completing population genetics to determine population size and genetic variation is needed.
- Consider reintroduction of the Atlantic Pigtoe in relatively pristine, high-quality habitat in South Carolina. Partner with North Carolina and or Georgia in these efforts.
- Protect critical habitats for the Atlantic Pigtoe from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Atlantic Pigtoe.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process and conduct surveys to determine if it is present prior to major projects.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

- Completion of targeted sampling efforts in the historical ranges and at sites with suitable habitat.
- If populations are found, completion of population genetics.
- If augmentation or reintroduction efforts are established, survival of the species would be success.
- Successful propagation of the species.

- Research into the life history of the species and their interactions with hosts in the wild.

Yellow Lampmussel

Lampsilis cariosa

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason (SCDNR)

Figure 1. Images of male (top) and female (bottom) *Lampsilis cariosa* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

The shell of the Yellow Lampmussel (Figure 1) is obovate (egg-shaped) in shape and moderately inflated with the anterior margin rounded, the ventral margin slightly curved, and the posterior margin bluntly rounded. The posterior ridge is poorly developed and rounded. Males have a gently curved ventral margin; the females have a distinct posterior swelling. The outer surface of the shell is waxy, shiny, and yellow but can become stained brown in certain habitats. Some shells may exhibit a trace of green. Thin dark rays are absent from the shell or restricted to the posterior slope. Older specimens are brownish and not as shiny. The inner surface of the shell is bluish-white and may be tinged with cream or salmon. The shell length of adults is approximately 120 mm (4.8 in.) (Bogan and Alderman 2004, 2008).

Female *L. cariosa* produce a modified mantle lure that mimics a small prey item to attract host fishes. Most lures have an eyespot but can range in complexity. Lures have mimicked shiners, minnows, and sunfish. Yellow Lampmussel females are long term brooders and have been found gravid from March-October, but gravidity is likely temperature dependent (Martell 2020).

This species is fairly distinct but small individuals can sometimes be mistaken with Atlanticoncha ochracea when living.

Status

NatureServe (2024) currently identifies the Yellow Lampmussel as having a global ranking of vulnerable (G3). It is ranked as vulnerable (S3) in North Carolina and Georgia and (S3?) in South Carolina. The species is presumed extirpated and critically imperiled in several northeastern states. The Yellow Lampmussel is a species of special concern.

POPULATION SIZE AND DISTRIBUTION

The Yellow Lampmussel ranges from the Ogeechee River Basin in Georgia to Nova Scotia, Canada. In South Carolina (Figure 2), it is found in the Steven's Creek sub-basin, and the Savannah, Wateree, Congaree, and Pee Dee River Basins (Bogan and Alderman 2004, 2008). The Congaree and Pee Dee Rivers may contain the best populations in the State. In South Carolina, there have been 114 total reported observations of the species with most reports from the Savannah River basin.

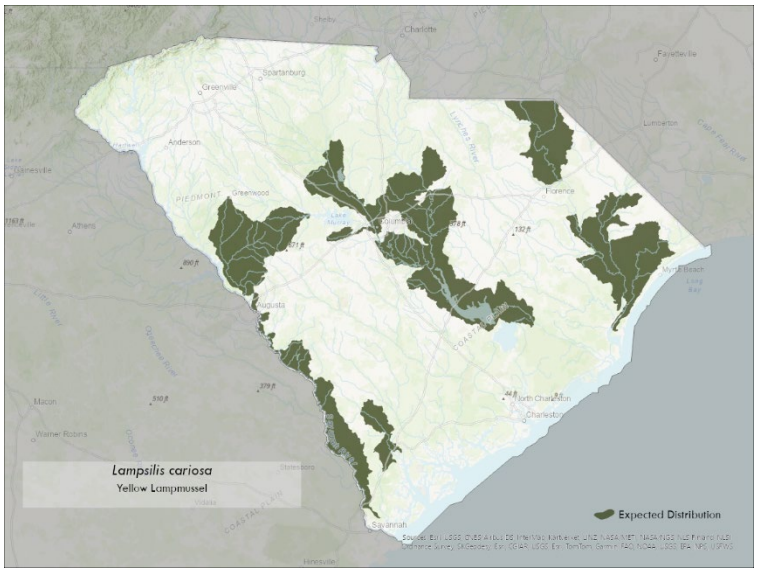

Figure 2. Expected distribution of *Lampsilis cariosa* based on reported observations at a HUC 10 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Yellow Lampmussel can be found in gravel bars and stable sandbanks (Sabine et al. 2004) in the margins of the flowing portions of water bodies, and in cracks in bedrock in moderate to large rivers. Most observations of the Yellow Lampmussel in South Carolina have been in large rivers which have been under surveyed by state agencies.
Laboratory trials show successful transformation on largemouth bass, black crappie, white bass, striped bass, white perch, and yellow perch (Eads et al. 2007, 2015; Martell 2020) White perch and yellow perch were confirmed host fishes in the wild (Kneeland and Rhymer 2008).

CHALLENGES

This species is known to have rapid decreases in population sizes across its historic ranges. The specific challenges for the species are not well understood but are associated with pollution from industry, agriculture, and energy production and invasive species (Williams et al. 1993; Nedeau et al. 2000; Sabine et al. 2004; Kelly and Rhymer 2005; Bogan and Woolnough 2017). The species is often found in large rivers and the impacts of impoundments on the species is not documented in South Carolina.

Like other freshwater mussels, the Yellow Lampmussel is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. Yellow Lampmussel must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Impoundments can lead to disjunct populations which have reduced genetic variation which could cause localized extirpation (Kelly and Rhymer 2005). Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

In 2023, a working group involving state and federal agencies and other stakeholders throughout the species range was created and opens communication across the range for conservation and management of the species moving forward. In 2024, SCDNR provided genetic material to other agencies for analysis and also provided wild collected gills of presumed host fishes for analysis to a different agency.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to document the extent of distribution and population size and range of the Yellow Lampmussel.
- Explore the need to upgrade the listing of the Yellow Lampmussel in South Carolina, based on survey results.
- Determine habitats that are critical for this species in South Carolina.
- Perform host fish trials to determine natural hosts for native populations.
- Conserve populations of host fish to insure reproduction of the Yellow Lampmussel in the wild.
- Protect critical habitats for the Yellow Lampmussel from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Yellow Lampmussel.
- Encourage responsible land use planning.
- Work to improve minimum flows and restoration of more natural hydrologic regimes in the Savannah River.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Yellow Lampmussel to various point and non-point sources of pollution and land use impacts.
- Conduct a thorough search of museum records for the Yellow Lampmussel and determine if there are any additional historical records for this species.
- Conserve populations of host fish to insure reproduction of the Yellow Lampmussel in the wild.
- Develop a restoration plan that considers the need for augmentation or reintroduction.
- Consider species needs when participating in the environmental permit review process.

MEASURES OF SUCCESS

- Completion of targeted surveys in areas of historic occupancy and similar habitat types in the Savannah Basin.
- Work to reduce or halt further disturbance to the habitat and natural hydrology of the Savannah River.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Comprehensive, range-wide genetic analysis of the species.
- Completion of thorough, standardized surveys in presumed range and habitat of the species.
- Determination of host fishes used for reproduction of the Yellow Lampmussel.

- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Yellow Lampmussel
- Determine the effects of channel modification, such as dams, on the Yellow Lampmussel.
- Determination of environmental and toxicological tolerances and endpoints.

Figure 1. Images of male (top) and female (bottom) *Lampsilis splendida* photographed by Briana Cairco, SCDNR.

Taxonomy and Basic Description

These two species are discussed together in this document due to taxonomic uncertainty. These species may represent geographical variation and phenotypic plasticity of a single species. Phenotypic plasticity, in this document, refers to non-heritable variation of size, shape, and coloration of individuals due to environmental parameters such as, but not limited to, substrate, shear stress, stream size, water chemistry, etc., that the individuals interact with during life.

Figure 2. Images of male (top) and female (bottom) *Lampsilis radiata* photographed by Briana Cairco, SCDNR.

In (1998), Turgeon et al. recognized nominal *L. radiata* and a single subspecies, *L. r. conspicua* but (Stiven and Alderman 1992) point to molecular and morphological data not supporting *L. r. conspicua* as distinct. Williams et al. (2017) placed both *L. r. conspicua* and *L. fullerkati* into synonymy with *L. radiata* based on molecular data from McCartney et al. (2016); this was a change from Turgeon et al. (1998) which recognized *L. fullerkati* as distinct. As of (2023), the Freshwater Mollusk Conservation Society does not recognize *L. r. conspicua* or *L. fullerkati* but does recognize *L. splendida* and *L. radiata*.

A Nei genetic identity value is a measure used in population genetics to quantify genetic similarity between populations and is calculated based on the proportion of shared alleles; the index ranges from 0 (no shared alleles) to 1 (identical). Kat (1983) calculated a Nei genetic

identity value based on electrophoresis of *L. splendida* and *L. radiata* found that *L. splendida* resembles *L. radiata* at a level of 0.805 ± 0.003 but maintained *L. radiata* and *L. splendida* as distinct species (Kat 1983). Additionally, Kat (1983) found that the stomach anatomy of L. splendida and L. radiata was 67% similar.

Comprehensive, range-wide genetic analysis is needed to determine if L. radiata and L. splendida are both valid taxa.

Individuals identified as *Lampsilis splendida* (Figure 1) have an elongate shell that is oval and greatly inflated. The anterior end is rounded. The posterior end of the shell is sexually dimorphic; in the male, this area is bluntly pointed, and in the female, it is more broadly rounded. There is a sharp posterior ridge and sometimes a secondary ridge on the shell of these species. The outer surface of the shell is wrinkled with a fuzzy appearance and is yellowish-green to reddish-brown in color. Further, the outer surface of the shell has numerous green rays that may become dark brown and obscured in older specimens. The inner surface of the shell varies from bluish-white to pinkish or purple and is iridescent. Rayed Pink Fatmucket mussels attain lengths of approximately 110mm (4.4 in.) (Bogan and Alderman 2004, 2008).

Individuals identified as the *Lampsilis radiata* (Figure 2) have shells that are subelliptical to subovate in shape, with the anterior end rounded. The shells of the male are elongated and not expanded posteriorly, while the shells of females are expanded in the postbasal area. The posterior ridge is low to absent. The outer surface of the Eastern Lampmussel shell is yellowish- or brownish-green with poorly defined dark green or black rays over the entire surface. The inner surface is white, pink, or salmon-colored. The shell may be greater than 120 mm (4.8 in.) in length (Bogan and Alderman 2004, 2008).

Observations of museum specimens show that mussels identified as *L. splendida* had thinner shells and a more prominent posterior ridge than those identified as *L. radiata*, but these morphological differences could be a result of geographical variation and phenotypic plasticity.

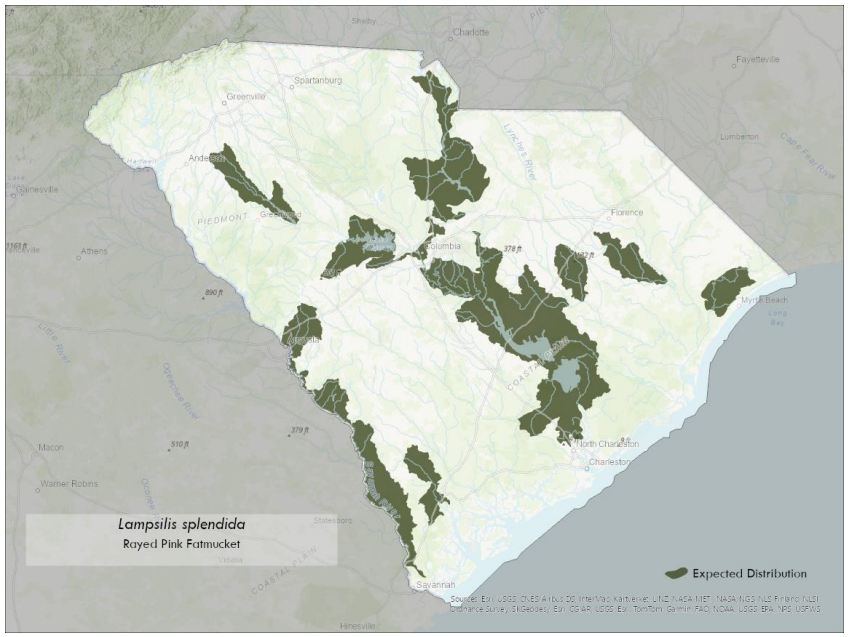

Figure 3. Expected distribution of *Lampsilis splendida* based on reported observations at a HUC 10 watershed level and designated ecoregions.

Status

The Rayed Pink Fatmucket is currently considered a species of special concern in South Carolina. NatureServe (2024) currently identifies *L. splendida* with a global status of vulnerable

(G3). In North Carolina, the species is ranked critically imperiled (S1), in South Carolina the species is ranked imperiled (S2?), and in Georgia the species is ranked vulnerable (S3).

NatureServe (2024) currently identifies the Eastern Lampmussel as secure globally (G5). In West Virginia the species is ranked critically imperiled (S1), in Virginia it is ranked as imperiled to vulnerable (S2S3), in North Carolina it is ranked vulnerable (S3), and in South Carolina it is ranked imperiled (S2?).

POPULATION SIZE AND DISTRIBUTION

Mussels currently classified as *L. splendida* are found from the Altamaha and Ogeechee Rivers in Georgia to the Cape Fear River Basin in North Carolina. In South Carolina, the species has been reported in the piedmont, sandhills, and coastal plain regions in all four major watersheds (Figure 3). Most reported observations come from the coastal plain region in and around Lake Marion and Lake Moultrie. There are also several reported observations throughout the Savannah River. Other observations have been made in Lake Greenwood, Lake Murray, and the Congaree and Wateree Rivers.

The Eastern Lampmussel (*L. radiata*), is globally more widespread and has a more northern distribution, reaching its southern limit in the Santee-Cooper basin South Carolina. In South Carolina, there are fewer reported observations of this species which have only been reported in the Santee and Pee Dee watersheds (Figure 4). Observations have been reported in the piedmont, sandhills, and coastal plain regions. Most observations of *L. radiata* were around Lake Greenwood and Lake Marion. A single observation has also been reported in the Waccamaw River.

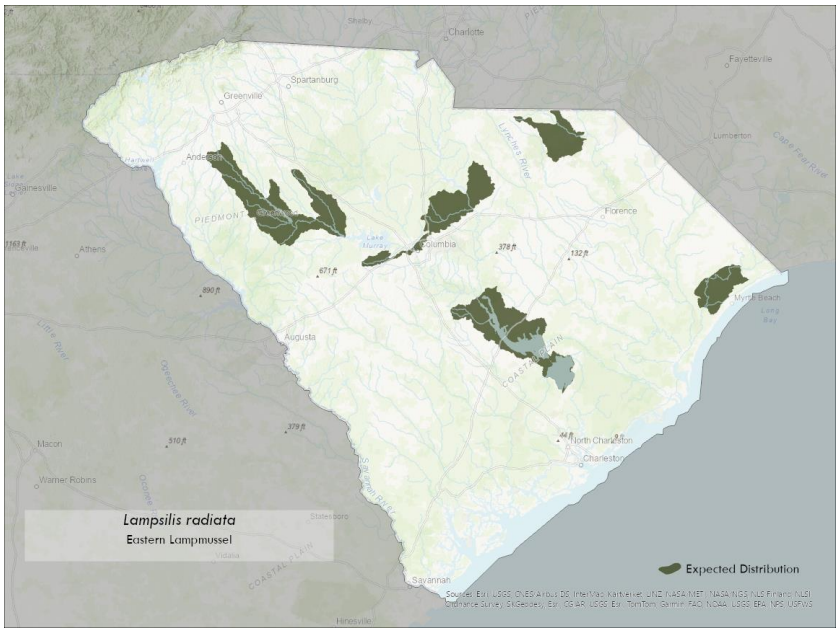

Figure 4. Expected distribution of *Lampsilis radiata* based on reported observations at a HUC 10 watershed level and designated ecoregions.

A gradient of phenotypes of both species are found in South Carolina and some individuals collected are difficult to give an ID to because they resemble both *L. radiata* and *L. splendida*. Overlapping morphology and misidentification make it difficult to determine population ranges.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Both the Rayed Pink Fatmucket and the Eastern Lampmussel are found in swift waters of large rivers on sand bars and gravelly areas as well as muddy and sandy areas in streams, and blackwater swamps. Meador et al. (2011) reported a catch per unit effort range of 7.0-15.0 individuals per person hour in slack water depending on sampling season in the Altamaha River. Through modeling, and the assumption that mussel abundance is an indicator of habitat preference, *L. splendida* preferred slack water and pool habitats in the Altamaha River (Meador et al. 2011).

Johnson et al. (2012) report collecting gravid *Lampsilis splendida* in the Altamaha River in October with a water temperature of 26°C. Meador et al. (2011) report collecting gravid females (15% of all *L. splendida* collected) during autumn, defined as (15°C < t < 25°C with decreasing temperature from the previous time period).

The Largemouth Bass was found as a suitable host fish in laboratory trials with a reported metamorphosis success (%) of 43.0 ± 5.5 (Johnson et al. 2012). Glochidia of Eastern Lampmussel have been found attached to Yellow Perch, Black Crappie, Smallmouth Bass, Largemouth Bass (Telda and Fernando 1969).

CHALLENGES

Eastern Lampmussel in South Carolina represent the southern edge of this species range. Because it is a more northern species, rising water temperatures may lead to local extirpation but research is needed to determine thermal tolerances of the species. Similarities in morphology between Eastern Lampmussel and Rayed Pink Fatmucket lead to difficulties in field ID which make it difficult to determine population ranges in South Carolina. The Eastern Lampmussel appears less abundant than Rayed Pink Fatmucket in South Carolina based on reported observations, but little work has been done to survey non-wadeable habitat where both species can be found. Due to overlapping morphologies, comprehensive genetic analysis is needed to determine if *L. radiata* and *L. splendida* are distinct species. Little is known about the reproductive and brooding behaviors of *L. splendida and L. radiata* and wild host interactions have not been studied.

Like other freshwater mussels, both the Rayed Pink Fatmucket and Eastern Lampmussel are sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The Rayed Pink Fatmucket and Eastern Lampmussel must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a

cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

A small number of individuals of Eastern Lampmussel were reared in captivity, and 11 tagged mussels were released in the lower Broad River in 2010 (C. Eads, pers. comm.).

CONSERVATION RECOMMENDATIONS

- Conduct comprehensive genetic analyses across the known ranges of both the Rayed Pink Fatmucket and Eastern Lampmussel and determine validity of species and range of species.
- Monitor population trends of the Rayed Pink Fatmucket and Eastern Lampmussel.
- Protect critical habitats for the Rayed Pink Fatmucket and Eastern Lampmussel from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Rayed Pink Fatmucket and Eastern Lampmussel.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Perform host fish trials to determine natural hosts for native populations of Rayed Pink Fatmucket and Eastern Lampmussel.
- Study interactions of laboratory host fishes in the wild with Rayed Pink Fatmucket and Eastern Lampmussel.
- Conserve populations of host fish to insure reproduction of the Rayed Pink Fatmucket and Eastern Lampmussel in the wild.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Rayed Pink Fatmucket and Eastern Lampmussel to various point and non-point sources of pollution and land use impacts.
- Work to improve minimum flows and restoration of more natural hydrologic regimes in river systems with suitable habitat for Rayed Pink Fatmucket and Eastern Lampmussel.

MEASURES OF SUCCESS

- Completion of targeted surveys in areas of historic occupancy and similar habitat types in the PeeDee Basin, Savannah Basin, and Santee-Cooper.
- Determine the host fish(es).
- Collection of genetic swabs of and Rayed Pink Fatmucket and Eastern Lampmussel to ensure successful identification of species range and distribution.
- Determine the effects of channel modification, such as dams, on the Rayed Pink Fatmucket and Eastern Lampmussel.

- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determination of environmental and toxicological tolerances and endpoints.
- Determination of life history of the Rayed Pink Fatmucket and Eastern Lampmussel including time of spawning and brooding.

Carolina Heelsplitter

Lasmigona decorata (Lea 1852)

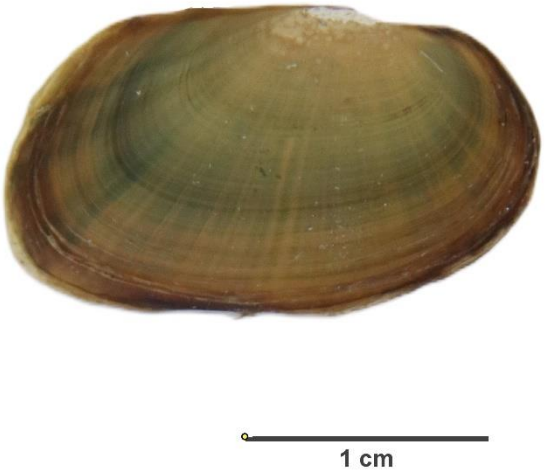

Figure 1. Images of wild *Lasmigona decorata* photographed by Briana Cairco, SCDNR.

Taxonomy and Basic Description

The shape of the Carolina Heelsplitter's shell is an ovate trapezoid with a straight dorsal margin that may end with a slight wing (Figures 1-3). The ventral margin is straight. The umbo is above the hinge. The outer surface of the shell is yellowish, greenish, or brownish and may have greenish or blackish rays. The inner shell surface ranges from iridescent white to mottled pale orange. The Carolina Heelsplitter shell can reach up to 118 mm (4.7 in.) in length; the mean shell length for this species is 78mm (3.1 in.) (Bogan and Alderman 2004, 2008).

Status

This is currently the only mussel species in South Carolina that is federally listed as endangered. NatureServe (2024) identifies the Carolina Heelsplitter as critically imperiled globally (G1) and critically imperiled in North and South Carolina (S1).

POPULATION SIZE AND DISTRIBUTION

The Carolina Heelsplitter is endemic to North and South Carolina. In 1993, Carolina Heelsplitter was listed as federally endangered with six critical habitat units designated in 2002. Five of these critical habitat units are in South Carolina. There are 11 surviving populations and all, but one, population can be found in South Carolina (USFWS 2019).

Figure 2. Image of hatchery produced *Lasmigona decorata* photographed by Briana Cairco, SCDNR. The specimen is from cohort 2302LdA-C.

The Pee Dee River System is home to two populations: Goose Creek/Duck Creek population found in Union County, North Carolina and Flat Creek/Lynches River in Lancaster, Kershaw, and Chesterfield Counties, South Carolina. The Catawba River System has 5 populations. Waxhaw Creek population found in Union County, North Carolina, and Lancaster County, South Carolina. Sixmile Creek population, found in Union and Mecklenburg Counties, North Carolina, and Lancaster County, South Carolina. Gills Creek/Cane Creek population in Lancaster County, South Carolina. Fishing Creek/South Fork Fishing Creek population found in Chester County, South Carolina and Bull Run Creek/unnamed tributary to Bull Run Creek/Beaverdam Creek/Hooper Branch (Rocky Creek population) found in Chester County of South Carolina. The Saluda River System has two populations, the Red Bank Creek population and the Halfway Swamp Creek populations found in Saluda County, South Carolina. The Savannah River System has two

populations, Turkey Creek/Mountain Creek/Beaverdam Creek/Sleepy Creek/Little Stevens Creek/Rocky Creek/Log Creek (Turkey Creek population) found in Edgefield and McCormick Counties of South Carolina and the Cuffytown Creek population found in Greenwood and McCormick Counties of South Carolina.

The entire extent of the Heelsplitter's historic range is not known, but evidence indicates that it was once more widely distributed in the Catawba, Pee Dee, Savannah, and Saluda River systems (USFWS 1997). The Carolina Heelsplitter has a spotty distribution where it is found (Figure 4) due to restrictions in suitable habitat (USFWS 1997). Where the Carolina Heelsplitter is found, it is no longer abundant; typically, only 1 to 3 individuals are discovered during a survey at any one site. In the 5-year review published by the US Fish and Wildlife Service in 2019, 4 of the 11 populations (Sixmile Creek, Gills/Crane Creek, Rocky Creek, and Turkey Creek) were considered declining. Recent surveys by SCDNR in Red Bank Creek and Halfway Swamp Creek, and the Lynches River did not recover any live Carolina Heelsplitter. All 11 of the surviving populations remain highly susceptible to extirpation from a single event or chronic conditions such as drought, chemical spills, stormwater runoff, sedimentation and bank instability etc.

Figure 3. Image of hatchery produced *Lasmigona decorata* photographed by Briana Cairco, SCDNR. Specimen photographed is from cohort 1502LdA-O.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Although it was once found in large rivers and streams, the Carolina Heelsplitter is now restricted to cool, clean, shallow, heavily shaded streams of moderate gradient. Stable streambanks and channels, with pool, riffle and run sequences, little or no fine sediment, and periodic natural flooding, appear to be required for the Carolina Heelsplitter (USFWS 2002). This species still exists in some degraded streams in pockets of viable habitats. Eads et al. (2010) performed laboratory host fish trials and reported metamorphosis of glochidia on Pirate perch (Aphredoderus sayanus), Largemouth Bass (Micropterus salmoides), Bluegill (Lepomis macrochirus), Satinfin Shiner (Cyprinella analostana), Bluehaead Chub (Nocomis leptocephalus), Golden Shiner (Notemigonus crysoleucas), Whitemouth Shiner (Notropis alborus), Highfin Shiner (Notropis altipinnis), Redlip Shiner (Notropis chiliticus), Spottail Shiner (Notropis hudsonius), Yellow Bullhead (Ameriurus natalis, Fantail darter (Etheostoma flabellare), and Tessalated Darter (Etheostoma olmstedi). Out of these, Satinfin Shiner (Cyprinella analostana), Bluehaead Chub (Nocomis leptocephalus), Golden Shiner (Notemigonus crysoleucas), Highfin Shiner (Notropis altipinnis), and Spottail Shiner (Notropis hudsonius) had mean

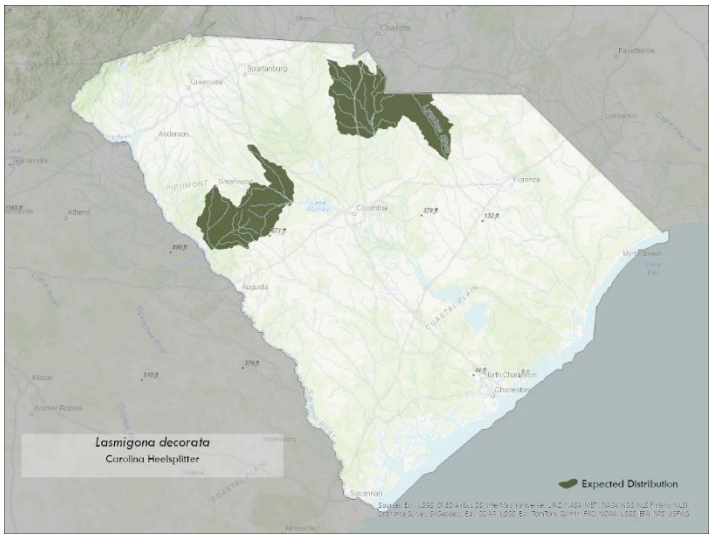

Figure 4. Expected distribution of *Lasmigona decorata* based on reported observations at a HUC 10 watershed level and designated ecoregions.

percentage of metamorphosis above 30% and have been targeted for propagation efforts. Bluehead Chub (Nocomis leptocephalus), Golden Shiner (Notemigonus crysoleucas), and Spottail Shiner (Notropis hudsonius) are more common and have been the primary hosts used in propagation. No information is available about infestation of hosts in the wild. Carolina Heelsplitter mussels are presumed to be long-term brooders, but research is needed to determine the reproductive cycle of *L. decorata*.

CHALLENGES

The Carolina Heelsplitter is vulnerable to a variety of threats related to human disturbance. Polluted wastewater from sewage treatment plants and industrial discharges are a threat. Storm water runoff carrying silt, fertilizer, pesticides, and other pollutants threatens the Carolina Heelsplitter, especially when erosion and stormwater control is inadequate (USFWS 2002).

Habitat alteration including impoundments, channelization, dredging, and streambank scouring by stormwater runoff have also contributed to the decline of the Carolina Heelsplitter and adversely affect remaining populations (USFWS 2002). Activities such as agriculture, forestry, road construction, mining, urban development, and other land use activities that do not adequately control stormwater runoff and soil erosion are likely to destroy Carolina Heelsplitter habitat (USFWS 2002). Current and potential land uses within the watersheds of streams supporting Carolina Heelsplitter results in increased discharge and runoff of silt, sediments, and organic and chemical pollutants that threaten habitat and water quality this species requires. Past and on-going agriculture and timbering operations negatively affect several of the populations due to the continued loss of riparian buffers which results in increased runoff of silt and other sediments as well as fertilizer, insecticide, and herbicide drift, and contamination of groundwater entering the streams. The loss of riparian buffers and livestock entering streams also contributes to the destabilization of streambanks and substrate that provide habitat for Carolina Heelsplitter (USFWS 2019).

A study on the natural host for Carolina Heelsplitter was attempted, (Polemen 2023) however no Carolina Heelsplitter glochidia were recovered attached to host fish. This type of study may be difficult to accomplish while the density of Carolina Heelsplitter at a site remains low.

CONSERVATION ACCOMPLISHMENTS

The United State Fish and Wildlife Service (USFWS) (1997) has created a Recovery Plan for the species that includes objectives such as research and monitoring of existing populations, reintroduction programs, and public education. They have also designated stretches of streams where the Carolina Heelsplitter is found as critical habitat (USFWS 2002) and have proposed that the establishment of sanctuaries, stream buffer zones and other protective measures should be encouraged.

SCDNR has been working cooperatively with the USFWS to develop standardized, routine surveys of populations in South Carolina that began in 2019. Genetic swabs collected in these efforts have been held for a planned population genetics study for the species.

Propagation efforts have been attempted and animals grown from Orangeburg National Fish Hatchery since 2015 and SCDNR Cohen Campbell Fisheries Center since 2021 have been stocked in the wild in South Carolina.

USFWS Programs including Recovery, Refuges, and Fisheries and Lancaster County, South Carolina have initiated work restoring fish passage and natural flows at road crossing structures, replacing undersized, round culverts with appropriately sized bottomless arch culverts. Three projects have been completed (Happy Trail, Langley Road, and Gills Creek Drive), reopening the entire length, approximately 6 miles of Critical Habitat Unit 3 to fish passage (USFWS 2019).

The Forest Service has also taken strides to retrofit and replace nonfunctioning culverts on their system of roads in the Long Cane Ranger District of the Sumter National Forest.

SCDNR is also incorporating fish passage restoration into much of their work, including Clean Water Act compensatory mitigation recommendations and state-wide property management plans. Hundreds of acres and thousands of linear feet of critical habitat in the Flat Creek watershed have been protected through conservation easements (Carolina Heelsplitter Conservation Bank) and fee simple transfer of property to the State of South Carolina. SCDNR has also contracted stream restoration to reduce sedimentation in a tributary of Flat Creek.

CONSERVATION RECOMMENDATIONS

- Partner with United States Fish and Wildlife Service to carefully evaluate the impact of all potential development projects proposed in the watersheds where the Carolina Heelsplitter is found.
- Partner with United States Fish and Wildlife Service to ensure implementation of the recovery plan and continue augmentation and reestablishment of populations through propagation and culture.
- Conduct population genetics analysis to guide recovery efforts.
- Encourage careful land use planning in the Charlotte metropolitan area to protect the upper Lynches River and Catawba River watersheds. Land protection through conservation easements and fee simple purchases should be a high priority, especially in the vicinity of Fishing Creek and the headwater streams in the upper Lynches River drainage. Land protection is also necessary in the Steven's Creek Basin, particularly around headwater streams. Careful land use planning is necessary in the Augusta and Aiken developing areas that are beginning to encroach upon this watershed. Such protection may be accomplished through conservation easements or fee simple purchase.
- Protect critical habitats for the Carolina Heelsplitter from future development and further habitat degradation by following Best Management Practices.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Carolina Heelsplitter.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Determine ecological and toxicological endpoints for the species.

MEASURES OF SUCCESS

- Completion of continued population monitoring of the populations of Carolina Heelsplitter in South Carolina.
- Successfully stocking of propagated animals to augment or restore populations in stable habitat.
- Completion of surveys to monitor the success of stocking propagated animals.
- Completion of population genetic analysis to determine the health of populations and guide recovery efforts.
- Continue outreach to relevant landowners about the importance of freshwater mussels and their habitats.

Eastern Pondmussel

Sagittunio nasutus (Say 1817)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason

Figure 1. Image of *Sagittunio nasutus* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan. The NCSM catalog number of the specimen photographed is 30040.2.

DESCRIPTION

Taxonomy and Basic Description

The Eastern Pondmussel (Figure 1) was petitioned to be reassigned to the genus *Sagittunio* in 2021 based on Watters (2018) and supplemental genetic work from Kuehnl (2009), Zanatta and Murphy (2006), and Raley et al. (2007). The petition was accepted and the scientific name *Sagittunio nasutus* was assigned (FMCS 2023), which differs from *Ligumia nasuta*, as seen in the 2015 SWAP.

The shell of the Eastern Pondmussel is elongated and sub-elliptical with a rounded anterior margin and a broadly curved ventral margin. The posterior margin is rounded and drawn out into a posterior angle or blunt point near the midline of the shell, and the posterior ridge is well developed and angular. The ventral margin of the female's shell is expanded in the postbasal region. The outer surface of the Eastern Pondmussel shell is dark olive green to brownish, often with faint, dark green straight and narrow rays, especially in juveniles. The shell also has irregular growth lines; sometimes a few ribs are present below the posterior ridge. The inner surface of the shell is bluish white, sometimes with salmon in the beak area, and is iridescent posteriorly. The shell can reach a maximum length of 102 mm (4.1 in.) (Bogan and Alderman 2004, 2008).

The Eastern Pondmussel is sexually dimorphic, and females have been documented displaying marginal papillae to attract hosts fishes when brooding. Corey et al. (2006) found that gravid *S. nasutus* papillae move rapidly and synchronously, allowing the striking white of the marsupial gills to be seen moving up and down the mantle margin, mimicking a copepod. A video produced by the Aquatic Epidemiology and Conservation Laboratory at NC State University shows that a small portion of the mantle is folded outward, and the fold varies in direction and speed up and down the mantle margin (Eads 2009). The displaying behavior attracts fish, and naïve fish readily attack the mussel, triggering the release of mussel larvae, glochidia. The display behavior slows in low light and stops in high turbidity or in the dark, regardless of time or day (Corey et al. 2006). When fish attack the mantle tissue, female *S. nasutus* release free glochidia; however, when probed by a pipette in laboratory conditions, mussels simply stopped displaying, closed their shells, and then resumed displaying after a few seconds (Corey et al. 2006). Fish that attacked and were exposed to glochidia were not likely to attack a second time. During the study, two captive *S. nasutus* ejected conglutinates at night when no fish were present then buried themselves and did not display any longer (Corey et al. 2006). Conglutinates were ~10mm long, elongated, and cream colored. Additionally, it was noted that displaying females

were very active at night, suggesting nocturnal movement before daytime displaying, potentially seeking new, naïve fish (Corey et al. 2006).
Sagittunio nasutus are reportedly long-term brooders, with the breeding season from August until the following June (Ortmann 1919). Corey et al. (2006) collected gravid females in May and June. North Carolina reports finding gravid females during the cooler months of the year (NCWRC). In Eads et al. (2015), gravid *S. nasutus* were collected in the spring.

Reported host fishes include Yellow Perch, Largemouth Bass, Bluegill, and Pumpkinseed based on laboratory trials (Eads et al. 2015).

Status

NatureServe (2024) currently identifies the Eastern Pondmussel's global status as vulnerable (G3). The species is ranked as imperiled (S2) in North Carolina, Vulnerable (S3) in Virginia, and imperiled to vulnerable (S2S3) in South Carolina. The Committee on the Status of Endangered Wildlife in Canada designated the species as endangered in April of 2007 but re-examined and designated the species as special concern in April 2017 (COSEWIC 2007; COSEWIC 2017).

POPULATION SIZE AND DISTRIBUTION

This historic range of the Eastern Pondmussel extends from the Savannah River Basin in Georgia north to Maine and Ontario and as far west as Michigan. In South Carolina, it was historically documented in the Savannah, Santee-Cooper, and Pee Dee Basins (Johnson 1970). Although the species has a larger range, it is considered critically imperiled and imperiled throughout the northern ranges largely due to invasive dreissenid mussels and habitat destruction in the 20th century (NatureServe2024; Scott et al 2016). In South Carolina, there have been a total of 62 reported observations of the species from 2002-2019 across the Pee Dee, Santee, and ACE watersheds (Figure 2). The species has been observed in the piedmont, sandhills, and coastal plain regions with an overwhelming majority of observations being around the shorelines of Lake Marion and Lake Moultrie. The species can be abundant when found, but extant populations are quite rare (Taxonomic Expertise Committee 2004).

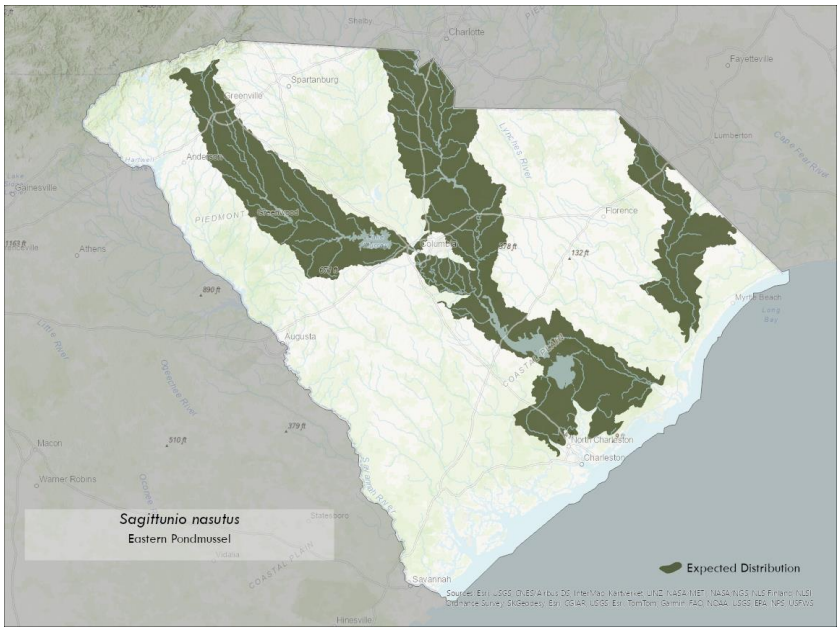

Figure 2. Expected distribution of *Sagittunio nasutus* based on reported observations at a HUC 8 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Eastern Pondmussel can be found in lakes, ponds, streams, and rivers of variable depths with muddy, sandy, or gravelly substrates. Often, it is found in very shallow water near the banks of rivers (Taxonomic Expertise Committee 2004). The Eastern Pondmussel is not known to be found in areas where saltwater intrusion is present and has a documented 24-hour EC50 of 1.7 ppt of sea salt for glochidia and 5.8 ppt 96-hour EC50 for juveniles (McIver et al. 2023).

CHALLENGES

Observations suggest that this species is sensitive to channel modification, pollution, salinity, sedimentation, and low oxygen conditions, but we do not know how the relative sensitivity of this species to these threats compares to other species. The tendency for the Eastern Pondmussel to inhabit shallow water near riverbanks may make it especially sensitive to sudden drops in water levels (Taxonomic Expertise Committee 2004).

CONSERVATION ACCOMPLISHMENTS

Additional populations have been located in Lake Greenwood and the lower Broad River (Savidge 2006; Price and Eads 2011). Two hundred individuals of Eastern Pondmussel were reared in captivity, and tagged individuals were released in the lower Broad River in 2010 (C. Eads, pers. comm.). Genetic analysis has placed the species, and others in a distinctive clade and microsatellite markers were developed and characterized for the species (Scott et al. 2016).

CONSERVATION RECOMMENDATIONS

- Conduct additional surveys to determine the status and distribution of the Eastern Pondmussel.
- Evaluate the need to list the Eastern Pondmussel based upon survey results.
- Examine museum specimens to determine the historic range of the Eastern Pondmussel; compare its present and historic distributions.
- Protect critical habitats for the Eastern Pondmussel from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Eastern Pondmussel.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct research into the reproduction of the Eastern Pondmussel.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Eastern Pondmussel to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Once the distribution of the Eastern Pondmussel is thoroughly evaluated, persistence of populations and increases in numbers where rare will indicate successful conservation efforts.
- Determination of environmental and chemical tolerances.
- Determination of gravidity time frame and environmental parameters that affect this.

Carolina Creekshell

Sagittunio vaughanianus
(Leas, 1838)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Morgan Kern (SCDNR)

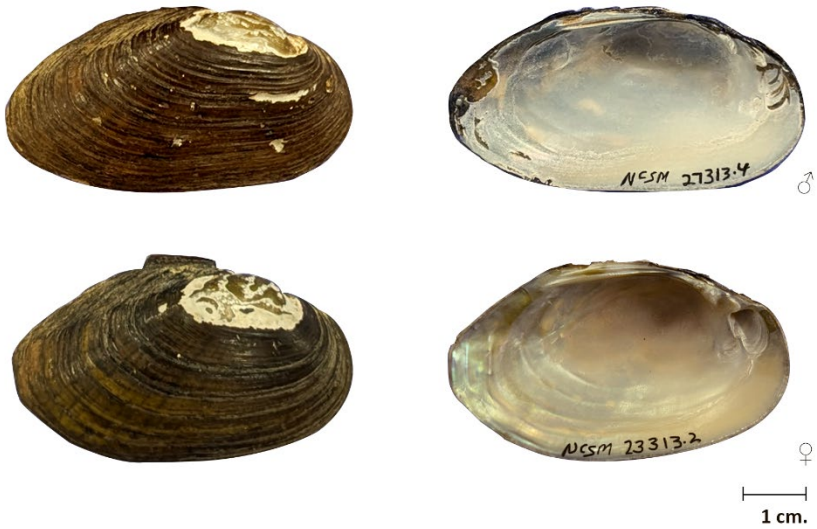

Figure 1. Images of male (top) and female (bottom) *Sagittunio vaughanianus* courtesy of the North Carolina State Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan. The NCSM catalog number of the male and female specimens are 27313.4 and 23313.2 respectively.

DESCRIPTION

Taxonomy and Basic Description

Carolina Creekshell was reassigned into the genus *Sagittunio* by the Freshwater Mollusk Conservation society in (2023) based on the work in Watters (2018) which established the genus *Sagittunio* with type species *Sagittunio nasutus* (Say, 1817). Several other unpublished studies (Kuehnl 2009; Raley et al. 2007) support the separation of the genus and the placement of Eastern Pondmussel and Carolina Creekshell in a distinct genus. The scientific name was changed from *Villosa vaughaniana* as it appeared in the 2015 SWAP.

Carolina Creekshell is a small mussel that rarely exceeds 2.5 inches in length and is sexually dimorphic (Figure 1). Females exhibit an expanded posterior end that accommodates the expanded marsupial gills when brooding. Carolina Creekshell has well developed pseudocardinal and lateral teeth. The anterior margin is rounded in both sexes. The posterior end is pointed about two-thirds of the way from the ventral margin. Males have a gently curved ventral margin, elliptical in shape; the female has a distinct posterior basal swelling and a straight ventral margin making them more ovate in shape. The outer surface of the Carolina Creekshell is moderately shiny and greenish-yellow to dark brownish-yellow with numerous continuous green rays. The inner surface is shiny, iridescent white or bluish-white. (Bogan and Alderman 2004, 2008; NCWRC 2024).

As with many of our native freshwater mussels, Carolina Creekshell can be easily misidentified especially when the individual is still living. Carolina Creekshell can be confused with the Eastern Creekshell, *Villosa delumbis*. Eastern Creekshell often have wide broken rays rather than complete rays as seen on Carolina Creekshell. The marsupium of Eastern Creekshell has a dark margin while it is ivory colored in Carolina Creekshell.

Status

NatureServe (2024) currently identifies the Carolina Creekshell as having a global ranking of imperiled (G2). This mussel is considered critically imperiled (S1) in South Carolina. The Carolina Creekshell has been historically found in several South Carolina streams but was only recovered from one historic site during a 2022 survey.

POPULATION SIZE AND DISTRIBUTION

The Carolina Creekshell is endemic to North Carolina and South Carolina and has been found in the Cape Fear River, Catawba River, Neuse River, Pee Dee River, and Santee-Cooper River Basins (Figure 2). In South Carolina, one individual was found at a historic site during recent survey efforts. The Carolina Creekshell was first described in 1838 from specimens found at Sawney's Creek in Kershaw County, South Carolina. In recent years, targeted surveys have been completed in and around Sawney's Creek and no animals have been located.

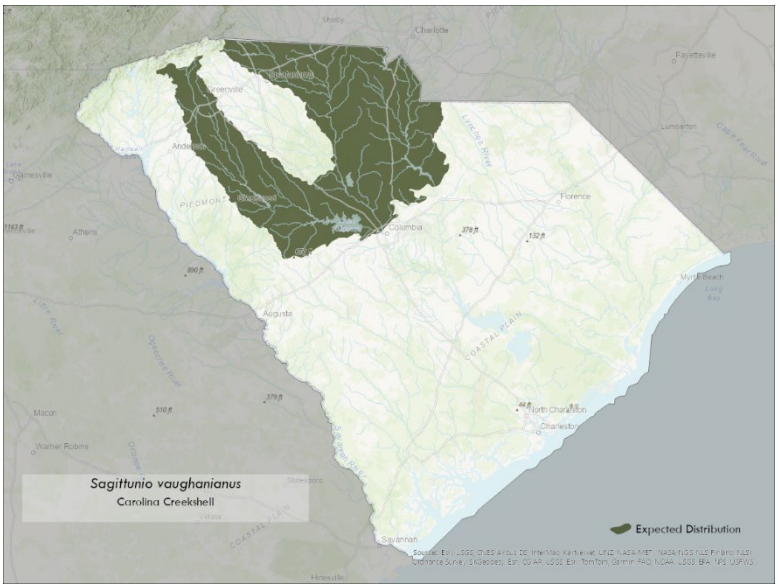

Figure 2. Expected distribution of *Sagittunio vaughanianus* based on reported observations at the HUC 8 watershed level and designated ecoregion.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Carolina Creekshell tends to be found in mud or sand near stream banks. Occasionally, this mussel is found in gravelly sand in the main channel of streams and medium-sized rivers. Regardless of the substrate, this species needs to be able to burrow.

The reproductive cycle, brooding behavior, and glochidia release by the Carolina Creekshell are understudied. Although not formally documented, a video produced by Chris Eads (2009) with the Aquatic Epidemiology and Conservation Laboratory at NC State University show that gravid females produce a mantle lure towards the ventral portion of the shell and the lure is similar to that of *S. nasutus*, moving papillae to expose white coloration. There are no known host fish(es) for *S. vaughanianus* although host fishes for *S. nasutus* may also act as hosts for *S. vaughanianus* but research is needed.

CHALLENGES

The Carolina Creekshell can easily be misidentified as Eastern Creekshell which makes determining population ranges and historic sites difficult. Surveys across the historic range of the species in South Carolina suggest that the species is becoming increasingly rare in South Carolina. Historic habitats such as the Lynches River appear unstable and may no longer be able to support this species. Little is known about the reproductive and brooding behaviors of *S. vaughanianus* and wild hosts are unknown. Work to recover this species through propagation would be difficult without access to broodstock in North Carolina.

Like other freshwater mussels, the Carolina Creekshell is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The hosts for the Carolina Creekshell are unknown, but like other freshwater mussels, the Carolina Creekshell must have adequate access to species-specific hosts and relies on host fish(es) for reproduction and distribution. Maintaining stream connectivity for host fish(es) is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

Efforts were made to survey for this species at sites of historic occupancy as part of a SWG Grant from 2022-2024. Genetic swabs from five presumed *S. vaughanianus* collected from this effort were provided to aid in a study being performed in North Carolina.

CONSERVATION RECOMMENDATIONS

- Conduct a thorough search of museum records for the Carolina Creekshell and determine if there are any additional historical records for this species.
- Conduct surveys to closely monitor population trends for the Carolina Creekshell and to look for populations near the type locality to determine if any other populations remain.
- Determine habitats that are critical for this species in South Carolina.
- Research the reproductive and brooding behavior of the species.
- Perform host fish trials to determine natural hosts for native populations.
- Study interactions of laboratory host fishes in the wild.
- Conserve populations of host fish to insure reproduction of the Carolina Creekshell in the wild.
- Develop a restoration plan that considers the need for augmentation or reintroduction.
- Encourage responsible land use planning.
- Protection of land by encouraging the use of best management practices, conservation easements, and land purchases.
- Prioritize the purchase and protection of land in the vicinity of Fishing Creek and other known habitats.
- Consider species needs when participating in the environmental permit review process.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Carolina Creekshell.
- Conduct further research to determine the degree of sensitivity of the Carolina Creekshell to various point and non-point sources of pollution and land use impacts.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

- Completion of targeted surveys where historic occupancy or suitable habitat are found.
- Determination of life history of the Carolina Creekshell including time of spawning and brooding.
- Determine the host fish(es) and complete surveys in suitable habitat for host fish(es).
- Collection of genetic swabs of Carolina Creekshell when found.
- Development of a restoration plan that may include propagation and culture to reintroduce the species in suitable habitat within its historic range.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Work to reduce or halt further disturbance to the habitat and natural hydrology of historic habitats.
- Determination of environmental and toxicological tolerances and endpoints.
- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Carolina Creekshell.

Creeper

Strophitus undulatus (Say, 1817)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason

Figure 1. Images of *Strophitus undulatus* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

Taxonomy for the species in the northern and eastern ranges of the species does not currently seem to be in question. There are taxonomy concerns in the western Gulf coast drainages (Texas, Louisianna, Alabama) regarding *Pseudodontoideus subvexus, P. connasaugensis, Strophitus undulatus, S. pascagoulaensis, S. radiatus,* and *S. williamsi*. Smith et al (2018) found polyphyly in *Strophitus* and resurrected the genus *Pseudodontoideus* for *S. connasaugaensis* and *S. subvexus.* They also found up to 4 evolutionary divergent clades within S. radiatus and formally describe 2 new species, *S. pascagoulaenis*, and *S. williamsi* (Smith et al. 2018). In (2023), Freshwater Mollusk Conservation Society recognized 4 species of *Strophitus.* Future, comprehensive, range-wide research may reveal that *S. undulatus* has a narrower range than previously thought.

The shell of the Creeper (Figure 1) is elliptical and somewhat rhomboid; the anterior end is rounded and the posterior end is bluntly pointed and often obliquely truncated. The posterior ridge is broadly rounded and may be compressed or quite pronounced. The outer surface of young individuals is yellowish or greenish and may have greenish, often wavy rays. Older individuals are dark brown, dark green, or black and usually without rays. The inner surface is white or bluish white and iridescent around the margins and center. The shell is usually less than 110 mm (4.4 in.) in length (Parmalee and Bogan 1998).

Status

NatureServe (2024) currently lists the Creeper as globally secure (G5) due to its wide range. In Alabama the species is ranked critically imperiled (S1), in Georgia the species is not ranked (SNR), in South Carolina the species is ranked imperiled to vulnerable (S2S3), in North Carolina the species is ranked vulnerable (S3), and in Virginia the species is ranked vulnerable to apparently secure (S3S4).

POPULATION SIZE AND DISTRIBUTION

The Creeper is widespread throughout the eastern and central United States and Canada including population in Ohio and Mississippi Rivers, Great Lakes systems, northern and southern Atlantic slope drainages, and part of the Canadian Interior basin. The southern and southeastern states seem to be along the periphery of the species range. In South Carolina the Creeper is found across the piedmont and sandhills region with most reported observations being in the Lynches River, Catawba River, and Turkey Creek and its tributaries (Figure 2). The Creeper, when found, is usually found in small numbers.

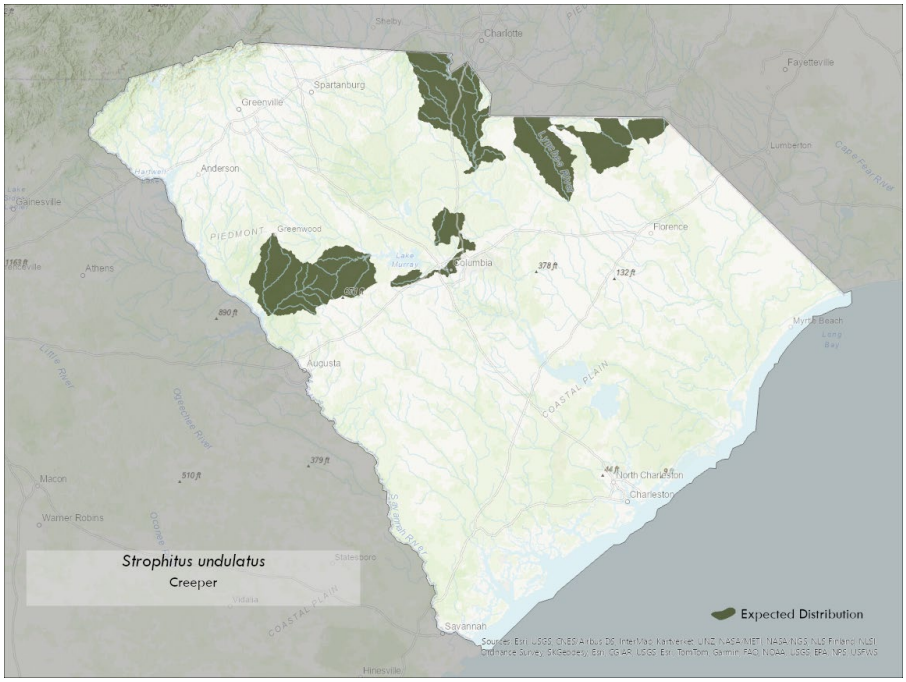

Figure 2. Expected distribution of *Strophitus undulatus* based on reported observations at a HUC 10 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Creeper can be found in shallow water in both small streams and large rivers, although it is not typically found in high gradient or mountain streams. It inhabits a variety of substrates, from silt and mud to boulder fields. In South Carolina, Creeper mussels are not usually found in lotic environments and are typically found in substrates of mixed mud, sand, gravel, and cobble. Research into the tolerances to habitat alterations, pollution, and environmental changes are needed.

The Creeper has a large distribution across Canada and the United States, and this is likely, in part, due to the species being a host generalist. Laboratory trials show Creeper mussels being able to transform on many host species including fish from the following families, Cyprinidae, Cottidae, Percidae, Ictaluridae, Centrarchidae, Acipenseridae, Salmonidae, Fundulidae, Gadidae, Gasterosteidae, and Umbridae; laboratory trials also show transformation on the Eastern Newt. Adequate access to host fishes do not seem to be a challenge for the Creeper mussel and because all native freshwater mussels rely on host fishes for distribution, it is understandable that the mussel species has a wide distribution. Lefevre and Curtis (1912) document that *Strophitus undulatus* larvae, glochidia, can transform in the marsupia, receiving nutrients from the parent mussel, but more research is needed to determine how, why, and how often this method of reproduction occurs. Research is needed to determine interactions between mussels and host species in the wild.

The Creeper uses a conglutinate to distribute glochidia. Watters (2002) found that the conglutinate was made of a homogenous, spongy material and that each glochidium was contained within its egg membrane and tethered by a glochidial thread. Glochidia remain inside of the membrane in the conglutinate until they are forced out from a pore in the membrane via osmotic pressure (Watters 2002). Watters (2002) suggests that when the conglutinate is being brooded in the marsupium it is bathed in a hypertonic solution and only after expulsion into the hypotonic water column does the spongy material of the conglutinate swell, forcing the glochidia out. The brief period of innate motion may attract host fishes and the connection of each glochidium to the conglutinate allows for a higher chance of attachment on host fishes if the conglutinate is ingested. Glochidia of the Creeper are hooked, having a stout, hinged hook at the ventral margin of each triangular valve (Coker at al. 1921).

Coker et al. (1921) note that the marsupium occupied the entire outer gills and egg masses lie transversely in the gills. The Creeper is presumed to be a long-term brooder, having eggs fertilized in the summer, and glochidia released the following spring. Coker et al. (1921) report finding females with glochidia from March to November; however, it is unclear the locality of these reports and the developmental stage of the glochidia.

In South Carolina, gravid females are generally sought out in March and April; however more research is needed to determine the reproductive cycle.

CHALLENGES

In South Carolina, Creeper mussels are not often found in lotic environments or in streams with high gradients or high velocities. Channel modifications including dredging and damming are likely to create environments that create unsuitable habitat for *Strophitus undulatus*. Like other freshwater mussels, the Creeper mussel is sensitive to changes in water quality and habitat degradation, although the degree of sensitivity is understudied. Even though *S. undulatus* is a host generalist, maintaining stream connectivity is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

The Creeper has an unusually wide range for a freshwater mussel, and there is some concern that mussels currently classified as the Creeper in different parts of its range may be other species which would result in a more restrictive range. Comprehensive, range-wide genetic analysis is needed to determine the effective range of *S. undulatus* and to determine if *S. undulatus* is the only species of the genera in South Carolina.

CONSERVATION ACCOMPLISHMENTS

As a part of a SWG grant, 4 sites with historic observation of the species were visited; one animal was collected from one of the survey sites.

CONSERVATION RECOMMENDATIONS

- Conduct additional surveys to look for new populations of the Creeper and closely monitor existing populations.
- Conduct research to determine if channel modifications are directly influencing populations of Creeper.
- Conduct genetic analysis on the Creeper throughout its range.
- Explore the need to elevate the listing of the Creeper based on survey results.
- Determine methods for impounded habitat restoration that will benefit the species, if warranted.
- Protect critical habitats for the Creeper from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Creeper.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Creeper to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Research showing the effects, if any, of channel modification on population distribution.
- Determination of the reproductive cycle of the species and their interactions with hosts in the wild.
- Completion of research into the ability of the species to reproduce without a host.
- Determination of environmental and toxicological tolerances and endpoints.

Savannah Lilliput

Toxolasma pullus (Conrad, 1838)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Morgan Kern (SCDNR)

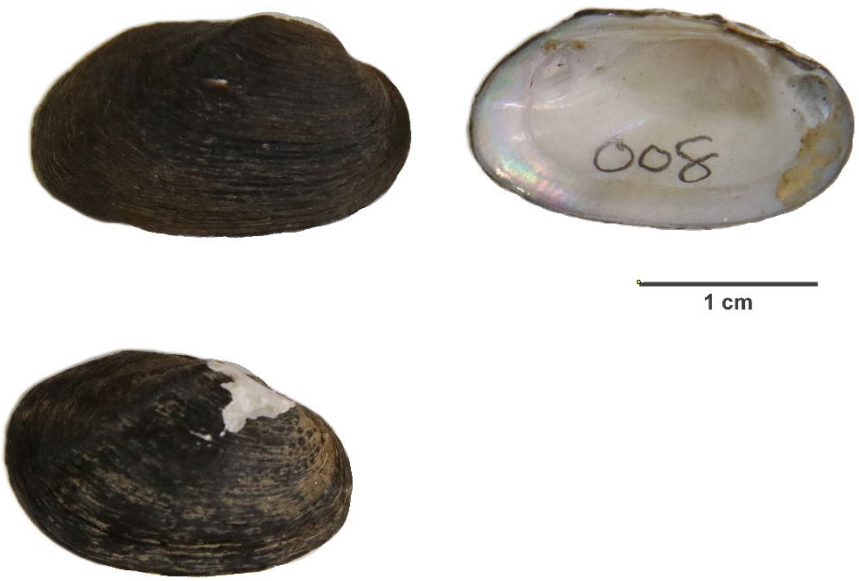

Figure 1. Images of male (top) and female (bottom) *Toxolasma pullus* photographed by Briana Carico, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

Savannah Lilliput from the lower Savannah River exhibit slightly different shell morphology: they have a more extensive beak sculpture than members of this species found elsewhere. They were once described as a separate species, *Carunculina patrickae* (Bates 1966), but *C. patrickae* was synonymized with *C. pulla* by Johnson (1970) and is now known as *Toxolasma pullus*.

The Savannah Lilliput (Figure 1) is a small mussel with an oval or elliptical shell and a double posterior ridge. This ridge is usually angular but is sometimes broadly rounded. Females have a broader, more truncated posterior end; males have a narrower, rounded posterior end. The outer surface of the shell is usually blackish, but sometimes brownish, greenish, or olive with very fine, obscure green rays. The inner surface of the shell is bluish-white with pink to purplish iridescence at the posterior end. Large specimens range from 30 to 35 mm (1.2 to 1.4 in.) in length (Bogan and Alderman 2004, 2008).

Status

NatureServe (2024) currently identifies the Savannah Lilliput as having a global status of vulnerable (G2). This mussel is ranked as critically imperiled to vulnerable (S1/S3) in South Carolina. This species has been a candidate for listing as Threatened or Endangered under the endangered species act since the publishing of the Partial 90-Day Finding on a Petition to List 404 Species in the Southeastern United States as Endangered or Threatened With Critical Habitat in 2011 to the federal register. No species status assessment has been completed to determine the need to list this species.

POPULATION SIZE AND DISTRIBUTION

The Savannah Lilliput once ranged from the Neuse River Basin in North Carolina to the Altamaha basin in Georgia (Bogan and Alderman 2004). This species is presently considered extirpated from the Neuse and

Waccamaw river basins in North Carolina (NCWRC 2024). Savannah Lilliput is found in the Savannah, Ogeechee, and Altamaha River systems in Georgia. It has been lost from the Neuse Basin and is declining rapidly throughout its range. In South Carolina, it has been found in the Saluda and Savannah River Basins (Figure 2). The species was originally described from the Wateree River in South Carolina. Found in Lake Marion, the Congaree River and Halfway Swamp Creek in recent surveys in South Carolina and was reported by GADNR in the Savannah River as recently as 2021. This species was found in Lake Greenwood and Cloud's Creek in the past. Two specimens were found in Crab Tree Swamp (Waccamaw River drainage) in 2007.

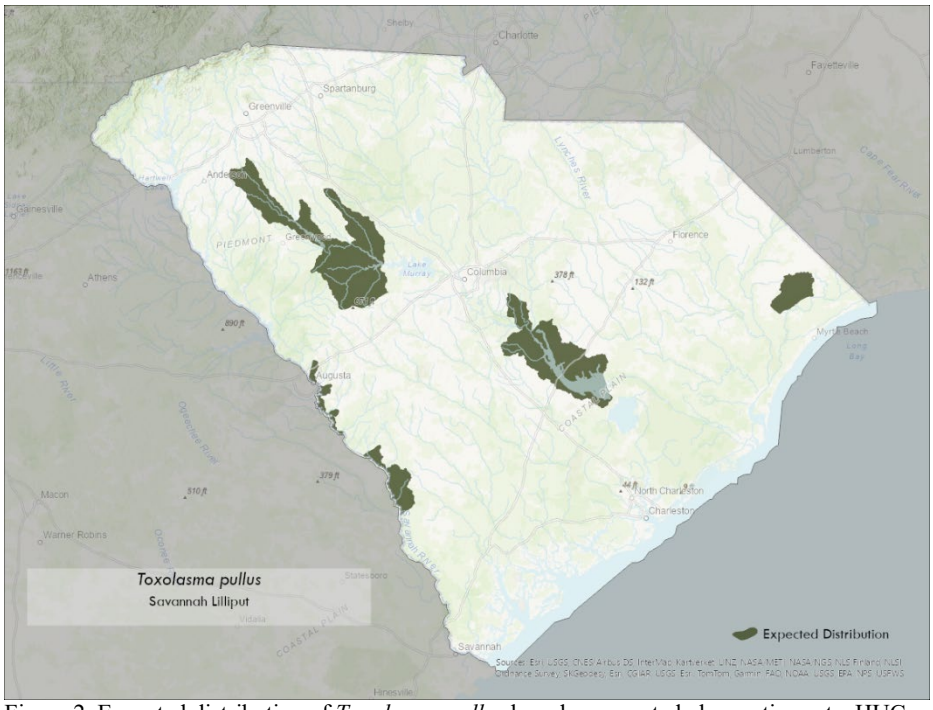

Figure 2. Expected distribution of *Toxolasma pullus* based on reported observations at a HUC 10 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Savannah Lilliput tends to inhabit shallow water, usually at the edges of streams, rivers and lakes; it may also be found in backwaters. This mussel is rarely found in deeper lake waters and tends to be found in mud or silty sand typically found in backwaters, sloughs, and oxbows (Johnson 1970).

Gravid females have been observed between late April through early August; gravid females collected in April had fully developed, active glochidia while gravid females collected in late July and August had only partially inflated marsupia which held mostly embryos and few glochidia (Hanlon and Levine 2004). Hanlon and Levine (2004) notes that gravid females brood in the outer demibranchs and fully charged marsupial gills were milky-white and inflated.

Hybrid Bluegill-Green Sunfish (*Lepomis macrochirus* x *L. cyanellus*) served as suitable host for glochidia of Savannah Lilliput from University Lake in North Carolina, suggesting that other *Lepomis* spp. might also be hosts (Hanlon and Levine 2004).

CHALLENGES

The Savannah Lilliput's primarily shallow water distribution makes it particularly susceptible to off-road motor vehicle traffic, droughts, and water draw-downs in reservoirs. Similarly, water level fluctuations in the Savannah River may affect this species. This species can be hard to detect in traditional stream bed surveys, often requiring intensive surveys of bank habitat and grubbing with low visibility.

Hanlon and Levine (2004) note that a total of 181 pairs of shells of *T. pullus* were collected from muskrat middens along the shoreline; predation of the species may be of concern due to inhabiting shallow areas of streams.

Like other freshwater mussels, the Savannah Lilliput is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. Like other freshwater

mussels, the Savannah Lilliput must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

Work on the propagation of this species has been ongoing at Bears Bluff National Fish Hatchery.

CONSERVATION RECOMMENDATIONS

- Conduct additional surveys for the Savannah Lilliput, in Lake Greenwood and Lake Marion. Additional surveys are needed in areas where the Savannah Lilliput was historically found to determine if populations are extant.
- Conduct genetic analyses across the range of the Savannah Lilliput to determine if populations in the Savannah River described as *Carunculina patrickae* (Bates 1966) are genetically distinct from other populations and if they warrant classification as a separate species.
- Closely monitor water levels and discourage shallow water activities at sites where the Savannah Lilliput is found.
- Study the effects of water draw-downs and low flows and propose new flow regimes if needed to protect the species from stranding, predation, or isolation from suitable habitats in both lotic and lentic habitats.
- Work with other state agencies (DHEC) to determine appropriate minimum flows to protect the Savannah Lilliput. Also, recommend minimum flows during the FERC relicensing process.
- Protect critical habitats for the Savannah Lilliput from future development and further habitat degradation by following Best Management Practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Savannah Lilliput.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Savannah Lilliput to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Development of a list of habitats where populations of Savannah Lilliput exist in South Carolina.
- Completion of targeted surveys where historic occupancy or suitable habitat for host fish. collecting genetic swabs to study the relationships between populations will be a measure of success.
- Achieving minimum flows from dams that are effective in reducing or eliminating mussel strandings.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determine the effects of channel modification, such as dams, on the Savannah Lilliput.
- Determination of environmental and toxicological tolerances and endpoints.

Barrel Floater

Utterbackiana couperiana (Lea, 1840)

Contributor (2005): Jennifer Price (SCDNR)

Reviewed and Edited (2012): William Poly (SCDNR)

Reviewed and Edited (2024): Ericah Beason (SCDNR)

Figure 1. Image of *Utterbackiana couperiana* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan. The NCSM catalog number of the specimen photographed is 48715.2.

DESCRIPTION

Taxonomy and Basic Description

Research from Mock et al. (2004) and Zanatta et al. (2007) found the genus *Anadonta* to be polyphyletic, with eastern North American species forming a monophyletic clade that is distinct from the clade that includes the type species (*Anadonta cygnea*, occurring in Eurasia) and western North American *Anadonta*. The knowledge of this distinctive clade led to the Barrel floater being reassigned into the genus *Utterbackia* by Graf and Cummings (2007) and Cummings and Graf (2010) but no discussion or supporting evidence was provided which led to the reassignment not being recognized. Because of this, the next available genus for the eastern North American clade (including *A. couperiana, A. heardim A. suborbiculata,* and *A. implicata*) was *Utterbackiana* (Frierson, 1927), the senior available name for the monophyletic clade, with the type species being *Anadonta suborbiculata.* The Barrel Floater (*Utterbackina couperiana*) name has been recognized by the Freshwater Mollusk Conservation Society based on the discussion in Williams et al. (2017). The name differs from *Anadonta couperiana* found in the 2015 SWAP.

The Barrel Floater (Figure 1) is laterally flattened (wide) and ranges in color from pale greyish yellow to yellowish brown. The ventral margin of the shell is broadly rounded while the dorsal margin is straight. The shell is thin and lacks pseudocardinal and lateral teeth. The length to height ratio of this species is approximately 1.5. The outer surface of the shell has fine green rays. Barrel floaters may reach over 100 mm (4 in.) in length (Bogan and Alderman 2004, 2008).

The Barrel Floater, like many native freshwater mussels, can be misidentified with other species. The Barrel Floater may be confused with the Paper Pondshell (*Utterbackia imbecillis*) or the Eastern Floater (*Pyganadon cataracta*), especially when alive. The Paper Pondshell umbo is never above the dorsal margin, whereas in the Barrel Floater, it can barely extend above the hinge margin. The Eastern Floater umbo is always above the hinge margin and is typically inflated.

Status

NatureServe (2024) currently identifies the Barrel Floater as having a global rank of apparently secure (G4). This species is ranked as critically imperiled to imperiled (S1S2) in South Carolina and is a species of special concern. The Barrel Floater is critically imperiled (S1) in North Carolina and apparently secure (S4) in Georgia.

POPULATION SIZE AND DISTRIBUTION

The Barrel Floater was once found from the Apalachicola region in Florida to the Cape Fear River Basin in North Carolina (Bogan and Alderman 2004, 2008). However, most records of the species in North and South Carolina are not recent, and it may have been extirpated from much of its former range (Taxonomic Expertise Committee 2004). A few populations are known in the Savannah River (Figure 2) and its tributaries, and there are a few old records from the Little Pee Dee and Edisto Rivers. It is not clear if some of these populations persist, since a recent survey of the Little Pee Dee failed to locate any Barrel Floaters (T. Savidge pers. comm., Jan. 25, 2005). It is quite rare when it is found (Taxonomic Expertise Committee 2004). There have been a total of 16 reported observations of the species in South Carolina from 1978-2006, mostly in the coastal plain region. Fuller (1979) stated that the Barrel Floater was found in much of peninsular Florida and not usually populous in the Atlantic drainages to the North, with South Carolina being on the periphery of its range.

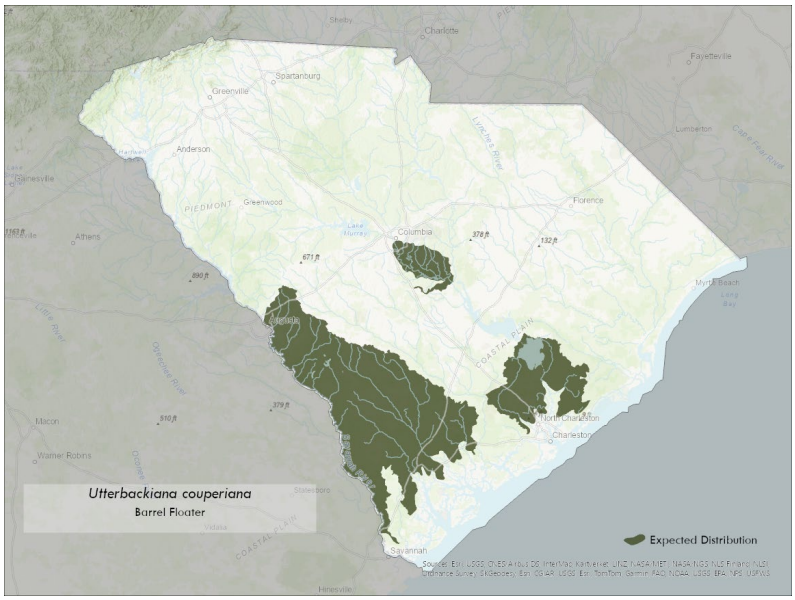

Figure 2. Expected distribution of *Utterbackiana couperiana* based on reported observations at a HUC 8 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Barrel Floater is found in ponds or slow flowing streams with soft, sandy or muddy bottoms (Fuller 1979). Often those bottoms are very deep with soft, unstable mud (Taxonomic Expertise Committee 2004). Although the Barrel Floater can tolerate softer sediments, like all South Carolina native mussels, it must be able to remain stabilized during high flow events. Although increased development from anthropogenic sources and stream modifications may provide more suitable substrate types for the Barrel Floater (Fuller 1979), it may result in higher flow during precipitation events due to increased runoff, making habitats undesirable because of the increased velocity and shear stress.

There are no reported host fish for the Barrel Floater. Host fish for species in the same genus include Alewife (Alosa pseudoharengus), Blueback Herring (Alosa aestivalis), and Striped Bass (*Morone saxatilis*) (Kneeland and Rhymer 2008). White Sucker (Catostomus commersoni), Pumpkinseed (Lepomis gibbosus), White Perch (Morone americana), and Threespine Stickleback (*Gasterosteus aculeatus*) are suspected hosts (Davenport and Warmuth 1965; Wiles 1975).

One report of the Barrel Floater notes an observation of a singular population in Florida containing gravis females in midwinter (Heard 1979).

CHALLENGES

Research into the life history and habitat preferences of the Barrel Floater is minimal. Observational data suggest that the species, unlike most native freshwater mussels, is tolerant of siltation but sensitive to toxicants (Taxonomic Expertise Committee 2004). The biggest challenge to this species is the sharp decline from its previous historic range and the extreme rarity with which it is encountered. Little is known about specific challenges to this species and the causes of its decline are not understood. No known ecological or toxicological endpoints for the species exist. The life history and host fish preferences are undetermined which are needed prior to producing animals for potential augmentation of populations.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments for the Barrel Floater at this time.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to determine the current status of the Barrel Floater.
- Determine host fishes used by the Barrel Floater.
- Explore the need to list the Barrel Floater within South Carolina, based on survey results.
- Closely monitor the presence of various pollutants in present and historic parts of the Barrel Floater's range.
- Evaluate the species' sensitivity to pollutants and address any point source pollutants that are found.
- Consider reintroduction of the Barrel Floater to parts of its historic range, where and when conditions seem to have improved.
- Protect critical habitats for the Barrel Floater from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Barrel Floater.

MEASURES OF SUCCESS

- Thorough, standardized surveys in historical ranges of the species which aid in a comprehensive status assessment of the species.
- Determination of host fishes used for reproduction of the Barrel Floater.
- Determination of life history of the Barrel Floater including time of spawning and brooding.
- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Barrel Floater.
- Collecting swabs, genetic material, or vouchers when needed to determine population genetics.

Alewife Floater
Utterbackiana implicata

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Morgan Kern (SCDNR)

Figure 1. Image of *Utterbackiana implicata* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

Alewife Floater (*Utterbackiana implicata)* was reassigned into the genus *Utterbackiana* in Williams et al. (2017). The scientific name was changed from *Anodonta implicata* (Say, 1829) as it appeared in the 2015 SWAP.

The shell of the Alewife Floater is a medium- to large-bodied mussel that can grow to around 6 inches in length (Figure 1). The umbo or beak of the shell is raised above the hinge line, which is straight or slightly curved. The majority of the shell is thin but thickens on the ventral margin moving from the posterior to anterior of the shell. This thickening is more pronounced in larger individuals. Shells lack pseudocardinal and lateral teeth. The shell surface is smooth and varies from almost shiny to rough. The shell surface may have irregular growth lines which can form ridges. The anterior margin of the shell is narrowly rounded; the posterior margin is bluntly pointed below the midline. The ventral margins are generally straight. The shell is elliptical and oblong to ovate. The color of the periostracum varies. Observed colors include yellowish-brown, greenish-brown, and reddish-brown; individuals often become dark brown to black with age. Shells of young Alewife Floaters may have fine green rays. The inner surface, nacre, of the shell varies from white, salmon, or purple and is generally darker in the beak

Figure 2. Images of *Utterbackiana implicata* courtesy of Tim Savidge, Three Oaks Engineering.

cavity (Smith 1991; Bogan and Alderman 2004, 2008; Nedeau 2008).

As with many of our native freshwater mussels, Alewife Floater can be easily misidentified especially when the individual is still living. They can closely resemble Easter Floater (*Pyganadon cataracta*) in shape, color, umbo or beak height. Both species lack pseudocardinal and lateral teeth. The main differentiating feature is the thickening of the shell which is absent in Eastern Floater.

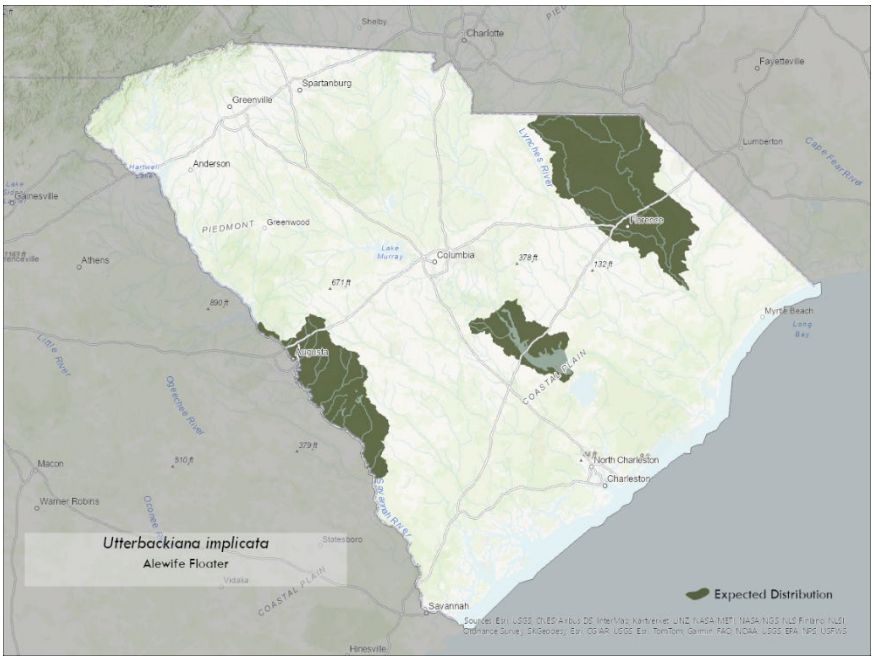

Figure 3. Expected distribution of *Utterbackiana implicata* based on reported observations at a HUC 8 watershed level and designated ecoregions.

Status

Nature Serve (2024) currently identifies this species as globally secure (G5). It is currently ranked as SU in South Carolina as no targeted efforts to survey for this species in SC have been made. Some shells have been identified by morphology as recently as 2023 but have not been confirmed genetically.

POPULATION SIZE AND DISTRIBUTION

The Alewife Floater is mainly a northern species with a primary range extending from Maryland to Canada, with disjunct populations in the Chowan and Pee Dee River basins in North Carolina. Shells have been found in the Santee River Basin of South Carolina (Alderman 2005) and in lake Wateree in 2023. This species may be found in deeper water which has been historically under surveyed in South Carolina and is similar in morphology to other native species which may cause this species to be misidentified when found alive. Its host fish are mainly anadromous species that travel through South Carolina to reach established populations found in North Carolina in the Pee Dee basin (Bogan and Alderman 2004, 2008). If carrying Alewife Floater glochidia during travel, the species could be throughout the Pee Dee basin. Fuller (1978) thought the species might be found eventually in the Outer Coastal Plain of South Carolina, particularly in the lower portions of rivers. Specimens have not been confirmed in South Carolina genetically.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Alewife Floater is found in streams, rivers, and pools and in a variety of substrates including silt, sand, and gravel across its range. Its distribution appears to be controlled by the distribution of its host fish, mainly clupeids such as the alewife (*Alosa pseudoharengus)* and other migratory fish such as Striped Bass (*Morone saxatilis*).

Reported hosts include Alewife (Alosa pseudoharengus), Blueback Herring (Alosa aestivalis), and Striped Bass (*Morone saxatilis*) (Kneeland and Rhymer 2008). White Sucker (Catostomus commersoni), Pumpkinseed (Lepomis gibbosus), White Perch (Morone americana), and Threespine Stickleback (*Gasterosteus aculeatus*) are suspected hosts (Davenport and Warmuth 1965; Wiles 1975).

CHALLENGES

Without opening its shell, the Alewife Floater can resemble the Eastern Floater and may be misidentified during surveys. Alewife Floater continues to be rare in the rivers of South Carolina and little work has been done surveying the state's reservoirs for freshwater mussels. Due to the lack of direct survey effort, this species is considered data deficient in South Carolina.

Like other freshwater mussels, this species is sensitive to channel modification, agriculture and urban pollution, sedimentation, and saltwater intrusion. Additionally, the Alewife Floater appears to be dependent on migratory fishes for reproduction. Impoundments obstructing migratory fish through the Pee Dee watershed are likely to threaten the Alewife Floater. Channel modifications and fragmented habitats directly impact the only method of dispersal by the species.

Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the Alewife Floater currently.

CONSERVATION RECOMMENDATIONS

- Conduct additional surveys in reservoirs in the Pee Dee Basin, collecting genetic swabs to determine Alewife Floater presence and abundance in this state.
- Complete genetic analysis to determine if individuals collected in South Carolina are Alewife Floater.
- Determine habitats that are critical for this species in South Carolina.
- Perform host fish trials to determine natural hosts for native populations.
- Facilitate the travel of anadromous fishes such as the alewife by keeping rivers and streams free of artificial obstructions or by using fish ladders at dams.
- Conserve populations of host fish to insure propagation of the Alewife Floater in the wild.
- Protect critical habitats for the Alewife Floater from future development and further habitat degradation by following Best Management Practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Alewife Floater.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.

- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

- Completion of targeted surveys in areas of historic occupancy and similar habitat types to determine the species range and distribution.
- Collection of genetic material of Alewife Floater and Eastern Floater to ensure successful identification of species range and distribution.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Comprehensive, range-wide genetic analysis of the species.
- Completion of thorough, standardized surveys in presumed range and habitat of the species.
- Determination of host fishes used for reproduction of the Alewife Floater in South Carolina.
- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Alewife Floater.
- Determine the effects of channel modification, such as dams, on the Alewife Floater.
- Determination of environmental and toxicological tolerances and endpoints.

Notched Rainbow

Venustaconcha constricta (Conrad, 1838)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Morgan Kern (SCDNR)

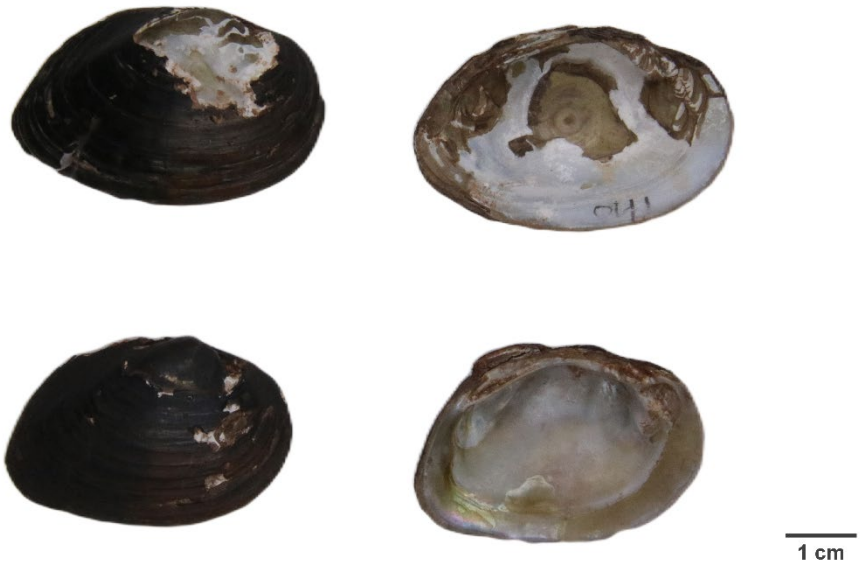

Figure 1. Images of *Venustaconcha constricta* photographed by Briana Cairco, SCDNR. Both specimens are presumed male based on shell morphology.

DESCRIPTION

Taxonomy and Basic Description

The Notched Rainbow was reassigned into the genus *Venustaconcha* by the Freshwater Mollusk Conservation society in (2023) based on the work in Watters (2018) and supporting evidence from Kuehnl (2009). The scientific name was changed from *Villosa constricta* (Conrad, 1838) as it appeared in the 2015 SWAP.

The shell of the Notched Rainbow (Figure 1) is rather small and short and is sub-elliptical in shape. The shell of the female has a posterior point a little more than midway up from the base with a small swelling along the outline. The shell of the male is often sub-rhomboid with the posterior point generally less than midway up from the base. The outer surface of the Notched Rainbow's shell is yellowish-green or green and has indistinct rays. The inner surface of the shell is bluish, sometimes purplish in the center and sometimes thicker in front (Bogan and Alderman 2004, 2008).

Status

NatureServe (2024) currently identifies the Notched Rainbow as vulnerable (G3) globally. This species is ranked critically imperiled (S1) in South Carolina and vulnerable in North Carolina and Georgia (S3).

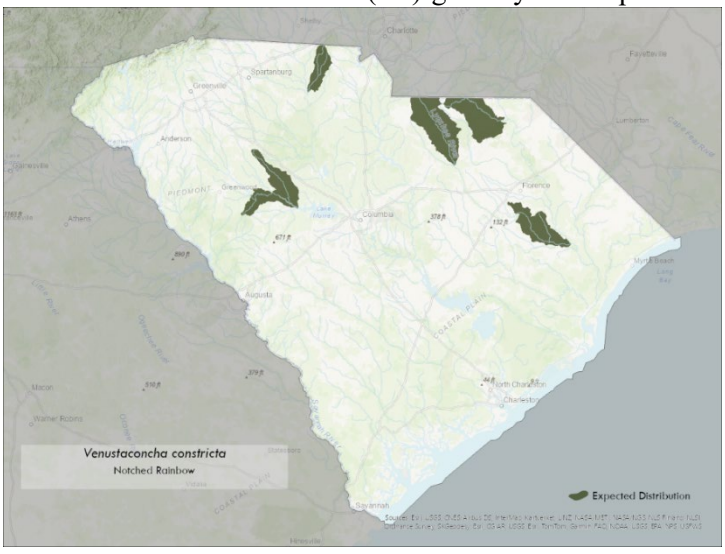

Figure 2. Expected distribution of *Venustaconcha constricta* based on reported observations at a HUC 10 watershed level and designated ecoregions.

POPULATION SIZE AND DISTRIBUTION

The Notched Rainbow ranges from the Rappahannock River Basin in Virginia to the Santee-Cooper Basin in South Carolina (Johnson 1970). In South Carolina, it has been found in the headwaters of the Lynches River, Hills Creek, Black Creek, and Deep Creek in the Pee Dee drainage as well as in the Little Sandy River in the Broad River Basin. It has declined in many portions of its range, especially in the larger rivers. In

recent, targeted surveys at historic sites have resulted in no animals of the species found. In 2024, a shell of *V. constricta* was collected in Thompson Creek in the Pee Dee watershed.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

This species is found in riffles, runs, and pools of streams and large rivers. It prefers sandy or sand and gravel substrates only in very clean, high-quality habitats.

This species has been found gravid March-May in North Carolina. Eads et al. (2006) reported Fantail darter as a possible host in a laboratory setting. Green Sunfish also produced a small number of juvenile Notched Rainbow but was not recommended as a host in that study (Eads et al 2006). Watters et al. (1999) reported small numbers of juveniles produced from infesting Smallmouth Bass, Central Stoneroller, Goldfish, Siamese Fighting Fish, Blackside Darter, Tessellated Darter, Logperch, Yellow Perch, Redbreast Sunfish, Longear Sunfish, Smallmouth Bass, Rockbass and a Bullfrog Tadpole in laboratory infestations. No work has been done to determine hosts in the wild and additional laboratory testing is still needed for fish species with overlapping ranges.

CHALLENGES

This species is becoming increasingly rare in South Carolina, historic habitats such as the headwaters of the Lynches River may no longer be able to support this species. Work to recover this species through propagation would be difficult without access to broodstock from North Carolina or Virginia. Little is known about the reproductive and brooding behaviors of *V. constricta,* and wild host fish(es) are unknown.

Like other freshwater mussels, the Notches Rainbow is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. Like other freshwater mussels, the Notched Rainbow must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

As a part of a SWG grant, 5 sites with historic observation of the species were visited; however, no live animals were collected during survey efforts.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to determine population status and distribution of the Notched Rainbow. Closely monitor known populations and any additional populations discovered in the surveys.
- Determine habitats that are critical for this species in South Carolina.
- Develop a restoration plan that considers the need for augmentation or reintroduction.
- Protect critical habitats for the Notched Rainbow from future development and further habitat

degradation by following best management practices and protecting and purchasing riparian areas.

- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Notched Rainbow.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Notched Rainbow to various point and non-point sources of pollution and land use impacts.
- Research the reproductive and brooding behavior of the species.

MEASURES OF SUCCESS

- Completion of targeted surveys where historic occupancy or suitable habitat for host fish.
- Collection of genetic swabs of Notched Rainbow when found.
- Development of a restoration plan that may include propagation and culture to reintroduce the species in suitable habitat within its historic range.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determination of environmental and toxicological tolerances and endpoints.
- Determination of life history of the Notched Rainbow including time of spawning and brooding.
- Determination of wild host fishes used for reproduction of the Notched Rainbow.

Reviewed and Edited (2024): Ericah Beason (SCDNR)

Figure 1. Images of male (top) and female (bottom) *Villosa vibex* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

In the 2015 SWAP, this mussel species was represented as the Eastern Rainbow (*Villosa modioliformis*) but has since been synonymized with the Southern Rainbow (*Villosa vibex*) based on review of the *Villosa* genus by Watters (2018), but attention was drawn to the uncertainty of the Atlantic Slope species differing from that found in the Gulf of Mexico drainages. *Villosa modioliformis* was first synonymized with *V. vibex* in (1970) by Johnson who examined shell specimens from across its range. The synonymizing of *V. modioliformis* into *V. vibex* was recognized by the Freshwater Mollusk Conservation Society in (2019) but there remains uncertainty in Atlantic Slope specimens. Comprehensive genetic analysis is needed to determine if individuals in South Carolina are *V. vibex* or *V. modioliformis*.

The shell of the Eastern Rainbow (Figure 1) is elliptical to an elongate egg-shape with the anterior and posterior margins evenly rounded and the dorsal margin straight. The ventral margin is straight to slightly curved in males and often more strongly curved in females towards the posterior. The posterior ridge is broadly rounded. The outer surface of the Eastern Rainbow's shell is greenish-yellow to olive brown with broad unbroken to slightly wavy dark green rays. These rays are occasionally absent or restricted to the posterior portion of the shell. The umbo is wide, very low, and sculptured with a few coarse, double-looped ridges. The inner surface of the shell is bluish-white and often iridescent posteriorly. The shell length averages 60 mm (2.4 in.) but may be up to 100 mm (4 in.).

This species can easily be mistaken for *Villosa delumbis and Sagittunio vaughanianus* when alive. *Villosa delumbis* females are more obviously sexually dimorphic than those of *Villosa vibex* and have broken rays. Individuals of *Sagittunio vaughanianus* are darker in color and have a more pointed posterior.

Status

NatureServe (2024) currently identifies the Southern Rainbow as having a global ranking of secure (G5). In Tennessee and Louisiana, the species is ranked as imperiled (S2) and in South Carolina the species is ranked as imperiled (S2?). Georgia has the species ranked as secure (S5) and Alabama and Mississippi have the species ranked as apparently secure (S4) and (S4?) respectively.

POPULATION SIZE AND DISTRIBUTION

The Southern Rainbow is found primarily in the Gulf Coast area and ranges from the Cape Fear Basin in North Carolina, south to peninsular Florida and west to the Pearl River in the Mississippi drainage. In South Carolina, there have been a total of 57 reported observations to date. This species has been most frequently observed in the Steven's Creek sub-basin of the Savannah River (Figure 2). Outside of this, observations are sparse and scattered throughout the following sub-basins: Salkehatchie, Upper Savannah, Middle Savannah, Broad-St. Helena, Lower Catawba, Black, Lynches, Lower Pee Dee, Lake Marion, Cooper, Saluda, Enoree, and South Fork Edisto. Even when found in South Carolina, the Southern Rainbow is never abundant. Although the Southern Rainbow is more abundant in Georgia, the individuals collected have a different appearance, which, to some researchers, indicates that the South Carolina and Georgia populations are actually different species (Taxonomic Expertise Committee 2004).

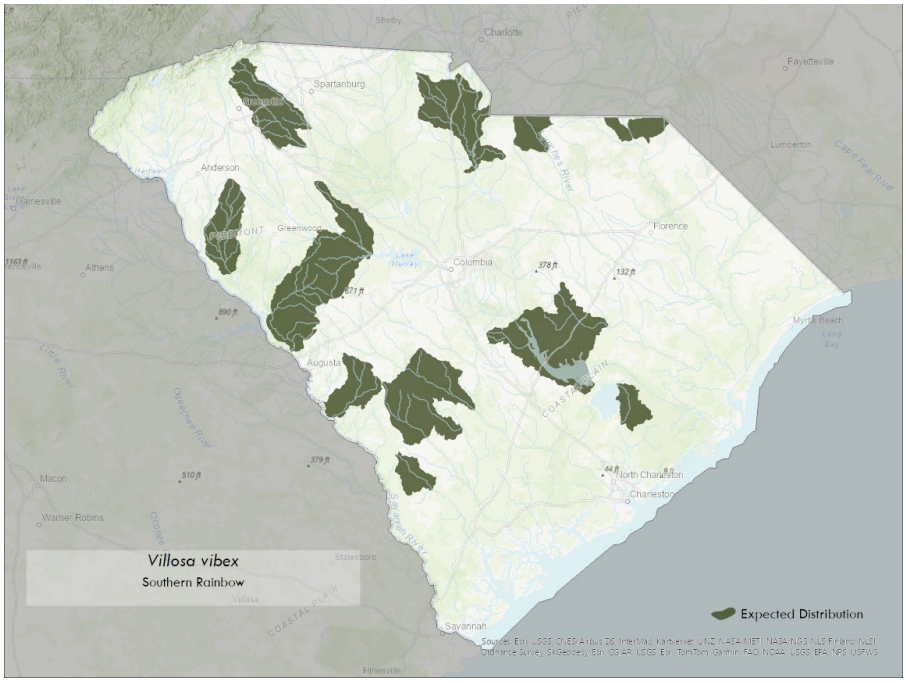

Figure 2. Expected distribution of *Villosa vibex* based on reported observations at a HUC 10 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Southern Rainbow is found in sandy runs of small to medium-sized creeks and small rivers. This mussel is sometimes found in rocky portions of the same types of rivers (Taxonomic Expertise Committee 2004). In the Conasauga River in Tennessee, the Eastern Rainbow has been reported to live in stretches with moderate current at depths of less than 0.9 m (3 ft.) (Bogan and Alderman 2004, 2008). Johnson (1970) notes the species being found in mud and soft sand, particularly with rich vegetable detritus.

Laboratory trials show that host fishes include Green Sunfish, Blackspotted Topminnow, Redeye Bass, Largemouth Bass, Spotted Bass, and Longear Sunfish, with Spotted Bass producing the most juveniles in the trial (Haag et al. 1999). During the study, 10 of the 13 gravid adult females collected from Shoal Creek in Alabama were observed displaying a mantle margin lure in March (Haag et al. 1999). Seven of the females were observed lying on their sides, completely exposed on top of the substrate and 3 females were exposed but near rocks; male *Villosa vibex* were mostly observed buried with only siphons exposed, with 1 exception that was found exposed. Haag et al. (1999) describe the modified female mantle as extending "…from a point immediately anterior to the incurrent siphon to a point directly ventral and opposite to the posterior-most end of the hinge ligament." Additionally, the observed mantle margins were "…ornamented with approximately 15 pairs of unbranched tentacle-like papillae about 15 mm in length that were thick at the base but tapered to a fine point." (Haag et al. 1999). Coloration of the papillae, the outer sheath, and inner surface of the sheath varied but had some variation of inky black, rusty orange, and fine black spots (Haag et al. 1999). All females observed had fully gravid gills visible just below the shell margin and the papillae were pulsated rapidly and actively (Haag et al. 1999).

Additional work shows that *V. vibex* mostly display during the day and require physical interaction before releasing large amounts of glochidia (Haag and Warren 2000). Watters (2018) noted seeing gravid females from June to the following February.

CHALLENGES

A comprehensive approach is needed to determine if animals of *Villosa vibex* being collected in South Carolina are the same species as those collected in Alabama and Mississippi. Drought conditions from 1999-2001 resulted in species decline in the Flint River drainage in Georgia as seen in surveys (Chastain et al. 2005).

Like other freshwater mussels, the Southern Rainbow is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. Like other mussels, the Southern Rainbow must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

Preliminary genetic analyses have been conducted on some populations of the Southern Rainbow. However, comprehensive genetic analysis is needed to determine if populations from different parts of its range represent distinct species.

CONSERVATION RECOMMENDATIONS

- Conduct additional, comprehensive genetic analyses across the range of the Southern Rainbow.
- Conduct additional surveys for the Southern Rainbow across SC and target areas where fragmented occurrences have been reported.
- Explore the need to list the Southern Rainbow within South Carolina, based on survey results.
- Protect critical habitats for the Southern Rainbow from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Southern Rainbow.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Southern Rainbow to various point and non-point sources of pollution and land use impacts.
- Determine habitats that are critical for this species in South Carolina.

MEASURES OF SUCCESS

- Resolving genetic issues across the range of the Southern Rainbow.
- Persistence of known populations and an increase in numbers of rare species will indicate the success of management activities.
- Verification of laboratory tested host fishes in the wild.
- Completion of targeted surveys in areas of historic occupancy and similar habitat types across SC.
- Determine the effects of channel modification, such as dams, on the Southern Rainbow.
- Determination of environmental and toxicological tolerances and endpoints.

Rotund Mysterysnail

Callinina intertexta (Say, 1829)

Contributor (2024): Ericah Beason and Jeff Smola (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Originally described by Say (1829) as *Paludina intertexta*, but over time has had many names synonymized to its current name. North American species of *Viviparus* were reassigned to genus *Callinina* by Stelbrink et al. (2020) where they determined the genus *Viviparus* is polyphyletic. In the 2023 Freshwater Gastropod list released by the Freshwater Mollusk Conservation Society, this change was recognized for *C. intertexta* (FMCS 2023).

Figure 1. Image of *Callinina intertexta* labelled *Viviparus intertextus* on web-based Freshwater Gastropods of North America. Image courtesy of Dillon et al. (2019).

Its shell is sub globose, yellowish-green or brownish, wrinkled, and with many thin, revolving lines. There are nearly four volutions and the suture is rather deeply indented (Figure 1). It is remarkable for its globular form and for the numerous obsolete lines. *Callinina* can be distinguished from *Viviparus* and the other genera with a concentric inverted-comma-shaped operculum by the following combination of characters: a thin marginal region that obviously differs in color from the enamel region; a shiny, smooth and relatively small nuclear region; and a narrow inner enamel region (Zhang and Rintelen 2021).

Callinina intertexta could be misidentified with *C. georgiana*, but *C. intertexta* has a relatively darker and thicker operculum in comparison to *C. georgiana* (Say 1829). Additionally, *C. georgiana* tends to have thick, dark bands attributing to its common name the "Banded Mysterysnail." Although, in tannic waters, it could be hard to see the bands due to shell staining.

Status

The species is globally ranked as apparently secure (G4) but is ranked as imperiled (S2) in North Carolina and ranked as imperiled to vulnerable in South Carolina (S2S3) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Rotund Mysterysnail is primarily found in the American interior basins but has many occurrences throughout the Atlantic drainages, ranging from Georgia to southern North Carolina; however, the presence of the species in these states seem peripheral. There have been a total of 41 reported occurrences of the species in South Carolina from 1965-2012 (Figure 2). More than half

of the observations were reported by Dillon and team. All observations have been in the coastal plain region or right on the boundary of the coastal plain and coastal zone. Animals have been found in all 4 major watersheds in South Carolina including the Pee Dee, Santee, ACE, and Savannah. Although we have observations of this species, we do not have a comprehensive understanding of their range, relative densities, habitat preferences, or population dynamics. The last reported occurrence of this species was in 2012, even though work within their presumed distribution was occurring.

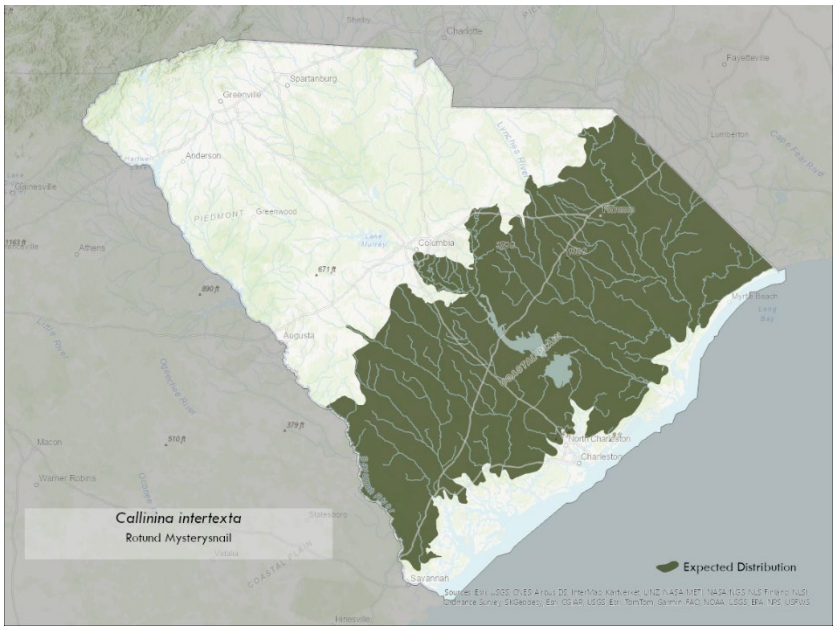

Figure 2. Expected distribution of *Callinina intertexta* in South Carolina based on reported observations at a HUC 6 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Dillon et al. (2019) report that individuals found in Atlantic drainages are typically in swamps and slow-moving rivers within the Coastal Plain. They note that individuals are often in shallow, isolated, or temporary habitats. Additionally, despite the dark tannic waters they inhabit, it has been observed that they are not overly acidic (Dillon et al. 2019). Nothing is known regarding the life cycle of *V. intertexta*, targeted surveys and research is needed. Cook (1949) has recorded the process of filter feeding in European *V. viviparus*. The stationary, burrowing habits observed in the European species closely resemble those exhibited by *C. intertexta* in the swamps of the US interior and coastal plain (Dillon et al. 2019).

CHALLENGES

The greatest challenge with the Rotund Mysterysnail in SC seems to lie in the unfavorable survey conditions of its preferred habitat. This species is often found in swamps which are difficult to navigate and pose additional challenges due to mosquitos, alligators, and deep, soft mud that is difficult to traverse. Additionally, not much is known about environmental and toxicological tolerances of the species and at present, there is not a standardized survey protocol for snails in South Carolina. The development of a standardized survey is needed to ensure accurate and insightful data collection to aid in our understanding of population dynamics of the species.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Rotund Mysterysnail.

CONSERVATION RECOMMENDATIONS

- Develop a standardized survey protocol for snails in the coastal plain and coastal zone.
- Collect voucher specimens to aid in the genetic confirmation of the species and family which it belongs
- Explore the need to list the Rotund Mysterysnail within South Carolina based on survey results.
- Conduct standardized surveys in coastal plain and coastal zone to determine the population range and life history requirements for the Rotund Mysterysnail.
- Carefully monitor existing populations of the Rotund Mysterysnail
- Determine habitat restoration methods that will benefit the Rotund Mysterysnail.
- Protect critical habitats for the Rotund Mysterysnail from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Rotund Mysterysnail to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Panhandle Pebblesnails.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

OVERVIEW

Freshwater snails are a diverse group of animals within the class Gastropoda (phylum Mollusca) and are broadly distributed worldwide. North America is of global importance, having one of the highest numbers of freshwater snail species recognized. In 2013, Johnson et al. completed a conservation assessment of 703 species of native freshwater snails from Canada and the United States representing 16 families and 93 genera. Here they described that freshwater gastropods have 67 species (10%) considered likely extinct, 278 (40%) endangered, 102 (15%), threatened, 73 (10%) vulnerable, and 26 (4%) have uncertain taxonomic status. This makes 74% of the entire fauna imperiled, exceeding levels of fishes (39%), crayfishes (48%), and even bivalves (72%) by a small margin. The remaining 157, only 26%, of North American species are considered stable. Freshwater gastropods are an important component in their aquatic ecosystems; most feed on periphytic and epiphytic algae and biofilms. In some habitats, freshwater gastropods may be the principal grazers and are capable of significantly influencing algal primary production. Others are suspension or deposit feeders, capturing and resuspending nutrients in the water column.

Like other aquatic organisms, freshwater gastropods are largely threatened by rapid habitat changes due to anthropogenic development, inputs, degradation, or modifications. Johnson et al. (2013) point to habitat destruction in medium and large rivers as the primary cause for most extinctions of highly endemic species (those occurring in a single lake, stream, or spring), citing damming and channelization (45 species, 67% of total), drainage or diversions of lakes (8 species, 12%), alteration of springs (4 species, 6%), and potential effects of exotic fish introduction (2 species, 3%).

In South Carolina, a total of 45 species are recognized to potentially occur in the state; however, 8 are non-native to SC and 2 need to be genetically confirmed. No recent standardized surveys have been completed across the state of South Carolina. The bulk of observations which lead to species

recognition in South Carolina came from Burch and Tottenham (1980) placing the species in SC, or Dillon et al. (2019) reporting observations from 1952-2019. Nomenclature and uncertain taxonomy pose a specific challenge when placing observation records in South Carolina, which can be seen in some species profiles below. The State Wildlife Action Plan aims to provide a framework for the conservation of species with the greatest need for conservation in the state; however, it proves difficult to place a conservation ranking on species with minimal data. Because of this, 9 species, representing 6 families are given a data deficient conservation ranking, highlighting the need to prioritize collection of baseline data.

FAMILY PLANORBIDAE

Family Planorbidae, the "Rams-horn Snails" is a family of air breathing, freshwater aquatic, pulmonated gastropods. There are a total of 16 genera and 52 species of Planorbidae recognized in the US, Canada, and Mexico by the Freshwater Mollusk Conservation Society as of 2023. Animals in this family can range in size from 1mm to over 30mm and in most cases are discoidal or coiled in a singular plain (Burch 1982), see Figure 1. In general, animals in the Planorbidae family have lost their gill, leaving respiration to occur across the entire mantle cavity. Planorbids are monoecious and able to cross- or self-fertilize and the egg masses are gelatinous, transparent, colorless, and sausage-shaped with numerous yellow eggs (Clarke 1981). Many species produce multiple generations in a year, and others may take a year to reach maturity (Burch 1989).

South Carolina recognizes 9 genera and 10 species of freshwater snails in the family Planorbidae, 2 of which are data deficient, the Flexed Gyro (*Gyraulus deflectus*) and the Thicklip Rams-horn (*Planorbula armigera*) of which are described below.

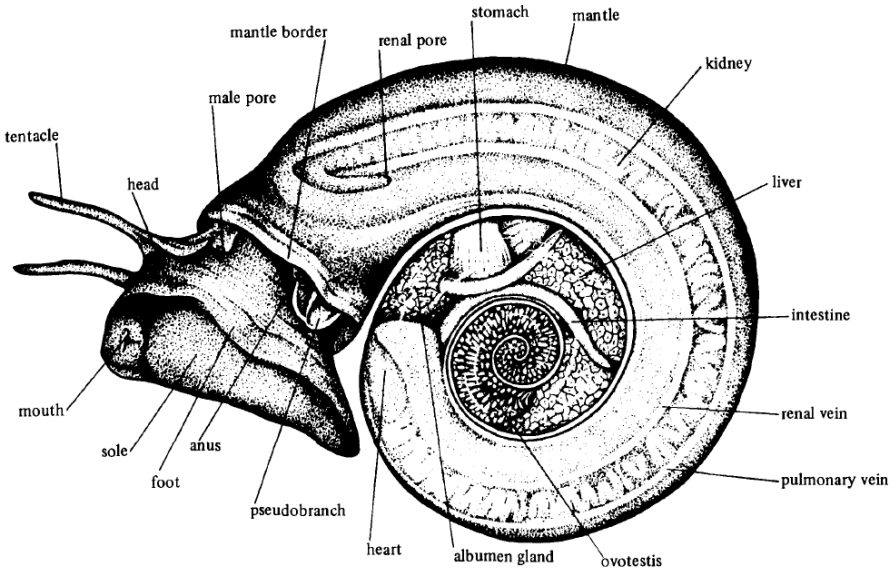

Figure 1. Planorbid (*Biomphalaria*) with shell removed to show aspects of anatomy (left side) pulled from Burch 1982 but originally seen in Barbosa et al. 1968, after Demian.

Flexed Gyro
Gyraulus deflectus (Say, 1824)

The Flexed Gyro was originally described as *Planorbis deflectus* by Say in 1824 and has a dextral shell with five whorls that are flattened and slightly rounded. The spire is not impressed, and the suture is indented but not profoundly. The shells are pale white to flat yellow in color and may exhibit some green.

Figure 1. Image of *Gyraulus deflectus* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

The Flexed Gyro populations are widely distributed across the northern ranges of the US, throughout Canada, and into the central Arctic. The Flexed Gyro has a global ranking of secure (G5); however, the species does not seem secure at the periphery of its southern range, receiving a conservation ranking of vulnerable (S3) in Virginia and imperiled (S2) in North Carolina (NatureServe 2024). In South Carolina, the species has a ranking of SU because of insufficient data on the species. Individuals are observed in several habitats including wetlands, marshes, ponds, lakes, and the shores of rivers, found in both perennial and intermittent waters, usually in mud or on vegetation where inhabiting (Clarke 1981, Burch 1989). Egg masses are small, containing only 2-5 eggs, and gelatinous (Clarke 1981). Although no individuals of *Gyraulus decflectus* have been observed in South Carolina, Burch and Tottenham (1980) placed the species in Virginia and later populations were found in North Carolina. Because no targeted efforts have been completed in South Carolina, the Flexed Gyro distribution cannot be confirmed or denied and therefore, a presumed species distribution map could not be generated.

To accurately determine a conservation priority for this species, presence/absence surveys must be conducted throughout the potential range, collecting voucher specimens or genetic material to confirm the species. Presence/absence surveys could be completed simultaneously with catch-per-unit-effort surveys to determine the relative abundance of the species at specific sites. A thorough study into the reproductive behavior and life cycle could give biologists a better understanding of their population dynamics.

Thicklip Rams-horn
Planorbula armigera (Say, 1821)

The Thicklip Rams-horn was originally described as *Planorbis armigerus* by Say in 1821 and has a dextral shell with a perfectly regular spire that is slightly concave. The suture is well impressed and there are four whorls with a profound umbilicus. The shell is often brownish in color but may exhibit some greenish-brown hues.

Figure 2. Image of *Planorbula armigera* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

Thicklip Rams-horn has a global ranking of secure (G5) and a South Carolina state ranking of SU due to insufficient data on the species (NatureServe 2024). Thicklip Rams-horn are widespread across the United States with scattered populations from Florida to Maine and as far west as Nebraska. Populations of this species seem to tolerate a multitude of habitat types including sluggish water, small order streams, large rivers, swamps, marshes, intermittent pools, and ponds. Although widespread throughout the US west of the Rocky Mountains, no individuals of *P. armigera* have been reported in South Carolina since Burch and Tottenham (1980) placed them in the state. This may be due to a lack of targeted sampling in the coastal plain region where fragmented populations may occur. Dillon and team collected individuals in the coastal plain region in North Carolina, but specimens were found closer to the VA border rather than SC border (Dillon et al. 2019). Because we are unable to confirm the presence of the species at this time, a presumed distribution map could not be generated.

To accurately determine a conservation priority, preliminary presence/absence surveys must be conducted throughout the potential range of the species, collecting voucher specimens or genetic material to confirm the identity of presumed individuals. Presence/absence surveys could be completed simultaneously with a catch-per-unit-effort survey to determine the relative abundance of the species at specific sites. Additionally, not much is known about the specific life history of the species outside of the generalized reproduction history of the family which it belongs. A thorough study into the reproductive behavior and life cycle of the species could give biologists a better understanding of their population dynamics.

FAMILY LYMNAEIDAE

The family Lymnaeidae, the “Pond Snails” is the most diverse family of freshwater gastropods and has a global distribution, being most diverse in the northern US and Canada. There are 13 genera and 61 species of Lymnaeids recognized in the US, Canada, and Mexico by the Freshwater Mollusk Conservation Society as of 2023. Lymnaeids are described by Clarke (1981) as dextrally coiled, mainly thin-shelled, with an elevated spire, with or without an umbilicus, and without an operculum. No Lymnaeids have planispiral shells like those of Planorbidae (Burch 1982). Species in the family Lymnaeidae primarily reproduce through self-fertilization but sexual fertilization can occur. Egg masses are gelatinous, transparent, colorless, and sausage-shaped with few to many eggs (Clarke 1981) and juveniles grow quickly, often with multiple generations produced in a

single year (Burch 1989). Additionally, animals in the Lymnaeidae family are well known for their capability of serving as intermediate hosts for trematodes, or flukes.

South Carolina recognizes 2 genera and 4 species of freshwater snails in the family Lymnaeidae, 2 of which are data deficient, the Golden Fossaria (*Galba obrussa*) and the Marsh Fossaria (*Galba humilis*), which are described below.

Golden Fossaria and Marsh Fossaria
Galba obrussa (Say, 1825) and *Galba humilis* (Say, 1822)

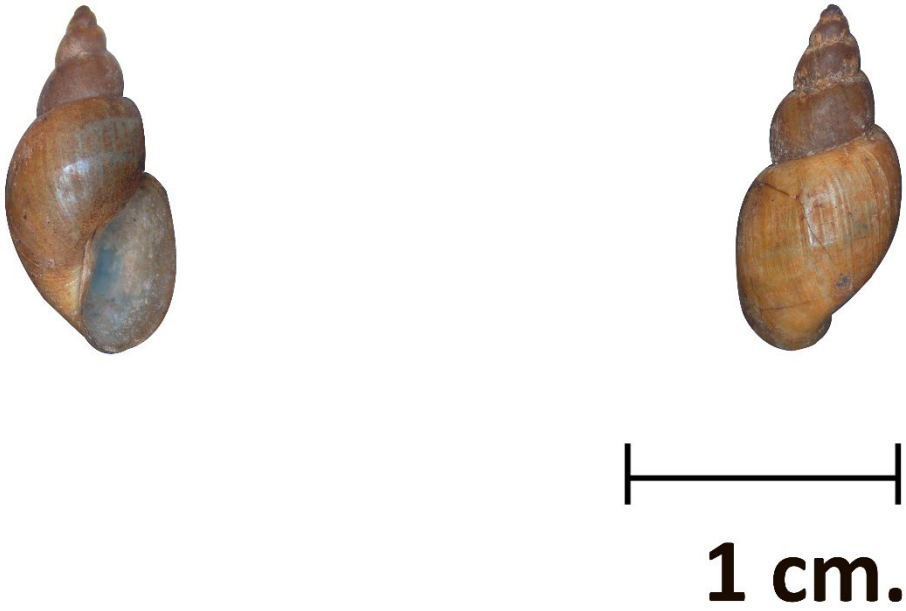

Figure 3. Image of *Galba obrussa* courtesy of the North Carolina State Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

The Golden Fossaria was originally described as *Lymneus obrussus* by Say in 1825 and is a pulmonated aquatic snail where respiration occurs across the entire mantle. It is a "left-handed snail," having the coils of the shell on the left side when viewed from the opening. The shell is oblong and rather slender having 5 whorls which are slightly rounded. The shells are yellow to a pale rust in color. Burch (1982) recognized this species as *Fossaria obrussa* prior to the genera change by Johnson et al. 2013. Alda et al. 2021 recommend *G. obrussa* as a junior synonym of *G. humilis*, however this has not been recognized by the Freshwater Mollusk Conservation Society, which the agency follows for nomenclature of species present in SC.

The Marsh Fossaria was originally described as *Lymneus humilis* by Say in 1822 and is a pulmonated aquatic snail where respiration occurs across the entire mantle. Like *G. obrussa*, *G. humilis* is a "left-handed snail", exhibiting nearly 6 whorls on the left side of the openings. The shell is ovate-conic, thin, and transparent. The labium has an obvious calcium deposit and shells are pale-reddish or yellowish-white in color.

Although minimal work has been completed on the life history of *G. obrussa* or *G. humilis*, Mattice (1975) suggests that temperatures above 15°C may negatively affect reproduction of *G. obrussa*. Animals in the Lymnaeidae family are well known for their capability of serving as intermediate hosts for trematodes, or flukes. *Galba humilis* is a known intermediate host of *Fascioloides magna*, a fluke that can infect deer, bovids, pigs, and horses (Davidson 1981). Additionally, in 2018, a

parasitic blood fluke found in dogs, *Heterobilharzia americana*, was reportedly found using *G. humilis* as an intermediate host (Loker et al. 2021).

The Golden Fossaria has a global ranking of secure (G5) and a South Carolina state ranking of SU due to insufficient data on the species (NatureServe 2024). The Golden Fossaria is widely distributed throughout the US, having populations in almost all the continental states and Canada.

The Marsh Fossaria has a global ranking of secure (G5) and a South Carolina state ranking of SU due to insufficient data on the species (NatureServe2024). The Marsh Fossaria has a more limited range than the Golden Fossaria and is mostly found in the Eastern US with scattered populations towards the west. Like the Carib Fossaria, the Golden and Marsh Fossaria snails are amphibious and prone to leave the water to graze. Individuals are typically found in muddy soils at or around the water line, in streams, marshes, ponds, and lakes regularly found attached to aquatic vegetation (Clarke 1981; Stewart and Dillon 2004).

Dillon et al. (2019) reported 12 observations of *Lymnaea (Galba) humilis* in South Carolina; however, Dillon includes Fossaria *or Galba humilis, obrussa, modicella, parva*, etc. under the *Lymnaea (Galba) humilis* name. The Freshwater Mollusks Conservation Society still recognizes *G. obrussa* and *G. humilis* as two distinct species and because of this, there are no known observations of *G. obrussa* or *G. humilis* in SC. Due to a lack of confirmed occurrences, a presumed distribution map could not be generated for either species. Additionally, not much is known about the specific life history of either species outside of the generalized reproduction history of the family which they belong.

To accurately determine a conservation priority for these two species, presence/absence surveys must be conducted throughout the potential range of the two species, collecting voucher specimens or genetic material to confirm whether both species are present in the state. Comprehensive genetic testing that includes animals from the entire range is needed. Presence/absence surveys could be completed simultaneously with catch-per-unit-effort surveys to determine the relative abundance of either species at specific sites. A thorough study into the reproductive behavior and life cycle of both species could give biologists a better understanding of their population dynamics. Research into the potential for them to be intermediate hosts for trematodes could aid in the understanding of their ecological impacts in SC.

FAMILY AMNICOLIDAE

Family Amnicolidae, the “Dusky Pebblesnails” is a family of freshwater aquatic, operculate gastropods. There are a total of 4 genera and 19 species of Amnicolidae recognized in the US, Canada, and Mexico by the Freshwater Mollusk Conservation Society as of 2023. In general, animals in the family Amnicolidae are unicolored, small (<5mm), higher than wide, and have few whorls with the environment playing significant roles in variation of shell (Berry 1943, Johnson et al. 2013). Amnicolids are dioecious and males have an external copulatory organ (verge) projecting from the side of the neck (Berry 1943). Eggs are laid singly or in clusters throughout the year attached to vegetation or other firm surfaces if temperatures are suitable (Davis 1961); females can store sperm from previous breeding cycles (Berry 1943). The family is of ecological importance, acting as a food source for freshwater fishes because of their small size (Berry 1943).

Species identification can be challenging, and the radula and verge should be examined (Hershler and Ponder 1998; Berry 1943).

South Carolina recognizes 2 genera and 3 species of freshwater snails in the family Amnicolidae, 1 of which is data deficient, the Indented Duskysnail, described below.

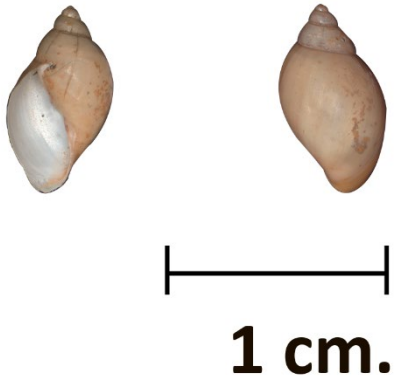
Indented Duskysnail
Lyogyrus retromargo (Thompson, 1968)

The Indented Duskysnail is a relatively new species, originally described as *Amnicola (Lyogyrus) retromargo* by Thompson in 1968 who placed the species in South Carolina. *Lyogyrus retromargo* is sub-globose in shape and pale yellow to brownish in color. It is dextral in shell morphology and has about 4 rounded whorls. The genus *Lyogyrus* is distinguished from other genera by having an operculum that is initially multispiral, becoming paucispiral in adult individuals (Dillon et al. 2019) but attention must be given to the male sex organ (verge) for identification.

The Indented Duskysnail has a global ranking of no status rank (GU). In Florida, it has a ranking of apparently secure (S4), and in South Carolina it has a ranking of SU due to insufficient data on the species (NatureServe 2024). The Indented Duskysnail is historically found in the southern United States including HUCs in Florida, Georgia, and South Carolina. Dillon et al. (2019) have documented ~35 observations of *Lyogyrus granum*, but in his description, lists *G. retromargo* a synonym of *L. granum* and does not recognize *L. retromargo* as a species in SC. Outside of Thompson placing the species in SC, there are no known occurrences of the species. Due to the limited information on its range and habitat preferences, a presumed distribution map could not be generated.

To accurately determine a conservation priority, preliminary presence/absence surveys must be conducted throughout the potential range of the species, collecting voucher specimens or genetic material to confirm presence of *L. retromargo* in SC. Presence/absence surveys could be completed simultaneously with a catch-per-unit-effort survey to determine the relative abundance of the species at specific sites. Additionally, not much is known about the life history of the species outside of the generalized reproduction history of the family which it belongs. A thorough study into the reproductive behavior and life cycle of the species could give biologists a better understanding of their population dynamics.

FAMILY PHYSIDAE



Family Physidae, the “Tadpole Pondsnails” is a family of freshwater aquatic, pulmonated gastropods which has been subject to numerous taxonomic revisions (Johnson et al. 2013).
There are a total of 5 genera and 48 species of Physidae recognized in the US, Canada, and Mexico by the Freshwater Mollusk Conservation Society as of 2023. In general, animals in the family Physidae are found in lentic environments and are sinistral (coiled to the left), have an elevated spire, and no operculum (Clarke 1981; Johnson et al. 2013). The mantle in Physidae animals has numerous digitate (finger-like) mantle lobes that project from the aperture over both sides of the shell (Clarke 1981; Burch 1989). Physa are monoecious and capable of cross- or self-fertilization. Egg masses are large, gelatinous, transparent, whitish, and crescent-shaped typically laid during

warmer months; multiple generations can be produced in a single year (Burch 1989; Clarke 1981; Johnson et al. 2013).

South Carolina recognizes 1 genus and 5 species of freshwater snails in the family Physidae, 1 of which is data deficient, the Tadpole Physa, described below.

Tadpole Physa
Physella gyrina (Say, 1821)

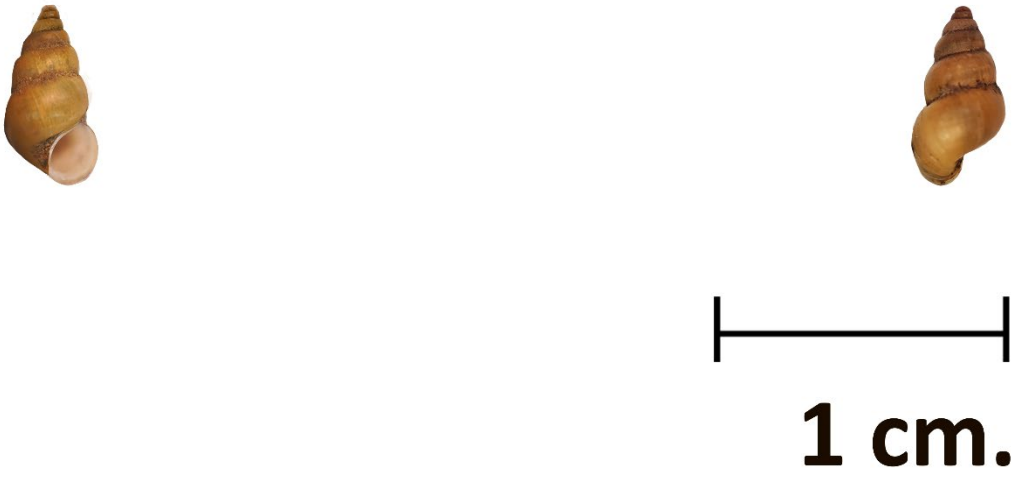
The Tadpole Physa was originally described as *Physa gyrina* by Say 1821 and the taxonomy of the genus which it belongs is long and complicated. The species contains many synonymies, recently including *Physella ancillaria, Physella johnsoni*, *Physella parkeri*, *Physella wrighti*, *Utahphysa microstriata* (FMCS 2023). Animals have a sinistral shell that is oblong with 5 or 6 whorls and an acute apex. The labrum is a little thickened on the inner margin, the aperture is 60-80% of the shell height, and the shell is pale yellowish brown to greyish brown in color. Tadpole Physa are monoecious and egg laying begins when morphological and physiological development has been reached. Dillon et al. 2004 found that (*Physa*) *gyrina* reproduced at a median age of 11-12 weeks. DeWitt (1954) points to reproduction being directly related to temperature.

The Tadpole Physa is historically abundant throughout Canada and all the US. Individuals are found occurring in many perennial habitats, intermittent pools of water, swamps, and mildly organic polluted water sources; where they are often occupying mud, sand, gravel, rock and plants (Clarke 1981; Turner and Montgomery 2009; Dillon et al. 2019). The Tadpole Physa has ecological importance, feeding on a multitude of organic sources including detritus, diatoms, fungi, algae, and vascular plants (Newman et al. 1996) which affects algal and macrophyte biomass (Hunter 1980). They are also a food source for many crayfish, fish, and other vertebrates. DeWitt et al. (2000) found that in habitats where crayfish regularly consumed snails, some Physa had narrowed apertures which may aid in animal protection from crayfish.

The Tadpole Physa has a global ranking of secure (G5) and a South Carolina ranking of SU due to insufficient data on the species (NatureServe 2024). While abundant throughout the US, no records of *P. gyrina* have been documented in SC; however, animals are found in NC and GA, suggesting that SC should be within its range. Due to a lack of observations in SC, an expected distribution map could not be generated.

To accurately determine a conservation priority, preliminary presence/absence surveys must be conducted throughout the potential range of the species, collecting voucher specimens or genetic material to confirm the species. Presence/absence surveys could be completed simultaneously with a catch-per-unit-effort survey to determine the relative abundance of the species at specific sites.

Toxicological studies could aid in the understanding of the species preferred habitat types and potential threats.



FAMILY POMATOPSIDAE

The family Pomatopsidae, the "Amphibious Walkers," is a family of small, dextral, operculated, amphibious gastropods with a loping mode of transportation. Animals are dioecious and males have a large external male organ located dorsally behind the head (Burch 1989).

There are 6 species of 1 genus in the US, Canada, and Mexico recognized by the Freshwater Mollusk Conservation Society as of 2023. Animals in this family can be found in freshwater or brackish water.

South Carolina recognizes 1 species in the family Pomatiopsidae which is data deficient, the Slender Walker, described below.

Slender Walker
Pomatiopsis lapidaria
(Say, 1817)

The Slender Walker was originally described as *Cyclostoma lapidaria* by Say 1817 and is a small (usually <5.5mm) operculated snail that is slender and has 6-7 flatly rounded whorls which are separated by incised sutures. The aperture is ovate and barely touches the penultimate whorl. The shell is reddish-brown to brown in color, sometimes having a greenish hue. It may exhibit small wrinkles on the periostracum (Say 1817; Clarke 1981). Sexes are separate (dioecious); eggs are laid singly in mud or soil during ideal temperatures (Clarke 1981). Males have a distinctive penis. This species can serve as the intermediate host of the oriental blood fluke, *Schistosoma japonicum* (Abbott 1948).

The Slender Walker is historically abundant throughout the eastern US and Canada. Individuals are amphibious, oftentimes being found along the edges of streams, seeps, in flowing water, and lakes (Burch 1989). It was once considered terrestrial or semiamphibious due to species occurrences always being near, not in, water (Walker 1918).

The Slender Walker has a global ranking of secure (G5) (NatureServe 2024). Burch and Tottenham (1980) placed this taxon as "widely distributed in the eastern US"; however, we currently do not have any known observations of this species in South Carolina. Therefore, the Slender Walker has

a ranking of SU until distribution can be confirmed. A presumed distribution map could not be generated for the species.

To accurately determine a conservation priority, preliminary presence/absence surveys must be conducted throughout the potential range of the species, collecting voucher specimens or genetic material to confirm the species. Presence/absence surveys could be completed simultaneously with a catch-per-unit-effort survey to determine the relative abundance of the species at specific sites. Further research into the species' ability to act as intermediate hosts for trematodes could aid in the understanding of their ecological importance.

FAMILY VALVATIDAE

Family Valvatidae, the "Gilled Flatsnails" is a family of freshwater, Holarctic snails, occurring in large lakes and rivers (Burch 1989). Animals in this family are usually small (<8mm) and have an operculum; they are dextral in shape. There are 11 species from 1 genus of Valvatidae recognized in the US, Canada, and Mexico by the Freshwater Mollusk Conservation Society as of 2023.
In general, animals in the family Valvatidae have a shell that is wider than high and a nearly circular aperture. Snails in this family can be distinguished from others by a gill protrusion (feather-like) to the exterior from the mantle cavity and a mantle tentacular appendage (Burch 1989; Clarke 1981). Because of the gill protrusion, animals may tolerate low DO (Burch 1989). Valvatids are hermaphroditic; egg capsules are spherical and contain 1-60 eggs; developing embryos are green in color (Burch 1989; Clarke 1981).

South Carolina recognizes 1 genus and 2 species of freshwater snails in the family Valvatidae, 1 of which is data deficient, the Threeridge Valvata, described below.

Threeridge Valvata
Valvata tricarinata (Say, 1817)

The Threeridge Valvata was originally described as *Cyclostoma tricarinata* by Say in 1817 and is a small (usually <5mm high and <6mm wide), operculated snail that is solid with 4 whorls. It is dextral and usually has 3 prominent spiral cords on the body whorl; the species has a round aperture, see figure 4. The operculum is horny, round, and multispiraled. Animals are uniformly white to whitish-pink, and shells are green to brown in color but may have greyish overtones.

Individuals often occur among vegetation and in perennial habitats such as lakes, rivers, and streams, they are rarely in ponds (Burch and Tottenham 1980; Clarke 1981). There seems to be a correlation between deep water with abundant vegetation and *V. tricarinata* (Moyle and Bacon 1968; Yang et al. 2001). Egg masses are gelatinous and found on aquatic vegetation, substrate, and other smooth surfaces during spring and summer (Clarke 1981; Jokinen 1992). Juveniles can emerge 12-15 days after eggs are laid.

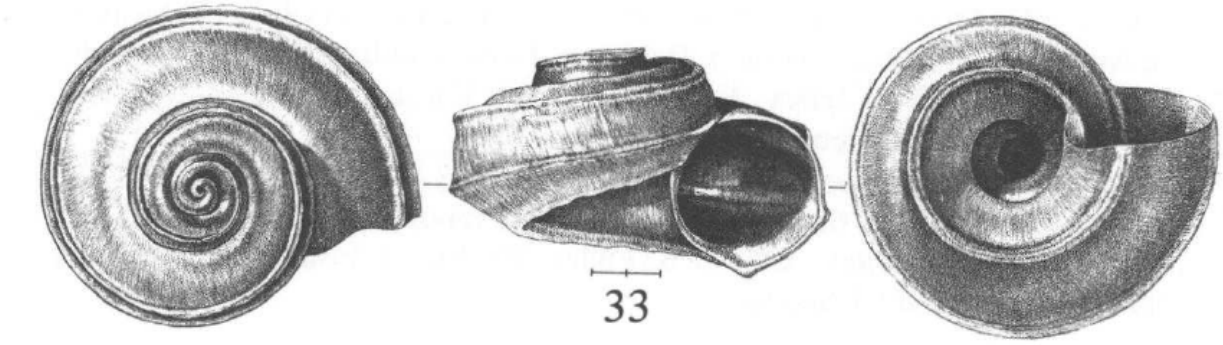


Figure 4. *Valvata tricarinata* spire, apertural, and umbilical views (left to right) as seen in Burch and Tottenham 1980.

The Threeridge Valvata is historically found throughout Canada and the US, being most abundant in the northern lakes and less common further south. The species has a global ranking of secure (G5) and a South Carolina ranking of SH, suggesting the species is likely extirpated from the state (NatureServe 2024). There has been only 1 observation of the species in South Carolina which was in the Savannah River in 1977 (Dillon et al. 2019). To our knowledge, SC is the southernmost observation of the species and with only 1 individual represented, it is likely that populations were either not able to establish or remain established in warmer temperatures.

To accurately determine a conservation priority, preliminary presence/absence surveys must be conducted throughout the potential range of the species, collecting voucher specimens or genetic material to confirm the species. Presence/absence surveys could be completed simultaneously with a catch-per-unit-effort survey to determine the relative abundance of the species at specific sites. Further research into the species' ideal temperature range could aid in the understanding of their native ranges.

Lapped Elimia

Elimia dislocata (Reeve, 1861)

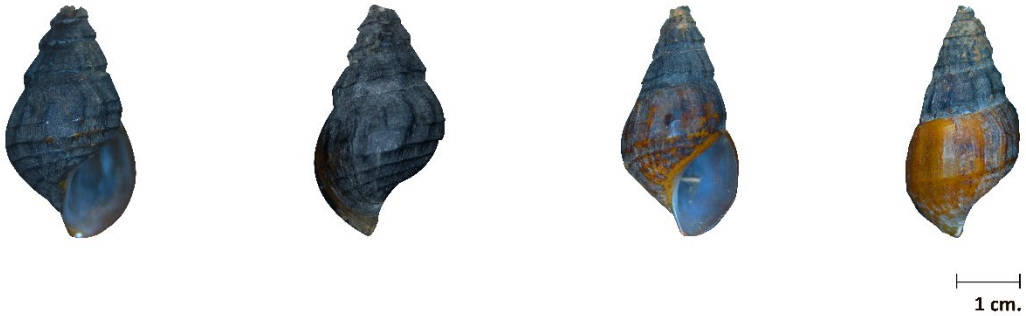

Figure 1. Images of *Elimia dislocata* showing shell morphology variation courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

Contributor (2024): Ericah Beason (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Lapped Elimia was originally described as *Melania dislocata* by Reeve in (1861) and belongs to the family Pleuroceridae which historically has complex taxonomic difficulties (Johnson et al. 2013). In 2023, the Freshwater Mollusk Conservation Society recognized 8 genera and 173 species in the family, 3 of which are recognized to occur in South Carolina (FMCS 2023). In the 2013 Conservation Status of Freshwater Gastropods of Canada and the United States summary, attention is drawn to the need for substantial revision of taxonomy to accurately reflect evolutionary history within the family (Johnson et al. 2013). The family is the second highest in diversity but also one of the most imperiled (79%) (Johnson et al. 2013).

The Lapped Elimia (Figure 1) is a larger snail (~20mm in length), and its shell is yellowish to brown in color. The shell is ovately turreted with convex whorls. It is longitudinally plicately ribbed, and the ribs are obsolete towards the base. The aperture is ovate, rather small, and is a little effused at the base (Reeve 1861).

Status

The species is globally ranked as apparently secure (G4), ranked apparently secure (S4) in North Carolina, and ranked vulnerable to secure (S3S5) in South Carolina (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

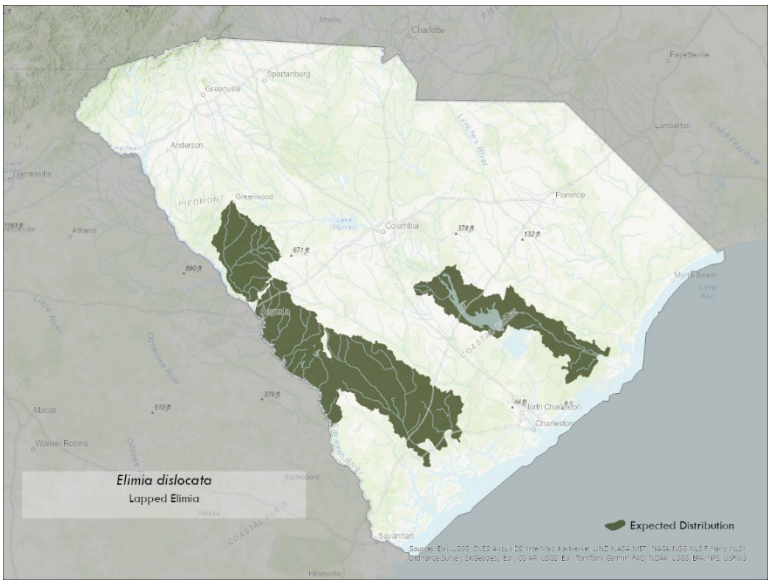

Figure 2. Expected distribution of *Elimia dislocata* in South Carolina based on reported observations at a HUC 8 level and designated ecoregions.

The Lapped Elimia has a fairly small distribution, being recognized in Virginia, North Carolina, and South Carolina by Burch (1989) and the Freshwater Mollusk Conservation Society (2023); however, Dillon et al. (2019) also places the species, which is referred to as "*Pleurocera catenaria dislocata*" as far south as tributaries to the Ogeechee River in Georgia. In South Carolina, there have been 20 reported observations across the Santee, ACE, and Savannah watersheds (Figure 2). Most observations have been in the upper coastal plain region and 2 have been in the piedmont regions. Some Pleurocerids can reach high densities (Johnson and Brown 1997), and high densities have been observed in cave springs that flow east into Lake Marion (Dillon et al. 2019).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Dillon et al. (2019) report that individuals of Elimia dislocata, which he refers to as "*Pleurocera catenaria dislocata*" are found in areas with limestone or marl outcroppings and typically not in acidic waters. Additionally, it is reported that the species may not be as strict as other species on the requirement of rocky substrates as they have been found on the bottoms of firm sand and woody debris (Dillon et al. 2019).

Not much is known about the life history of the Lapped Elimia, but based on generalized life history of the family, it is likely that the Lapped Elimia reach maturity around 2 years and have several years of reproduction, having a presumes maximum lifespan of 2-6 years (Dazo 1965; Brown et al. 2008; Johnson et al. 2013; Dillon et al. 2019). Generally, males lack a penis, and females attach egg capsules to firm substrate singly, in lines, or well-defined clutches (seen in Johnson et al. 2013 from Whelan et al. 2012a, 2012b).

CHALLENGES

The greatest challenge with the Lapped Elimia is unresolved taxonomy of the family. The Lapped Elimia was raised to the species level and placed in Pleuroceridae by Turgeon et al. (1998) but in (2011), Dillon and Robinson placed the genus *Goniobasis* and *Elimia* under *Pleurocera*. In the gastropod review by Johnson et al. (2013) attention is drawn to interim taxonomy arrangements being likely inadequate and recommends that classifications remain those of Turgeon et al. (1998) until comprehensive taxonomy is constructed. In South Carolina, species names follow those of

the Freshwater Mollusk Conservation Society (FMCS) and in (2023), the name recognized for the Lapped Elimia was *Elimia dislocata*, which is how we will refer to the species until changes are petitioned and accepted by FMCS.

Little is known about the reproductive cycle of the species. Additionally, not much is known about environmental and toxicological tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short- and long-term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Lapped Elimia.

CONSERVATION RECOMMENDATIONS

- Develop a standardized survey protocol for snails.
- Collect voucher specimens to aid in the genetic confirmation of the species and family which it belongs.
- Explore the need to list the Lapped Elimia within South Carolina based on survey results.
- Conduct standardized surveys in the ranges of the Lapped Elimia to determine the population range and life history requirements.
- Carefully monitor existing populations of the Lapped Elimia.
- Determine habitat restoration methods that will benefit the Lapped Elimia.
- Protect critical habitats for the Lapped Elimia from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Lapped Elimia to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Collecting vouchers of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Lapped Elimia.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.

- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

Carib Fossaria

Galba cubensis (Pfeiffer, 1839)

Contributor (2024): Ericah Beason (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

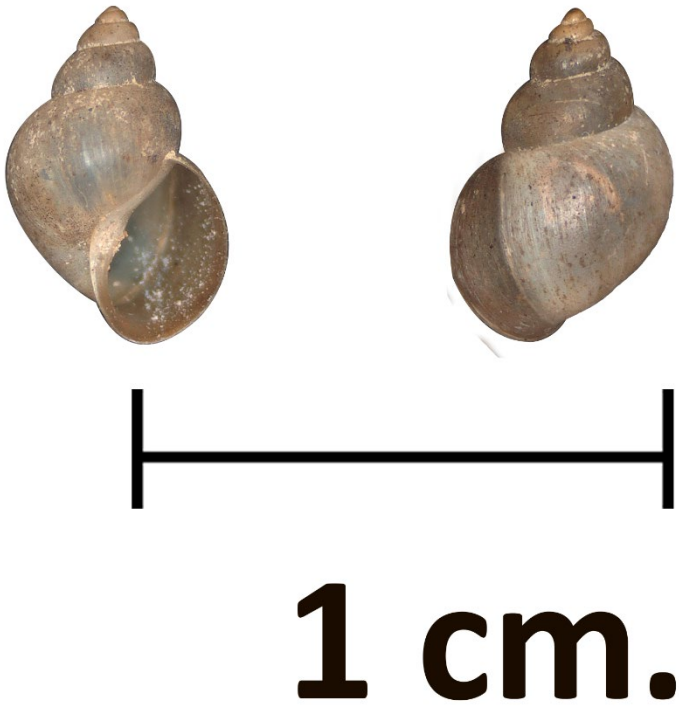

Figure 1. Image of *Galba cubensis* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

The Carib Fossaria was originally described as *Limnaeus cubensis* by Pfeiffer in 1839 and is a pulmonated aquatic snail (Figure 1). It is a "left-handed snail," having the coils of the shell on the left side when viewed from the opening which is ovate to oblong in shape. It is typically yellow to brown in color and the shell is formed by rounded spirals. The genus has been reassigned numerous times until settling into the *Galba* genus following Johnson et al. (2013).

The taxonomy of this species is largely intertwined with *G. humilis* and *G. viator* and the genus *Galba* has many redundancies in nomenclature with regular revisions. In 1989, Burch originally recognized 55 species in 7 genera, but Hubendick (1951) recognized 13 species and placed them in a singular genus, *Lymnaea*. Standley et al. (2013) cited the need to combine molecular, morphological, and ecological variables to develop a solid taxonomic framework based on 3 species of *Galba* analyzed in Argentina. More recent work in 2021 suggests that *Galba* comprises 5 species or species complexes by using an integrative approach using both phenotypic and molecular approaches (Alda et al. 2021). Here they confirm the suggestions of Correa et al. (2011) and Lounnas et al. (2017) that *G. neotropica* (Bargues et al. 2007, 2011) be considered synonyms of *G. cubensis/viator*. Alda et al. (2021) discuss the difficulties of *G. viator* and the uncertainty of it being considered a clade within *G. cubensis*, or a species on its own; however, *G. viator* is not recognized in the US, Canada, or Mexico by FMCS (2023). Researchers suggest a cautious position be considered; the two species may constitute a species complex or a species with wide diversity, as has been found in other freshwater snails from the *Hygrophila* family (Alda et al. 2021).

Work in Cuba has shown that *G. cubensis* is an intermediate host for the common liver fluke *Fasciola hepatica* (Vazquez et al. 2014) which has distribution throughout the Americas (Mas-Coma et al. 2009). More recently, Baniya et al. (2024) found a parasitic schistosome, a blood fluke, He*terobilharzia americana*, using *G. cubensis* as an intermediate host in California.

Status

The Carib Fossaria has a global ranking of secure (G5), a national ranking of secure (N5), and a SC state ranking of imperiled to vulnerable (S2S3) (NatureServe 2024). Carib Fossaria have populations across the southern United States, but most populations seem to have settled in the southeastern region with individuals in AL, FL, GA, SC and NC.

POPULATION SIZE AND DISTRIBUTION

There are a total of 21 observations across the piedmont, coastal plain, and coastal zone regions in South Carolina ranging in collection dates from 1958-2004. Figure 2 provides an expected distribution of the species based on these reported observations. Although we have observations of this species, we do not have a comprehensive understanding of their range, relative densities, habitat preferences, or population dynamics. The last reported occurrence of this species was in 2004, even though work within their presumed distribution was occurring. Additionally, not much is known about the specific life history of the species outside of the generalized reproduction history of the family which it belongs.

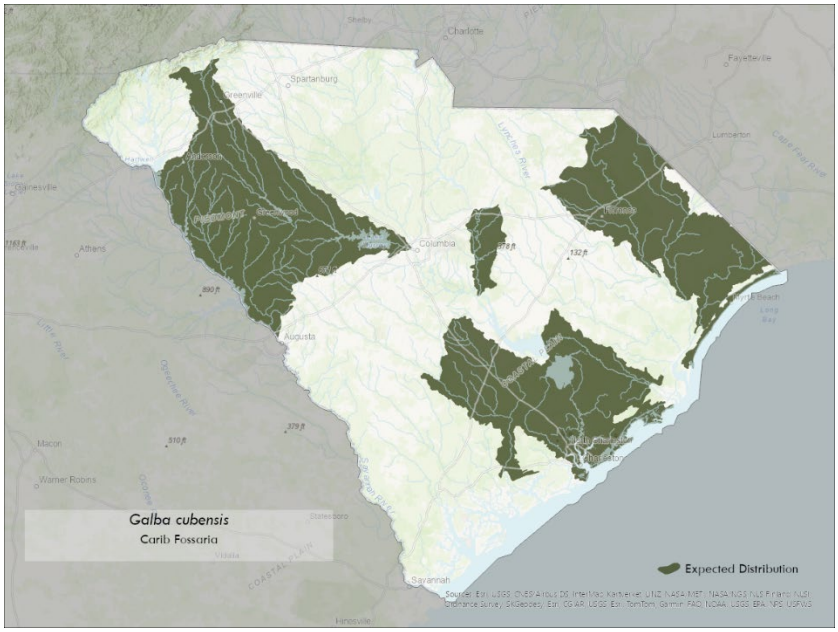

Figure 2. Expected distribution of *Galba cubensis* in South Carolina based on reported observations at a HUC 8 watershed level and designated ecoregions.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Galba cubensis is an amphibious species typically found in muddy soils, attached to aquatic vegetation or other solid surfaces. Dillon et al. (2019) stated that the species (which he refers to as *Lymnaea cubensis/viator*) apparently spend a substantial fraction of their lives grazing on mud above the water level, noting that populations typically colonize ditches, vernal ponds, and the muddy margins of larger coastal plain rivers.

CHALLENGES

Taxonomy of the species is in question and may need some revision due to one of the suggested synonyms only occurring in South America. Additionally, the species is amphibious and may not

be detected if survey approaches are fully aquatic. Like other snails, degradation of habitat and a loss of nutritious food sources are of concern. Little is known about the species specific life history.

Not much is known about environmental and toxicological tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short- and long-term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Carib Fossaria.

CONSERVATION RECOMMENDATIONS

- Develop and conduct standardized surveys specific for amphibious snail species to better determine the population range.
- Collect voucher specimens throughout its range for genetic analysis.
- Explore the need to list the Lapped Elimia within South Carolina based on survey results.
- Study the life history strategy of the species.
- Carefully monitor existing populations of the Carib Fossaria.
- Discourage structural alteration of rivers such as damming, channelization, and dredging.
- Determine habitat restoration methods that will benefit the Carib Fossaria.
- Protect critical habitats for the Carib Fossaria from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Carib Fossaria.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Carib Fossaria to various point and non-point sources of pollution and land use impacts.
- Research their potential to be intermediate hosts for trematodes to aid in the understanding of their ecological impacts in SC.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Carib Fossaria.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

Henscomb Hydrobe

Littoridinops tenuipes (Couper, 1844)

Contributor (2024): Ericah Beason (SCDNR)

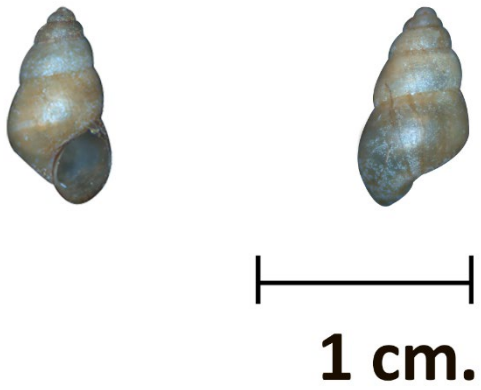

Figure 1. Image of *Littoridinops tenuipes* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

DESCRIPTION

Taxonomy and Basic Description

The Henscomb Hydrobe was originally described as *Amnicola tenuipes* by Couper in (Haldeman 1844) and belongs to the family Cochliopidae which was previously a subfamily of Hydrobiidae before evolution to the family level (Wilke et al. 2001). Animals in the family are small-sized (<5mm adult shell length) and taxonomically remained unknown in the 19th century (Johnson et al. 2013). Members of the family are highly localized and have a high imperilment rate (91%) (Johnson et al. 2013).

The Henscomb Hydrobe is a small snail that has a pale yellowish to light brown shell. Couper describes the shell as subumbilicated, oblong-ovate, turreted, thin, and smooth (Halderman 1844). The growth lines are slightly marked, and shells have 5 volutions. The suture is slightly impressed, and the aperture is ovate, oblong, angulated above and rounded at the base. The labrum is simple and sharp. Males possess a distinct penis on the side of their neck that is fringed with numerous papillae (Hershler and Thompson 1992).

Status

The species is globally ranked as secure (G5) but ranked critically imperiled to vulnerable in South Carolina (S1S3). In North Carolina, Virginia, Maryland, New Jersey, and Delaware the species is not ranked. In Georgia and Florida, the species is ranked as secure (G5) but in Connecticut the species is ranked as critically imperiled to imperiled (S1S2) and in Massachusetts the species is ranked as critically imperiled (S1) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Henscomb Hydrobe is primarily found in eastern states that border the Atlantic coast but seems to have more secure populations in southeastern states. There have been a total of 12 reported observations of the species in South Carolina in the coastal plain and coastal zone regions. Animals have been found in all 4 major watersheds in South Carolina including the Pee Dee, Santee, ACE, and Savannah. The last reported observation was in 2015, and the animal was found in a pond in Hilton Head Island, SC.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Dillon et al. (2019) report that individuals found in Atlantic drainages are typically in coastal rivers, estuaries, and freshwater tidal marshes. Furthermore, samples are associated with blades of emergent vegetation, specifically *Typha*, and other organic debris on the water's surface (Dillon et al. 2019). Although there are no species-specific life history studies, it is presumed that the Henscomb Hydrobe, like other hydrobiids, have a lifespan of less than two years (Johnson et al. 2013).

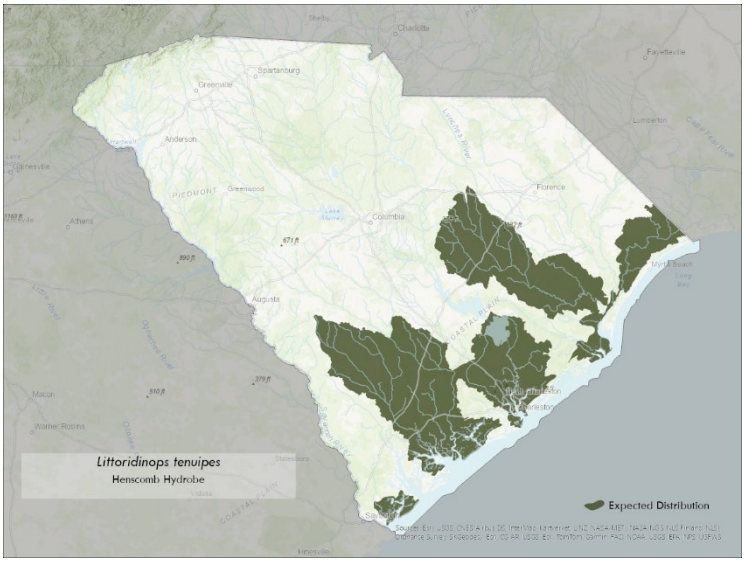

Figure 2. Expected distribution of *Littoridinops tenuipes* based on reported observations at a HUC 8 watershed level and designated ecoregions.

CHALLENGES

Like the Rotund Mysterysnail, one of the greatest challenges with the Henscomb Hydrobe in SC seems to lie in the unfavorable survey conditions of its preferred habitat. This species is often found in coastal rivers, estuaries, and freshwater tidal marshes. Nothing is known about the specific reproduction of the species. Additionally, not much is known about environmental and toxicological tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short- and long-term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Henscomb Hydrobe.

CONSERVATION RECOMMENDATIONS

- Develop a standardized survey protocol for snails.
- Collect voucher specimens to aid in the genetic confirmation of the species and family which it belongs.
- Explore the need to list the Henscomb Hydrobe within South Carolina based on survey results.
- Conduct standardized surveys in coastal plain and coastal zone to determine the population range and life history requirements for the Henscomb Hydrobe.
- Carefully monitor existing populations of the Henscomb Hydrobe.
- Determine habitat restoration methods that will benefit the Henscomb Hydrobe.

- Protect critical habitats for the Henscomb Hydrobe from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Henscomb Hydrobe to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Henscomb Hydrobe.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

Carolina Physa

Physella carolinae (Wethington, Dillon, and Wise, 2009)

Contributor (2024): Ericah Beason (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Carolina Physa (Figure 1) is a relatively new species described by Wethington, Dillon, and Wise in 2009 as *Physa carolinae*. In 2023, the Freshwater Mollusk Conservation Society recognized the recommendation that the species be reassigned to the genus *Physella* based on the findings of Young et al. (2021). The full description can be found in Wethington et al. (2009) but in summary, the shell is sinistral, narrowly elongate-ovate, high spired, thin, and translucent with faint spiral growth lines. The body whorl is roughly 85% of the shell length and there are 4-5 whorls as an adult. Individuals have a moderately auricular aperture, approximately 70% of the shell length, and have a thin outer lip.

Figure 1. Image of *Physella carolinae* labelled *Physa carolinae* on web-based Freshwater Gastropods of North America. Image courtesy of Dillon et al. (2019).

Physella carolinae can be confused with *P. acuta, P. hendersoni,* and *P. pomilia*; however, the Carolina Physa animal is distinctly dark, and shells are slender. Dillon found through breeding experiments, *P. carolinae* freely hybridize with *P. acuta* but F1 hybrids are sterile (Dillon et al. 2019).

Status

The Carolina Physa does not have a global status rank, likely due to limited data associated with the distribution of the species. It is ranked as vulnerable to secure in South Carolina (S3S5) (NatureServe 2024). Targeted, standardized surveys are needed to determine a more accurate ranking.

POPULATION SIZE AND DISTRIBUTION

The Carolina Physa is recognized to have distributions in the southeast from Virginia to Florida (FMCS 2023). In South Carolina, there are a total of 37 reported observations, all of which have been in the coastal plain or coastal zone regions. Three observations have been on the cusp of the sand hills region, but none have been found in or above the region. Individuals are reported to be in all four of the major river basins in South Carolina including the Pee Dee, Santee, ACE, and Savannah. The last reported observation of the species was in the Charleston area in 2014.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Carolina Physa is reportedly found in shallow waters, ditches, or temporary water sources in forested lands throughout the coastal plain, but their abundance may be seasonal; however, due to habitat alterations and degradation, more individuals are being found in manmade drainage ditches nearby roads (Wethington et. al 2009). They seem to graze on organic debris and detritus when in water sources and burrow as water becomes scarce (Wethington et al. 2009). Dillon and team (2019) report that laboratory cultures of the species reach maturity around 7-9 weeks post hatch which is about a week later than other *Physella* species and they reach a greater maximum size.

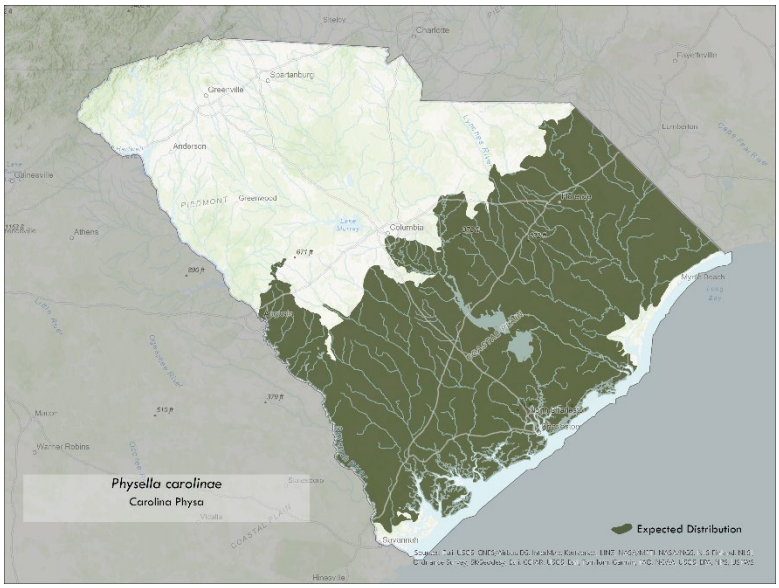

Figure 2. Expected distribution of *Physella carolinae* in South Carolina based on reported observations at a HUC 6 watershed level and designated ecoregions.

CHALLENGES

Challenges associated with the Carolina Physa are largely associated with the shift from individuals occupying natural habitat types to inhabiting manmade habitats which may not be ecologically sound. Additionally, due to climate change, weather events are becoming more severe, and drought conditions are likely to reduce the number of the currently occupied habitats by the species.

Not much is known about environmental and toxicological tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short and long- term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Carolina Physa.

CONSERVATION RECOMMENDATIONS

- Develop a standardized survey protocol for snails in the coastal plain and coastal zone.

- Collect voucher specimens to aid in the genetic confirmation of the species and family which it belongs.
- Explore the need to list the Carolina Physa within South Carolina based on survey results.
- Conduct standardized surveys in coastal plain and coastal zone to determine the population range and life history requirements for the Carolina Physa.
- Carefully monitor existing populations of the Carolina Physa
- Determine habitat restoration methods that will benefit the Carolina Physa.
- Protect critical habitats for the Carolina Physa from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Carolina Physa to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Carolina Physa.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

Sharp Sprite

Promenetus exacuosus (Say, 1821)

Contributor (2024): Ericah Beason and Briana Cairco (SCDNR)

Figure 1. Image of *Promenetus exacuosus* on web-based Freshwater Gastropods of North America. Image courtesy of Dillon et al. (2019).

DESCRIPTION

Taxonomy and Basic Description

Originally described as *Planorbis exacuosus* by Say in 1821, *Promenetus exacuosus* is a small, up to 7mm wide snail in the family Planorbidae, the Rams-horn snails. Snails in this family are distinguished by their round, flat, compressed appearance. The name "Sharp Sprite" may seem rather unfitting at first glance, but a defining characteristic of *Promenetus exacuosus* is the "sides obliquely descending to an acute lateral edge, below the middle" (Say 1821). The Sharp Sprite shell has almost 4 whorls, is biconvex, and dextral. The spire is low, convex, or flattened.

This animal is easily distinguishable from other species by its biconex, flattened form, and rapidly expanding whorls (Clarke 1981).

Status

The species is globally ranked as secure (G5) but is ranked as imperiled (S2) in North Carolina, vulnerable (S3) in Virginia, and critically imperiled to vulnerable in South Carolina (S1S3) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Sharp Sprite ranges from Atlantic to Pacific coasts, and from the boreal zones of Canada to northern Texas. Although widespread in distribution, populations may be patchy, especially so in the Atlantic slope. There have been 9 reported observations of *P. exacuous* in South Carolina, ranging in report dates from 2003-2013. Most observations (8) were in the coastal plain region. The remaining account was reported in the piedmont region in a tributary to West Creek. Dillon and team (2019) note that this species is among the less-commonly encountered of the planorbids in the Eastern US. It has been nearly a decade since the last reported observation of the species even though survey work has been conducted in their presumed range.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Dillon et al. (2019) report that individuals found in Atlantic drainages are sparsely distributed in ponds and sluggish waters. The species has been reported to inhabit shallow waters, marshes, ponds, small lakes, roadside ditches, swamps and intermittent ponds (Baker 1928; Burch and Tottenham 1980; Clarke 1981). This species is found where submersed vegetation is present, and animals are typically found in mud substrate (Clarke 1981; Jokinen 1983). The Sharp Sprite are hermaphroditic and capable of self-fertilization, adults lay egg masses armed with a thick outer coating and die shortly after reproducing (Colton 1918; Dillon 2011). These short-lived snails reach adulthood and reproduction in a matter of months, and populations may often go through two generations through the course of a year (Jokinen 1985).

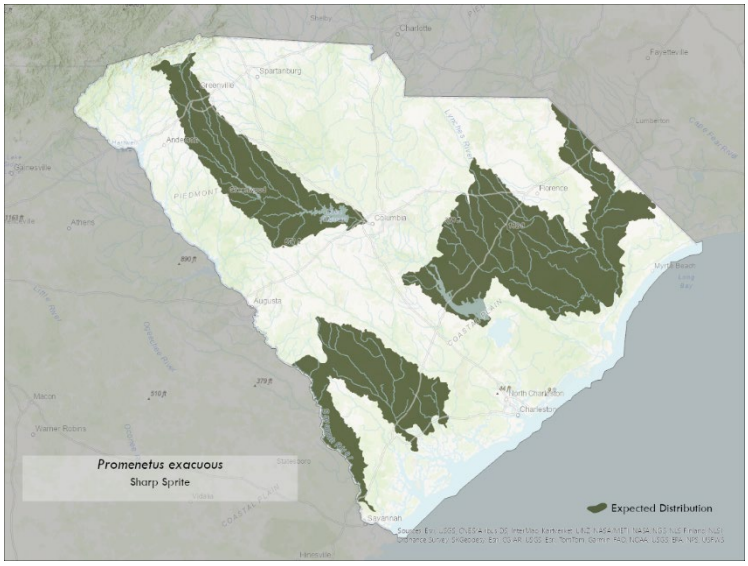

Figure 2. Expected distribution of *Promenetus exacuosus* in South Carolina based on reported observations at a HUC 8 watershed level and designated ecoregions.

CHALLENGES

Like many mollusks, the Sharp Sprite are sensitive to environmental degradation. In southern Manitoba, a rapid decline in occurrence was observed between 1978 and 1998 when agriculture and anthropogenic impacts increased (Pip 2000). Not much is known about toxin tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short and long- term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Sharp Sprite.

CONSERVATION RECOMMENDATIONS

- Develop a standardized survey protocol for snails, accounting for different habitat requirements.
- Explore the need to list the Sharp Sprite within South Carolina based on survey results.
- Conduct standardized surveys in the piedmont and coastal plain to determine the population range and life history requirements for the Sharp Sprite.
- Carefully monitor existing populations of the Sharp Sprite.

- Determine habitat restoration methods that will benefit the Sharp Sprite.
- Protect critical habitats for the Sharp Sprite from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Collect voucher material that can be used to aid in identification of the species and be used for future genetic analysis.
- Conduct further research to determine the degree of sensitivity of the Sharp Sprite to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Sharp Sprite.
- Conduct outreach to relevant landowners about the importance of freshwater snails and their habitats.
- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

Panhandle Pebblesnail

Somatogyrus virginicus
(Walker, 1904)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Briana Cairco (SCDNR)

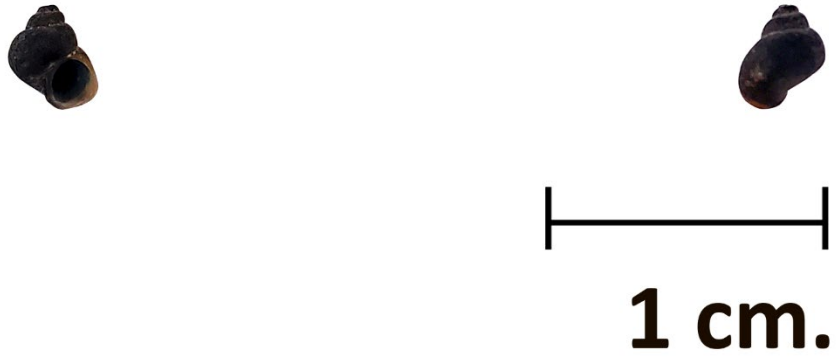

Figure 1. Image of *Somatogyrus virginicus* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

DESCRIPTION

Taxonomy and Basic Description

Somatogyrus virginicus was first described by Walker in 1904. It is a small snail, 3-5mm, with a globosely conic shell and paucispiral operculum (Figure 1). Shells are light greenish-yellow, smooth, and have very fine growth lines; there are about four whorls. Two forms are known for this species, one being slenderer than the other (Walker 1904). Little is known about the life history of *S. virginicus*, but it is thought to be like other *Somatogyrus* species in that individuals are typically dioecious (either male or female), the lifecycle is annual with females lay eggs singly in the spring, and adults dying shortly after reproducing (Johnson et al 2013).

This species could resemble *S. pennsylvanicus* and *S. hinkleyi* however it is smaller in size with a more convex body whorl.

Status

The status of the Panhandle Pebblesnail is not easy to discern. From the time of its original description by Walker in 1904, until the early 2000s it was believed to be endemic to the Rapadan River in Virginia and in 2000 the IUCN Redlist status assessment classified it as endangered due to declines in habitat within the narrow range it was believed to occur (Hilton-Taylor and Brackett 2000). Subsequent surveys outside of Virginia recorded snails matching its description in North Carolina, South Carolina, and Georgia. In 2012 the IUCN evaluated the Panhandle Pebblesnail and listed it as least concern, owing to the incorporation of several populations in North and South Carolina (Cordiero and Perez 2012). Despite the vast increase in known range and observed populations, threats to its populations remain prevalent across the entire range. As of 2024, the Pandhandle Pebblesnail has a global ranking of imperiled (G2G3) and a state ranking of S2S4 with a conservation priority ranking of high (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Panhandle Pebblesnail populations are patchy but widespread across the Atlantic piedmont. Within South Carolina, observations have been reported in the Savannah, Santee, and PeeDee watersheds. There have been 46 reported observations of the species in SC from 1987-2016. No observations of the species have been reported since 2016. Of the 46 observations, 40 have been in the piedmont region, 2 have been in the sandhills that are on the cusp of the piedmont, 3 have been in the sand hills, and only 1 has been in the coastal plain region, observed in 2011 (Figure 2).

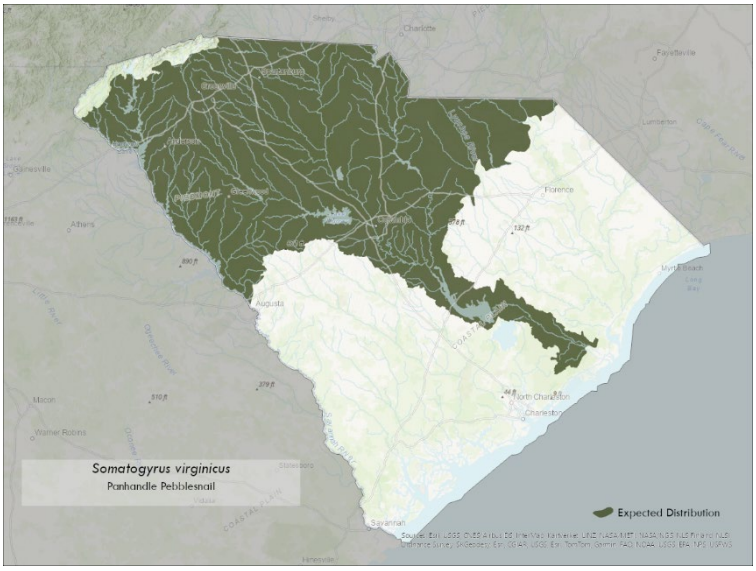

Figure 2. Expected distribution of *Somatogyrus virginucus* based on reported observations.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Across their range, Panhandle Pebblesnails are associated with solid substrate, especially rocky riffles in moderately productive water bodies. They inhabit medium to large rivers with moderate to high gradient (Dillon et al. 2019). The emergent macrophyte *Podostemum* often co-occurs with populations that have been observed (Dillon et al. 2019). Interestingly, in 2005 Morse and Lenat discovered a rare species of caddisfly, *Ceraclea joannae,* that feeds on *Somatogyrus virginicus*; however, this caddisfly is apparently restricted to a small segment of the Little River downstream of Asheboro, NC.

CHALLENGES

Siltation of streams and rivers through agricultural runoff and erosion of unstable stream banks appear to be the main challenge to *Somatogyrus virginicus*. Historically, siltation has occurred due to land clearing for farming, residential development, forestry practices, mining operations, and construction of dams. Absence of sufficient riparian buffers significantly contributes to siltation (Moglen 2000). Clear-cutting a substantial part of a watershed can also contribute to siltation, even if a riparian buffer is maintained. Livestock and feral pigs degrade stream banks and bottoms as they drink and search for food. Impervious surfaces, such as roads, buildings, and parking lots, increase erosion in adjacent areas and contribute to flooding (NCWRC 2002). Use of motor vehicles in streams and along banks can also disturb stream flow and increase siltation. All these factors that contribute to siltation can also alter the topography of streams and rivers by changing the slope of the bank and eliminating heterogeneity in the channel. The patchy

occurrence of this species seems to indicate that historically, they had a more robust presence across their range, prior to habitat loss (Archambault and Cope 2016; Dillon et al. 2019). Additionally, certain herbicides used to manage invasive aquatic plants such as *Hydrilla*, can negatively impact hatching success of *S. virginicus* eggs and adult stages (Archambault and Cope 2016). Not much is known about environmental and toxicological tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short and long- term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

Aside from several survey efforts that have revealed a wider distribution, there have not been any significant conservation achievements for the Panhandle Pebblesnail.

CONSERVATION RECOMMENDATIONS

- Develop a standardized survey protocol for snails.
- Collect voucher specimens to aid in the genetic confirmation of the species and family which it belongs.
- Conduct standardized surveys in the piedmont, sand hill, and coastal plain ecobasin to better determine the population range and life history requirements for the Panhandle Pebblesnail.
- Explore the need to list the Panhandle Pebblesnail within South Carolina based on survey results.
- Carefully monitor existing populations of the Panhandle Pebblesnail.
- Discourage structural alteration of rivers such as damming, channelization, and dredging.
- Determine habitat restoration methods that will benefit the Panhandle Pebblesnail.
- Protect critical habitats for the Panhandle Pebblesnail from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Panhandle Pebblesnails.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Panhandle Pebblesnail to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with

populations of Pandhandle Pebblesnails.

- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

Two-Ridge Valvata

Valvata bicarinata (Lea, 1841)

Contributor (2024): Ericah Beason and Jeff Smola (SCDNR)

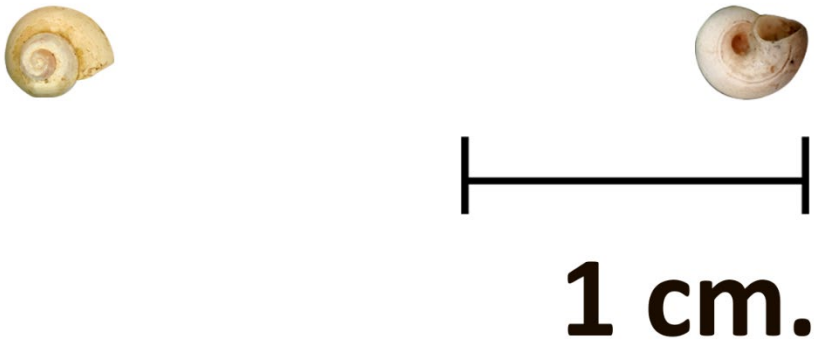

Figure 1. Image of *Valvata bicarinata* courtesy of the North Carolina Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan.

DESCRIPTION

Taxonomy and Basic Description

Valvata bicarinata was originally described by Lea in 1841 and it is similar to *Valvata tricarinata* but differs in the number of carinae (Figure 1); however, the *Valvata* species are polymorphic, and one population can contain several morphological variations (Burch 1989). Additionally, both *V. bicarinata* and *V. tricarinata* can produce polymorphs which closely resemble the other species (Burch 1989).

The Two-Ridge Valvata belongs to the family Valvatidae, the "Gilled Flatsnails" which is a family of freshwater, Holarctic snails, occurring in large lakes and rivers (Burch 1989). Animals in this family are usually small (<8mm) and have an operculum; they are dextral in shape. In general, animals in the family Valvatidae have a shell that is wider than high and a nearly circular aperture. Snails in this family can be distinguished from others by a gill protrusion (feather-like) to the exterior from the mantle cavity and a mantle tentacular appendage (Burch 1989; Clarke 1981). Because of the gill protrusion, animals may tolerate low DO (Burch 1989). Valvatids are hermaphroditic; egg capsules are spherical and contain 1-60 eggs; developing embryos are green in color (Burch 1989; Clarke 1981).

Status

The Two-Ridge Valvata is globally secure (G5) but is considered vulnerable (S3) in Georgia and Alabama and is critically imperiled to imperiled in South Carolina (S1S2) due limited observations across its range in SC (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

This species is endemic to North America and can be found throughout the southeast and into the Midwest. This is a rare species in southern Atlantic drainages. We have 4 reported observations in the coastal plain region of South Carolina. Animals have been reported in the Santee and Savannah River basins. Two of the collections were from larger rivers and 1 was from a PONAR sample collected at a depth of 3.2 m from Lake Marion, SC, in 2009. This species, like *Valvata tricarinata* may be associated with deep waters and surveys that target those deep habitats are needed. See Figure 2 for an expected species range map which was rendered using the reported observations in South Carolina.

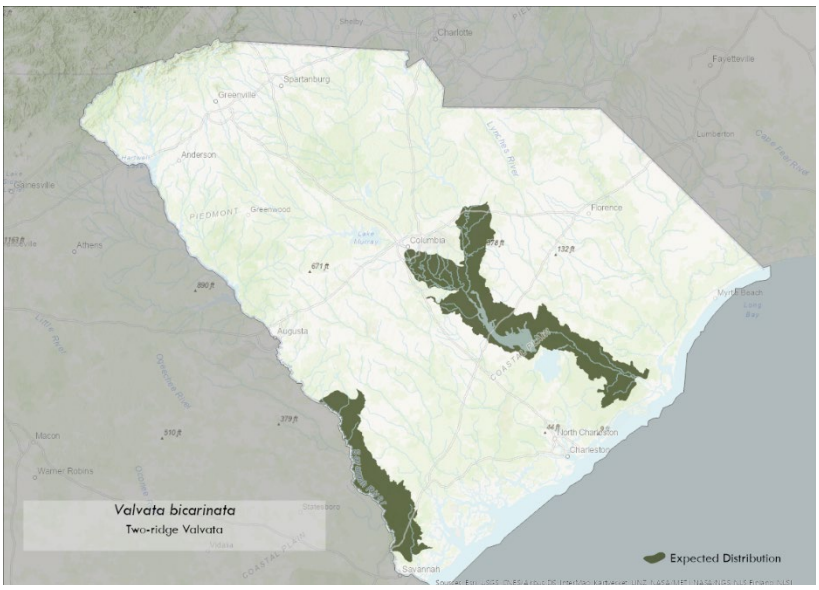

Figure 2. Expected distribution of *Valvata bicarinata* based on reported observations.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Not much is known about the specific habitat requirements of the species; however, if it is like *V. tricarinata*, individuals of *V. bicarinata* may occur among vegetation and in perennial habitats such as lakes, rivers, and streams (Burch and Tottenhan 1980; Clarke 1981). Survey efforts are needed to determine specific habitat requirements of the species. Based on our most recent record in SC, there is a need to thoroughly sample large impoundments.

CHALLENGES

The polymorphism of this species and *V. tricarinata* make it difficult to accurately determine species presence without further species confirmation. Although this species is widespread, South Carolina is part of the peripheral southern Atlantic slope range where animals are rare.

Additionally, not much is known about environmental and toxicological tolerances of the species and no standardized surveys have been completed in South Carolina, making it difficult to properly assess short and long- term population trends. There is a challenge alone in establishing standardized freshwater snail surveys as many species have patchy distribution and very specific, microhabitat requirements that can be overlooked when sampling at a large scale. Attention is needed to establish a standardized survey protocol that takes these concerns into consideration.

CONSERVATION ACCOMPLISHMENTS

There are currently no known conservation accomplishments specifically for the Two-Ridge Valvata.

CONSERVATION RECOMMENDATIONS

- Develop and conduct standardized surveys in the native ranges coupled with specific surveys for deep water snail species to better determine the population range.
- Study the life history strategy of the species.
- Carefully monitor existing populations of the Two-Ridge Valvata.
- Determine habitat restoration methods that will benefit the Two Ridge Valvata.
- Protect critical habitats for the Two-Ridge Valvata from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Conduct further research to determine the degree of sensitivity of the Two-Ridge Valvata to various point and non-point sources of pollution and land use impacts.
- Collect voucher specimens throughout its range for genetic analysis.

MEASURES OF SUCCESS

- Performing standardized surveys across the range of the species.
- Protecting land and maintaining healthy riparian habitat adjacent to habitats with populations of Two-Ridge Valvata.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.

- Development of a species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

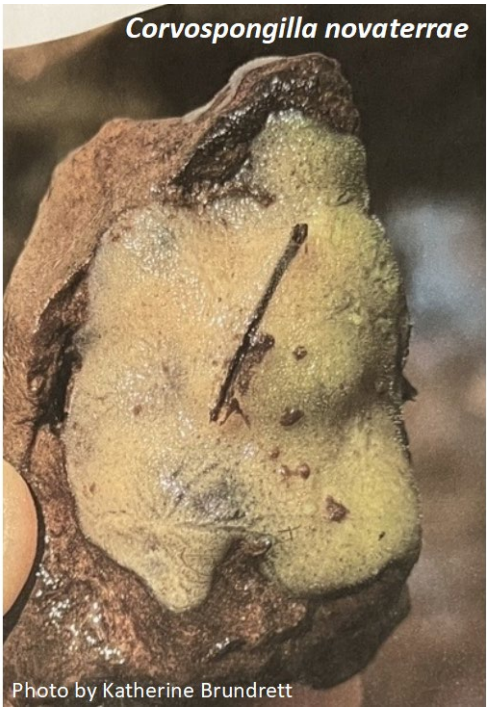
Freshwater Sponges

Species:

Corvospongilla becki
Corvospongilla novaterrae
Corvospongilla sp. 1
Ephydatia fluviatilis
Eunapius fragilis
Heteromeyenia baileyi
Heteromeyenia latitenta
Heteromeyenia longistylis
Racekiela ryderi
Racekiela sp. 1
Radiospongilla cerebellata
Radiospongilla sp. 1
Spongilla lacustris
Trochospongilla horrida
Trochospongilla latouchiana
Trochospongilla leidyi
Trochospongilla pennsylvanica

Contributors (2024): Christopher Freeman (College of Charleston), Josie Shostak (College of Charleston), Alexander Parry (College of Charleston)



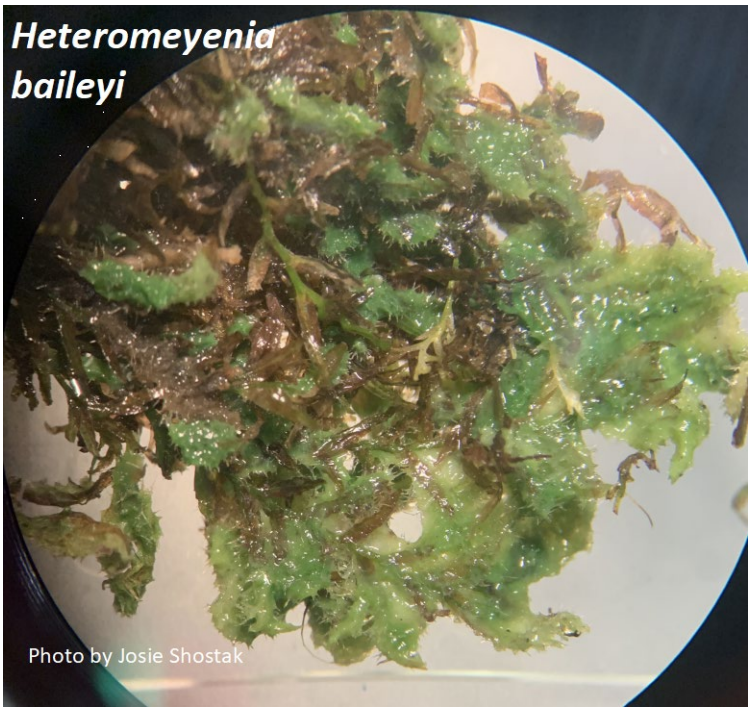
DESCRIPTION

Taxonomy and Basic Descriptions

This guild includes 14 species and three individual sponges that are identified to genus. All sponges are in the family Spongillidae. These species are typically small (<6 cm long) but can reach up to 24 cm long on some floating docks. Species are identified by their skeletal elements (silicious spicules) after digesting tissue in bleach. Species are also identified based on spicules within gemmules (asexual buds found embedded in or under sponge tissue). All species adopt encrusting or cushion growth forms, and many have obvious pores and canal structures that are part of their water filtration system.

Corvospongilla becki- encrusting on 3D substrates like moss and vegetation attached to a dock, tan-brown, 5-7 mm thick, pores are obvious, spicules protruding from surface can be easily seen

Corvospongilla novaterrae- tan to green (the green color is likely from algal symbionts), thin to medium (5-10 mm) thickness, cushion-like appearance, obvious canal structures, found on rock in shallow stream

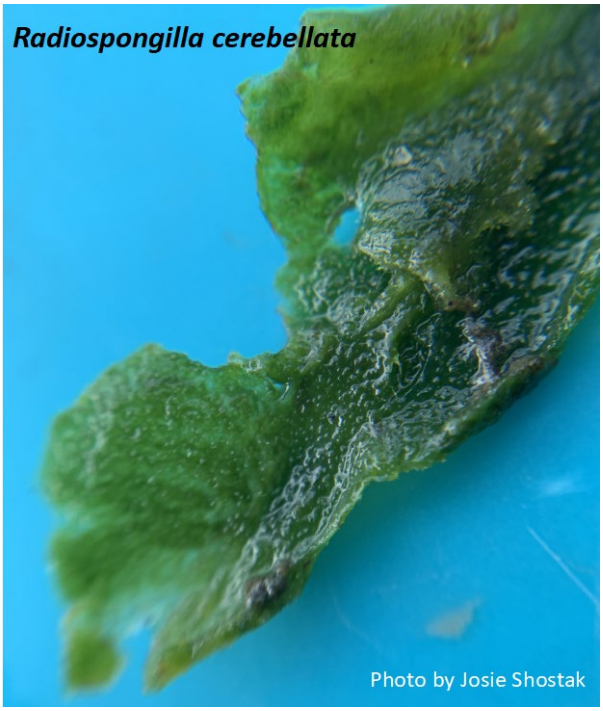


Corvospongilla sp.-no photo available; thin to thickly encrusting, pipe-shaped, growing on and associated with moss, pale, no visible pores, soft and cushion-like

Ephydatia fluviatilis- tan, thin to thickly (3-10 mm) encrusting, found on floating log, obvious canal structures

Eunapius fragilis- thinly (1-3 mm) encrusting, growing on and surrounded by moss, pale green, visually porous with a soft and fragile texture

Heteromeyenia baileyi- Bright green with obvious spicules protruding from tissue, soft cushion-like texture, growing on and surrounded by moss.

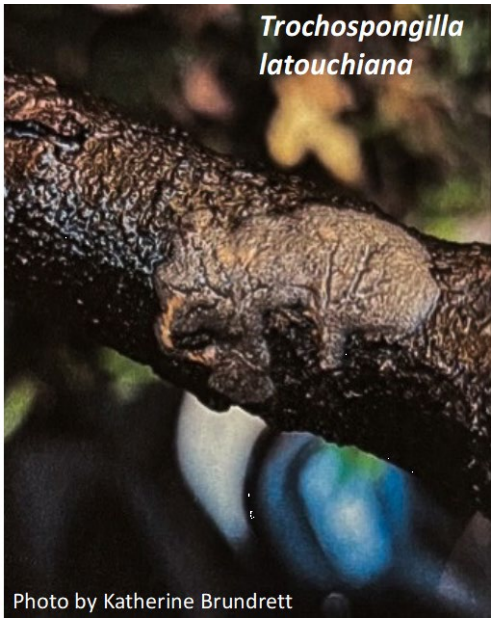


Heteromeyenia latitenta - no photo available; found associated with moss, pale green

Heteromeyenia longistylis- no photo available; tissue was dead on collection, tan in color, thinly (3-5 mm) encrusting

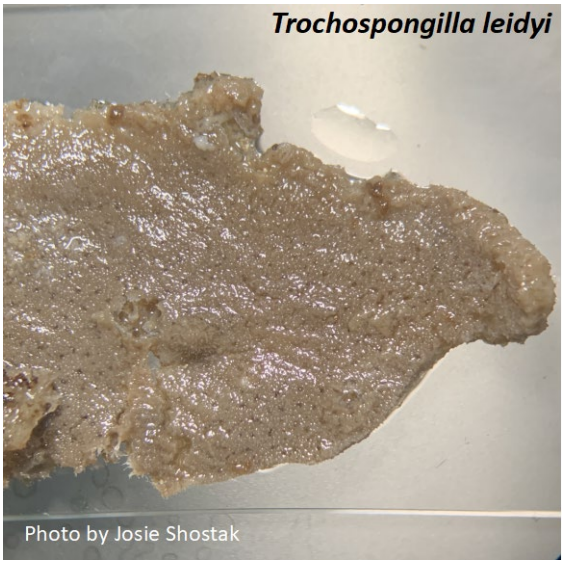
Racekiela ryderi- tan with a strong earthy smell, thin to thick (5-15 mm) encrusting, cushion-like texture, not associated with moss or plants, no obvious canal structure.

Racekiela sp.- no photo available; large (about 10 cm long), thickly encrusting (up 1 cm), dark brown and green, very porous, strong earthy smell



Radiospongilla cerebellata- thinly encrusting (2-5 mm), bright green, no visible pores, canal structures visible, spicules sometimes protrude from surface

Radiospongilla sp. no photo available; thinly (2-5 mm) encrusting, pale green, clear canal structures, found on rock, porous with cushion-like texture



Spongilla lacustris- no photo available; green-brown sponge, thin to thick (3-10 mm) encrusting, found on plastic dock

Trochospongilla horrida- thin to thickly (3-10 mm) encrusting, tan-pale green, obvious canal structures visible, found on both rock and docks, soft and compressible.

Trochospongilla latouchiana- small and thinly (<5 mm) encrusting, pale green or tan color, soft tissue with visible canals

Trochospongilla leidyi- brown-tan, thinly (3-5 mm) encrusting, found deeper on dock piling, strong smell, pores visible on surface, flexible and brittle tissue

Trochospongilla pennsylvanica- tan, thin (<5 mm) encrusting, found on floating log with obvious canal structure

Status

These populations of freshwater sponges in South Carolina are not listed as threatened or endangered. Species are given Natural Heritage ranks as follows: *Corvospongilla becki*: S4, *Corvospongilla novaterrae*: S3S4, *Corvospongilla* sp. 1: S3S4, *Ephydatia fluviatilis*: S3, *Eunapius fragilis*: S3S4, *Heteromeyenia baileyi*: S3S4, *Heteromeyenia latitenta*: S*3*, *Heteromeyenia longistylis*: S3, *Racekiela ryderi*: S3S4, *Racekiela* sp. 1: S3S4, *Radiospongilla cerebellata*: S3, *Radiospongilla* sp. 1: S3S4, *Spongilla lacustris*: S3, *Trochospongilla horrida*: S3S4, *Trochospongilla latouchiana*: S3S4, *Trochospongilla leidyi*: S3S4, *Trochospongilla pennsylvanica*: S3S4.

POPULATION SIZE AND DISTRIBUTION

Historically, freshwater sponges were reported from a single location near Columbia, South Carolina in Adams Pond (Harrison, 1977; Brisbee, 1992) where five sponges were found: *Corvomeyenia carolinensis, Heteromeyenia baileyi, Anheteromeyenia (Racekiela) ryderi, Spongilla lacustris*, and *Trochospongilla pennsylvanica.* Recent records indicate widespread distribution of this guild with species present at diverse sites within both the Coastal Plain and Coastal Zone Ecobasins.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The species in this guild are found in diverse environments including fast flowing and deep rivers and shallow (<3 cm deep) streams, as well as slow flowing ponds and ephemeral wetlands. Species grow on both natural (rock, vegetation roots and stems, live and dead wood) and artificial (plastic and wooden docks and pilings) substrates. Sponges are found near the surface and down to a depth of ~ 10 cm. Species are generally found in clear water but have been identified at sites both distant from and near human development and pollution, as well as in turbid waters (but this is rare).

CHALLENGES

Sponges as a group are not threatened globally, but freshwater sponges may be at increased risk due to pollution and temperature fluctuations (Bell et al., 2015), as well as habitat destruction.

CONSERVATION ACCOMPLISHMENTS

There are no known conservation accomplishments pertaining to freshwater sponges, but any initiatives that protect wetlands and maintain water quality are likely to protect habitat for these organisms.

CONSERVATION RECOMMENDATIONS

- Determine the role of freshwater sponges in nutrient and organic matter cycling in freshwater systems in South Carolina.
- Establish baseline growth rates for dominant species.
- Assess the use of freshwater sponges by aquatic insects (particularly the use of sponges by insect larvae).
- Examine reproductive cycles and seasonality of freshwater sponges and their use of gemmules to survive high or low temperatures or other disturbances
- Protect wetlands from human development or other anthropogenic impacts that might destroy sponge habitat or contribute to pollution

MEASURES OF SUCCESS

Current surveys are providing critical information on the distribution of these species, but more work is needed to study the ecology (growth rates, diet, contribution to organic matter and nutrient cycling, and reproduction) of freshwater sponges. This research should also evaluate seasonal variation in freshwater sponge populations and their use of gemmules to survive environmental fluctuations and promote dispersal. Recurring populations in ephemeral wetlands distant from humans, rivers or streams near human development, and after seasonal die-offs due to temperature extremes is a measure of success for this group.

Contributors (2024): Bronwyn W. Williams (NC Museum of Natural Sciences), William E. Moser (Smithsonian Institution National Museum of Natural History)

New England Medicinal Leech
Macrobdella sestertia

The New England Medicinal Leech was described in 1886 from eastern Massachusetts. It took nearly a century, in 1976, to be collected a second time (Smith 1977), and nearly two decades more to be collected a third time (Smith and Hanlon 1997), in Maine. In 2008, 9 specimens of *M. sestertia* were collected in southwestern South Carolina (Poly 2011), representing a significant expansion of its historically reported New England distribution. Two additional specimens of the species from South Carolina were found in the collections of the Charleston Museum and North Carolina Museum of Natural Sciences (NCSM) (Poly 2018); these specimens are currently housed in the NCSM Non-molluscan Invertebrates (NMI) Collection. Carlson and Phillips (2020) presented an extinction model for *M. sestertia* throughout its patchy and disparate range, concluding that the species may have gone extinct, but urging for surveys and a focus more generally on leech conservation. Ironically, this paper was in press when Dr. Bronwyn Williams, joined by Dr. Anna Phillips, collected several *M. sestertia* specimens in southern New Hampshire; Dr. Williams had also collected a handful of *M. sestertia* specimens in South Carolina the previous year. In South Carolina, the New England Medicinal Leech is known to occur only in Edgefield County. *Macrobdella sestertia* has a Global Status of imperiled (G2) and is currently considered Possibly Extirpated in Massachusetts. It has no current status rank in South Carolina (NatureServe 2024). Nearly nothing is known about the local and range-wide distribution of this species or any aspect of its natural history; fewer than 30 individuals have been collected since its description over 140 years ago.

"A terrestrial leech"
Haemopis septagon

The terrestrial leech, *Haemopis septagon*, was described in 1976 from Durham County, North Carolina. Its known distribution ranges from New Jersey south into Georgia throughout coastal plain and lower Piedmont habitats. While it is truly a terrestrial species, *H. septagon* occupies damp riparian areas and microhabitats containing an abundance of earthworms, its primary prey. A substantial amount of information about the natural history of this species has been recently gleaned through collecting and husbandry efforts by a handful of herpetologists in the southeast. That said, *H. septagon* remains poorly documented in South Carolina, reported only from Georgetown, Charleston, and Lee Counties (Sawyer and Shelley 1976, NCSM NMI Collection

database). Basic surveys, ideally coincident with efforts focused on amphibians, are needed to assess the distribution and abundance of this species in South Carolina (Sawyer 1979). It was recommended for Special Concern status by Sawyer (1979). This species is currently unranked (NatureServe 2024).

Appalachian Leech
Placobdella biannulata

This species is found free-living and as a parasite on salamanders of the genus *Desmognathus*. Formerly known by the name *Oligobdella biannulate*, it is known to occur in South Carolina only in the Blue Ridge Ecoregion in Oconee, Pickens, and Greenville Counties (Sawyer and Shelley 1976; Moser et al. 2005). Sawyer (1979) recommended Special Concern status for the species. In its entirety, the species occurs in a relatively small area encompassing mountainous portions of Georgia, North Carolina, South Carolina, and Tennessee (Moser et al. 2005). This species has no current status rank in South Carolina (NatureServe 2024).

Nuchal Leech
Placobdella nuchalis

The nuchal leech was originally described by Sawyer and Shelley (1976) from one site in South Carolina (Orangeburg County) and a few localities in North Carolina. Little is known about the natural history of this species except it being reported as a temporary parasite of fishes (Shelley and Braswell 1981; Klemm, 1982). *Placobdella nuchalis* has been rarely collected since its description. Moser et al. (2017) added new information on its anatomy and a molecular characterization. Poly (2018) discovered individuals of this species to be hitchhikers of a collection of *M. sestertia* in South Carolina. The nature of this association is unknown but warrants further study. This species does not have any conservation rank currently assigned to it, but basic surveys are needed to assess its distribution and abundance.

Translucent Leech
Placobdella translucens

The translucent leech was originally described by Sawyer and Shelley (1976) from Georgetown and Berkeley Counties, South Carolina and from a site in Louisiana. *Placobdella translucens* is infrequently encountered and its range is Alabama, Florida, Georgia, Louisiana, North Carolina, and South Carolina (Sawyer and Shelley 1976; Klemm 1982, 1991). It is most likely a blood feeding leech, but there are no reported hosts for this species. Basic surveys are needed to assess its distribution and abundance of *P. translucens*. It has no current status rank in South Carolina (NatureServe 2024).

"A marine leech"
Branchellion ravenelii

This marine leech was described by Girard in 1850 from Charleston, South Carolina. It is parasitic on rays and skates and occurs along the southeastern Atlantic Coast to the Gulf of Mexico, although reports in South Carolina are exceedingly rare (Sawyer et al. 1975, Sawyer 1979). In 2024, a staff member of the Charleston Aquarium contacted Megan McCuller,

Collections Manager of NMI at the NCSM reporting a *B. ravenelii* on a batoid housed at the facility. If confirmed – and the leech specimen may end up in the NCSM NMI Collection – this would be a welcome recent finding. Sawyer (1979) recommended state endangered status for the species; such a status in turn reflects a conservation focus on the hosts of this leech. *Branchellion ravenelii* is likely present in nearshore areas of South Carolina but may be rare, or appear rare, given this region is the northern extent of its range. Typically, little attention is paid to ectoparasites of marine vertebrates, particularly if the parasites occur in small numbers. As such, this species may be relatively common, but just not reported. *Branchellion ravenelii* has no current status rank in South Carolina (NatureServe 2024).

Common bottlenose dolphin (offshore)

Tursiops truncatus

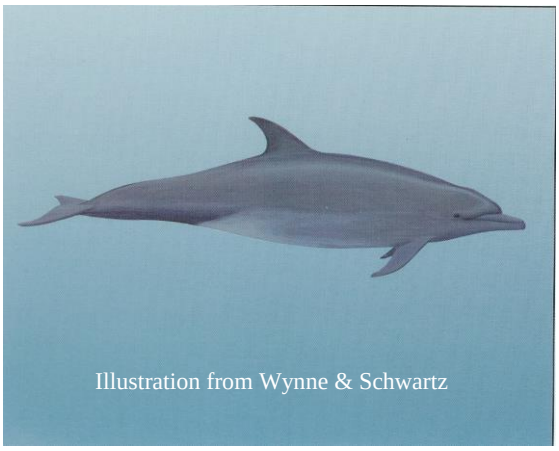

Illustration from Wynne & Schwartz

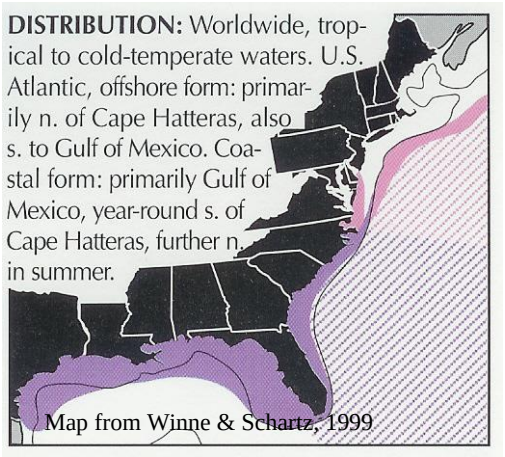
Contributors (2005): David Cupka and Margaret Murphy [SCDNR]
Reviewed and Edited (2013): Wayne McFee (NOAA); Updated (2024): Wayne McFee (NOAA) and Todd Speakman (NMMF)

DESCRIPTION

Taxonomy and Basic Description



The bottlenose dolphin, *Tursiops truncatus*, was first described by Montagu in 1821. The body and head are robust with a short, thick, well-defined beak. Based on distribution, genetics, morphology, parasites and prey items, two distinct species are now recognized; the "coastal form" (*Tursiops erebennus*) is shorter and slimmer than the larger "offshore form", *Tursiops truncatus* (Costa et al., 2022). The flippers are pointed with deeply notched flukes. The teeth are small and conical and number between 40 to 52 in the upper row and 36 to 48 in the lower row. The dorsal fin, located mid-back, is tall and falcate with a broad base. Adult size varies considerably, ranging from 1.9 to 3.6 m (6 to 12 ft.) (Wynne & Schwartz 1999). The bottlenose has been reported to weigh up to 650 kg (1,432 lb) (Minasian et al. 1984).

Status

The bottlenose dolphin is not listed as threatened or endangered under the Endangered Species Act (ESA). In 1993, the National Oceanic and Atmospheric Administration (NOAA) Fisheries Service (National Marine Fisheries Service or NMFS), treating the coastal population as a single migratory stock, designated the stock as "strategic" under the Marine Mammal Protection Act (MMPA). The action was due to a massive die-off of coastal bottlenose dolphins between 1987 and 1988 (Waring et al. 2002). From 1995 through 2001, the NMFS recognized only a single migratory stock of coastal bottlenose dolphins in the western North Atlantic; therefore, the entire stock was listed as depleted. Current stock assessments have identified 5 coastal stocks of bottlenose dolphins based on genetic studies (Rosel et al. 2009), photo-id (Zolman 2002), strandings (McLellan et al. 2003), and satellite telemetry data (Southeast Fisheries Science Center, NMFS, unpublished data): the Northern Migratory and Southern Migratory stocks, South Carolina/Georgia Coastal stock, Northern Florida Coastal stock, and the Central Florida Coastal stock (Hayes et al. 2022). Further, there are at least 10 recognized Estuarine Stocks on the east coast of the US: a Northern NC Estuarine System stock, a Southern NC Estuarine System stock, a Northern South Carolina Estuarine System stock, a Charleston Estuarine System stock, a Northern Georgia/Southern SC Estuarine System stock, a Central Georgia Estuarine System stock, a Southern Georgia Estuarine System stock, a Jacksonville Estuarine System stock, an Indian River Lagoon Estuarine System stock, and a Biscayne Bay Estuarine System stock (Hayes et al. 2022). Because one or more of the stocks may be depleted, all stocks retain the depleted designation.

The western North Atlantic offshore bottlenose dolphin (offshore ecotype) is also not listed as threatened or endangered under the ESA. Potential Biological Removal level or PBR is an estimate of the maximum number of animals, not including natural mortalities, which may be removed from a marine mammal stock while allowing that stock to reach or maintain its Optimum Sustainable Population (OSP). PBR's are established under the MMPA. The average annual fishery-related mortality and serious injury for western North Atlantic offshore bottlenose dolphin from 1996 to 2000 is unknown and the PBR is 519 animals; therefore, the status of this stock is unknown (Hayes et al. 2022).

POPULATION SIZE AND DISTRIBUTION

Two bottlenose dolphin ecotypes inhabit waters in the western North Atlantic Ocean: a shallow water or nearshore/coastal ecotype and a deep water or offshore ecotype (Curry and Smith 1997). Based on work to date, it appears that the western North Atlantic offshore stock consists primarily of the offshore ecotype. Relatively little is known about the distribution of the offshore ecotype except that it is typically concentrated along the continental shelf break in deeper waters and can, in lower concentrations, extend beyond the continental shelf into continental slope waters (Kenney 1990). However, the offshore ecotype has been documented to occur close to shore near Cape Hatteras, NC and points south. Although the ranges of the coastal and offshore ecotypes overlap to some degree, Torres et al. (2003) found a statistically significant break in the distribution of the two ecotypes at 34 km (18 nautical miles) from shore. Torres reports that the offshore ecotype is found seaward of 34 km and in waters deeper than 34 m (112 ft.), and the coastal ecotype is found within 7.5 km (4 nautical miles) offshore. The best available abundance for the offshore stock of bottlenose dolphins in <40 m (131 ft.) depth is 26,849 and in >50 m (164 ft.) water depth is 44,953. Data are insufficient to determine current population trends for the offshore stock (Waring et al. 2009a). The most recent and best available estimate for the entire offshore stock of common bottlenose dolphins in the western North Atlantic is 62,851 with a minimum population estimate of 51,914 (Hayes et al. 2022).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Bottlenose dolphins are both a coastal and an oceanic species, with the coastal ecotype preferring waters of less than 30 m (98 ft.) in depth. The offshore ecotype seems to be adapted for cooler, deeper waters. Certain characteristics of their blood indicate that this form may be better suited for deep diving. They typically occur in deep waters of the continental shelf and inner continental slope (Hersh and Duffield 1990).

CHALLENGES

A variety of factors, both natural and human-related, can affect bottlenose dolphins. Natural factors include predation by large sharks, disease, parasites, exposure to naturally occurring biotoxins, changes in prey availability, and reduction or loss of habitat due to environmental variation. Human-related causes of mortality and injury to this species include loss of habitat due to coastal development, exposure to pollutants, vessel strikes, entanglement in debris, as well as noise and pollution related to oil and gas development. Bottlenose dolphins have also increasingly become the target of dolphin watching and wild dolphin interaction programs. There is growing concern that these activities may result in altered behavioral patterns, especially where people enter the water with dolphins and where they are fed. In the latter case, behavioral patterns are altered significantly and increased aggression may occur (Bryant 1994).

In addition, recreational and commercial fisheries directly and indirectly affect bottlenose dolphins. Coastal bottlenose dolphins are taken as bycatch in various kinds of fishing gear including gillnets, seines, longlines, shrimp trawls and crab pots (Waring et al. 2002). Bycatch of offshore bottlenose dolphins has been observed in the pelagic drift gillnet, pelagic pair trawl, New England multispecies sink gillnet, North Atlantic bottom trawl, mid-Atlantic coastal gillnet and pelagic longline fisheries. The pelagic drift gillnets and pelagic pair trawl fisheries no longer exist. Mortalities of bottlenose dolphins due to ingestion of hooks and/or line have also been documented (Gorzelany 1998; Well et al. 1998). The gear most likely had been discarded or was consumed by the dolphin by eating a fish that had been hooked then broke away with the gear. Estimates of fishery-attributed interactions suggest that mortality exceeds the PBR of several coastal stocks considered depleted by the 1987 through 1988 die-off and, thus, may be impeding their recovery.

CONSERVATION ACCOMPLISHMENTS

SCDNR and South Atlantic Fishery Management Council (SAFMC) personnel serve as members of the Bottlenose Dolphin Take Reduction Team (BDTRT), which was convened in 2001. The BDTRT works with NOAA Fisheries to develop the Bottlenose Dolphin Take Reduction Plan (BDTRP) for coastal stocks. The short term goal of the plan is to reduce, within 6 months of its implementation, the incidental mortality or serious injury of western North Atlantic coastal bottlenose dolphins incidentally taken in commercial fishing operations to levels less than the potential biological removal (PBR) level. The long term goal of the take reduction plan is to reduce, within five years of plan implementation, incidental mortality and serious injury of coastal bottlenose dolphins incidentally taken in the course of commercial fishing operations to insignificant levels approaching a zero mortality rate goal (ZMRG). The BDTRT has developed a number of recommendations to achieve these goals and to be incorporated into the BDTRP. The BDTRP was amended in December of 2008 (73 FR 77531) with an effective date of January 20, 2009.

The BDTRT has made a number of recommendations to be incorporated into the BDTRP for coastal stocks including regulatory suggestions, based on management units, which apply to specific fisheries. Generally, these recommendations seek to reduce soak times, the amount of fishing gear in the water at any given time, or to modify practices in order to limit interactions with and the take of bottlenose dolphins. The BDTRT also adopted non-regulatory recommendations for all management units including education and outreach, as well as

improved research, monitoring, collection of strandings data, and observer coverage. The finalized specific recommendations were published on April 26, 2006 (FR 50CFR Parts 223 and 229) and SCDNR will continue to explore avenues to implement these recommendations, working together with members of the BDTRT as funding opportunities become available.

SCDNR conducted a marine mammal stranding program from 1991 to 2005 in order to obtain data on marine mammals that strand along the South Carolina coast. Data from the program are used to further our knowledge regarding these animals and the extent to which anthropogenic factors are responsible for or contribute to their stranding. From 2006-2008, the NOAA National Centers for Coastal Ocean Science in Charleston, SC assumed responsibility of the network, Coastal Carolina University administered the program from 2009-2021, and the Lowcountry Marine Mammal Network has assumed responsibility of the Network since 2021, having received grant awards from the Prescott Grant.

CONSERVATION RECOMMENDATIONS

- Improve understanding of stock structure and population trends in order to assess the greatest threats to bottlenose dolphins.
- Determine the significance of periodic die-offs, especially to relatively small, isolated populations of bottlenose dolphins.
- Assess the impact of contaminants on marine mammals, particularly the repercussions of high contaminant loads in individual bottlenose dolphins as well as their offspring.
- Measure the effects of interactions between humans and dolphins in the wild, including behavioral disruption, habituation, injury and death.
- Mitigate threats to bottlenose dolphins posed by entanglement in fishing gear through support of methods proposed by the BDTRT.
- Continue to explore avenues to partner in implementation of recommendations to be published by the BDTRT.

MEASURES OF SUCCESS

A take reduction plan has been developed for coastal bottlenose dolphins to reduce the incidental take of animals in commercial fishing operations to below the Potential Biological Removal (PBR) level. SCDNR personnel will continue to serve on the BDTRT in order to help develop and implement programs and activities designed to reduce bottlenose dolphin non-natural mortalities to insignificant levels approaching a zero mortality and serious injury rate (the Zero Mortality Rate Goal or ZMRG).

Florida Manatee

Trichechus manatus latirostris

Contributors (2005): Thomas M. Murphy and DuBose B. Griffin
Reviewed and Edited (2012): Clay George (GADNR) and Wayne McFee (NOAA)
Reviewed and Edited (2024): Michelle Pate and Melanie Olds (USFWS)

DESCRIPTION

SCDNR

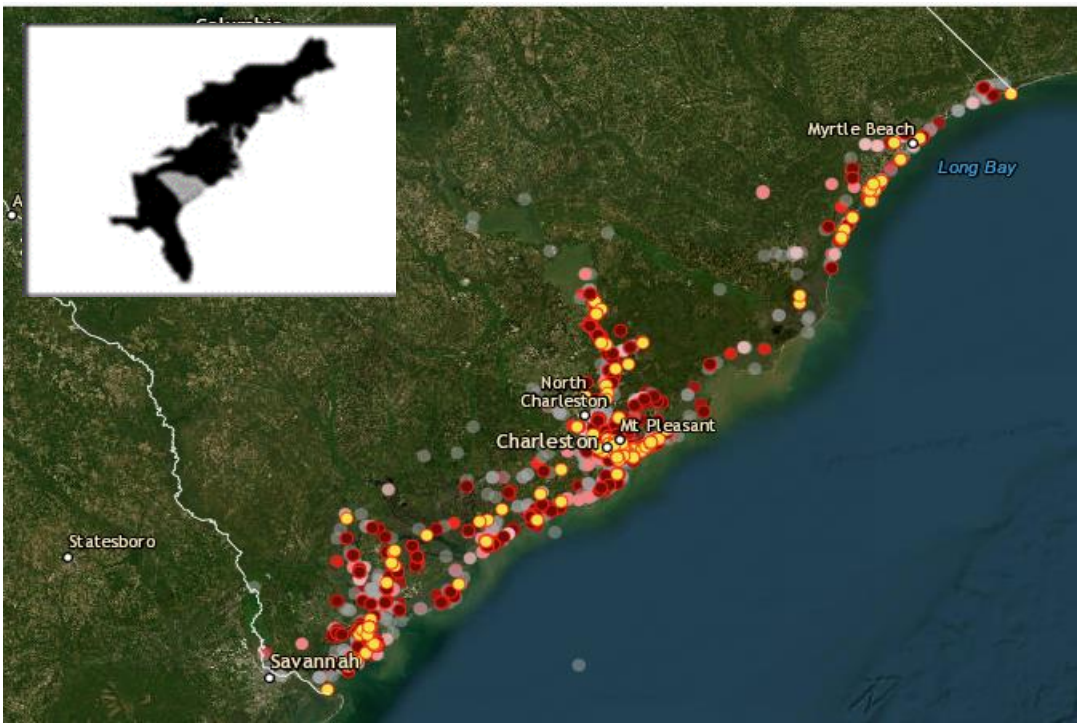
Taxonomy and Basic Description

Manatees are aquatic mammals in the order Sirenia. The order includes manatees, dugongs and the extinct Steller's sea cow. The West Indian manatee is one of three species in the family Trichechidae. Linnaeus named the single genus *Trichechus* in 1758. Two subspecies of West Indian manatee are now recognized: the Florida manatee, *T. manatus latirostris*, which occurs in the southeastern United States, and the Antillian manatee, *T. manatus manatus* that is found throughout the remainder of species' range (USFWS 2001).

Manatees are large, robust marine mammals with short, paired flippers and a distinct paddle-shaped tail. On average, manatees reach lengths of 3.5 m (11.5 ft.) with females tending to be larger than males. Average weight is approximately 1000 kg (2200 lbs.). In the murky waters of South Carolina, only the small head is sometimes seen as the animal surfaces for air. The head is rounded and indistinct from the body with no neck area apparent. Stiff vibrissae (tactile hairs) are present around the small mouth, and two circular-valved nostrils are situated on the top of the muzzle. The eyes are small with a small lid and nictitating membrane, a clear inner eyelid that protects the eye. External ear flaps are absent. Manatee pectoral flippers are flexible and aid in moving over the substrate, maneuvering in the water column, scratching, manipulating food, and embracing other manatees. The large tail is rounded and horizontally flattened for locomotion and steering. The tail is used to propel the manatee forward with a strong up-and-down pumping motion, which creates circular swirls on the surface of the water known as "footprints."

Monica Ross, Clearwater Aquarium

Manatees are semi-social and can be found alone or in small groups. They are not territorial. Ranges of individuals often overlap, with male ranges ("circuits") being larger and encompassing several female ranges. Manatees see well and are sensitive to audible and tactile cues. They



communicate with a variety of high-pitched squeaks and chirps. Manatees often return to the same wintering and summering habitats year after year. Females reach sexual maturity by 5 years of age and males by age 3 - 4 years. Lifespan can exceed 50 years. Breeding usually takes place in mating herds, which form when several males are attracted to a female in estrus. Mating herds may remain together for a few days to over a month, during which as many as 20 males may compete intensely for access to the focal female. Manatees mate and calve year-round. Female manatees usually give birth to a single calf, but twins are born on rare occasions. Calves remain with their mothers for 1 - 2 years after birth. Newborns average 1.2 to 1.4 m (4 to 4.5 ft.) in length and weigh about 30 kg (66 lbs.) (Odell 1981). Manatees have slow metabolic rates which makes them intolerant of water colder than 20°C (68°F).

Conservation Status

The West Indian manatee is listed as threatened throughout its range under the Endangered Species Act of 1973 as amended (16 U.S.C. 1531 *et seq.*) having been downlisted from endangered in 2017 (82 FR 16668). The manatee is listed as "vulnerable" under the International Union for Conservation of Nature (IUCN). It is also protected under the South Carolina Nongame and Endangered Wildlife Species Act (§§ 50-15-10-50-10-90) and the Marine Mammal Protection Act (MMPA) of 1972 as amended (16 U.S.C. 1461 *et seq.*). Manatees in South Carolina have state rankings of S2/S3 indicating the species is of high conservation concern. Critical habitat for the Florida subspecies was designated in 1976 (50 CFR Part 17.95(a)), the first for an endangered marine mammal. The largest population of manatees is found in the southeastern United States. Outside the United States, manatees occur in the Greater Antilles, on the east coast of Mexico and Central America, along the north and northeast coast of South America, and in Trinidad and Tobago (Lefebvre et al. 1989). A petition to reclassify the West Indian manatee, including its subspecies the Antillean manatee and Florida manatee, as endangered species under the Act has been filed (88 FR70634) prompting the initiation of a status review to determine if the petition actions are warranted. That review is ongoing as of 2024.

POPULATION SIZE AND DISTRIBUTION

Commercial and subsistence harvests in the 1800's probably significantly reduced the population. Minimum population size has been based on counts of manatees at all known winter refuges in Florida and Georgia. Aerial and ground counts at winter refuges are highly variable depending on weather, water clarity, manatee behavior and other factors (Packard et al. 1985). It is estimated that 9,790 manatees live between Florida's east and west coasts as of 2022 (Gowan, T.A. *et al.* 2023).

Manatee Sightings in South Carolina: 1850 to 2023.

Between 1850 and 1981, a total of 23 records of manatees in South Carolina were documented (Rathbun et al. 1982). Four additional records were reported by O'Shea (1988) from 1981 through 1986. Between 1986 and 1992, an additional 25 records were recorded by SCDNR (unpublished data). Therefore, only 52 records of manatees were documented in South Carolina over a period of 142 years, suggesting that manatees are rare visitors. In 1998, a record 190 sightings were made of manatees in SC. The farthest inland a manatee has traveled in South Carolina is to Santee State Park along the shores of Lake Marion in Orangeburg County in November of 2012. The individual died due to cold stress. Since active surveillance was initiated in 1993, more than 2,300 manatee sightings have been reported in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In the Southeast, manatees are found in rivers, bays, or estuaries with submerged aquatic vegetation from which they forage. Manatees migrate to SC during the spring when water temperatures are approximately 68F or higher and stay through the warm summer months and then migrate back to Florida in the winter. Sightings in SC are highest from June-September than other times of the year. Any manatees sighted in SC during December-March would be outliers; possibly animals attracted to industrial warm water outfalls associated with industrial sites. Such individuals would likely be in imminent danger of mortality from cold stress given the low ambient water temperature in SC during winter. In South Carolina, manatees occupy fresh, brackish, and marine habitats and move freely between salinity extremes. Because of our high tidal amplitude, manatees feed on abundant *Spartina alternaflora* grasses at high tide and frequently move to submerged *Ulva sp*. beds at low tide. Manatees will move up rivers until the water is too shallow for passage or is blocked by a dam. South Carolina sightings indicate that manatees are frequently reported in areas where food resources exist including occurring near locations of *Hydrilla verticillate* available on the upper Cooper River. This area is the only site

with extensive stands of the introduced exotic plant *Hydrilla verticillata* accessible to manatees in the state and analysis of sightings records suggests they are utilizing it to a lesser extent for forage as well (Leslie 2017).

CHALLENGES

The greatest known human-related cause of manatee mortality in the southeastern United States is collisions with watercraft. There is limited documented collision-mortality in South Carolina and few of the many manatees sighted are reported to have fresh wounds. However, the lack of extensive collision mortality may be a result of the low number of animals present. It is likely that manatees are prone to being struck by fast moving boats when foraging in shallow areas; however, most boat operators avoid shallow water hazards in South Carolina. The high tidal amplitude and abundant oyster beds present in this state reduce the frequency of collisions.

Cold stress may have a significant effect on manatees in South Carolina because the state is in the northern range of manatees. The threat of cold stress is complicated by use of heated water discharges at a variety of industrial sites in the fall. Unlike power plants and paper mills, many of these smaller discharge sites are not in continuous operation and do not provide a predictable source of warm water. Many are being eliminated as alternative treatments for heated effluent are being adopted. Although based on a limited sample, several manatee mortalities in South Carolina were related to low water temperature exposure.

USFWS

Manatee mortality by trauma or drowning can be associated with the operation of locks and water control gates. One such site in South Carolina is the Pinopolis Lock on the upper Cooper River that transports boats between the river and Lake Moultrie. Manatee mortality has occurred in two ways at lock sites. Several manatees have died from exposure to cold-water temperatures after they failed to navigate back to the lock in the fall during its limited operation. The other source of mortality is from drowning or being crushed during in the lock during operation. Several of these locks sites have a lock operation plan that is aimed at preventing passage of manatee and to prevent injury if the manatee gets into the lock.

Although documented in Florida (O'Shea et al. 1991), harmful algal blooms have not been documented as a source of manatee mortality in South Carolina. However, documentation of the state's first large-scale marine algal bloom (*Heterosigma akashiwo*) in the spring of 2003 increases the likelihood of future blooms.

An unusual mortality event (UME) is ongoing in Florida associated with the lack of available food resources such as seagrass. A record number of 841 manatee deaths were documented over a six-month period in 2021. This UME is the first due to starvation. This type of event has not

been documented in South Carolina, but individuals may utilize available foraging areas outside of their Florida range when resources are limiting, prompting more individuals to travel to places like South Carolina.

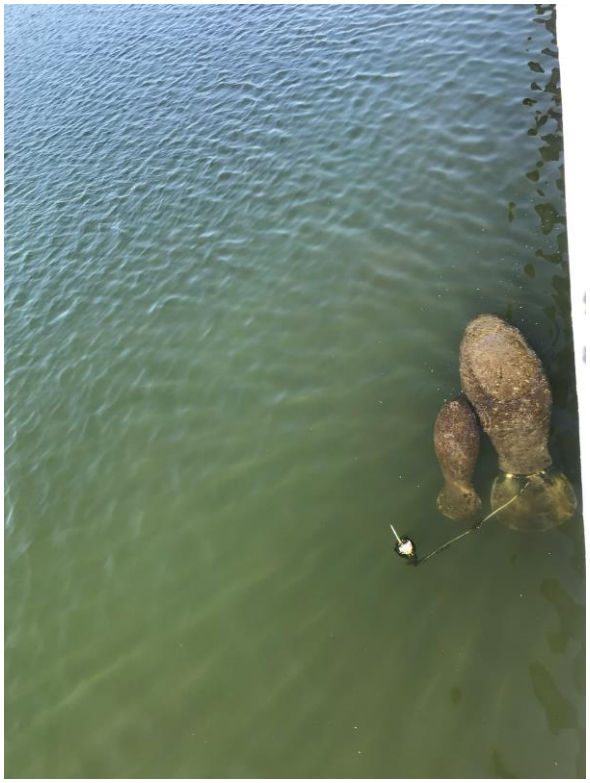
Several manatee mortalities have been associated with the shrimp trawl fishery, though not in South Carolina. The interaction between shrimp trawlers and manatees appears to be rare because manatees should be able to outswim the approaching nets or surface to avoid them.

A changing climate may have effects on foraging, distribution, and habitat use of manatees. Sea water temperature data recorded for Charleston Harbor indicates relatively constant water temperatures between 1970 to 1985. As of 1985, data recorded indicates a warming trend for this area (SCDNR). During recent years manatees have been observed earlier in South Carolina waters, the earliest yet occurred in February 2022 (SCDNR unpublished data). Changing water temperatures may also have effects on available forage and timing of availability.

CONSERVATION ACCOMPLISHMENTS

Geographic distribution of and seasonal use by manatees in South Carolina continues to be documented through reports from the public. A manatee web site has been maintained since 2003 to inform the public about manatees in South Carolina and to provide an online form for reporting manatee sightings. The online reporting system has been upgraded to GIS platform utilizing the ArcGIS Survey123 form.

New signage was created and installed at marinas in coastal and riverine areas that directs the public to the online reporting form. This signage also reminds boaters of manatee's presence in our waters.



The approval of a new Manatee Protection Plan for Santee Cooper's Pinopolis Lock on the Cooper River. The plan was mandated by the Federal Energy Regulatory Commission to receive a new license to operate. The plan outlines continued efforts to reduce the likelihood that manatees will enter Lake Moultrie from the Tailrace Canal, and "avoid and minimize project-related effects on the West Indian Manatee" (order issuing new License, 2023).

Installation of a diffuser on the WestRock plant to disperse heated effluent and reduce use of the area by manatees when water temperatures drop and subsequent mortality during fall and winter season. Though WestRock has since shut down operations as of 2023. Other warm-water discharge sites have changed operations to include two-cycle cooling and more monitoring for adverse impacts to manatees.

CONSERVATION RECOMMENDATIONS

- Document seasonal use and evaluate the relationship between manatee reports and actual population size.
- Continue cooperation with Clearwater Marine Aquarium Research Institute in monitoring manatees tagged with radio instruments to determine manatee use areas in the northern portion of the range.

- Attempt to identify individual manatees to better understand patterns of use.
- Continue to document the relationship between use of heated effluent by manatees and distribution of these animals in northern waters as well as any associated manatee mortality.
- Protect the quality of wetlands in South Carolina by preventing the rise of harmful algal blooms. This can be accomplished by reducing nutrient loading of coastal water bodies through best management practices and land use planning.
- Collaborate with port and shipping operation authorities to develop contingency plans for oil spill events that will result in protection to manatees.
- Collaborate with port and shipping operations authorities for the installation of manatee bumpers to prevent large container ships "crushing" manatees.
- Continue to solicit and summarize sightings of manatees from the public to determine habitat use.
- Monitor the causes of manatee injury and mortality.
- Monitor water uptake and discharge areas at industrial sites for manatee use and evaluate the potential for conflicts involving entrainment and cold-stress mortality.
- Monitor the effectiveness of Turtle Excluder Devices in preventing drowning of manatees in trawl nests.
- Maintain an updated, interactive manatee web site at https://www.dnr.sc.gov/manatee/ to increase public awareness of manatee threats while continuing to solicit sightings information from the public.

Tagged manatee and calf observed along the concrete wall of the Hugh Leatherman terminal, Charleston, South Carolina. Tagged by Clearwater Marine Aquarium Research Institute in 2022.

MEASURES OF SUCCESS

Since low visibility in coastal waters limits the utility of aerial surveys for manatees unless they are at the surface, other means, mentioned above, will allow monitoring of manatees in South Carolina. As additional data on manatees in South Carolina are accumulated and a better understanding of the distribution and habitat use of state waters, further management recommendations can be developed. Data collected will continue to be used in stock assessments and the permit review process.

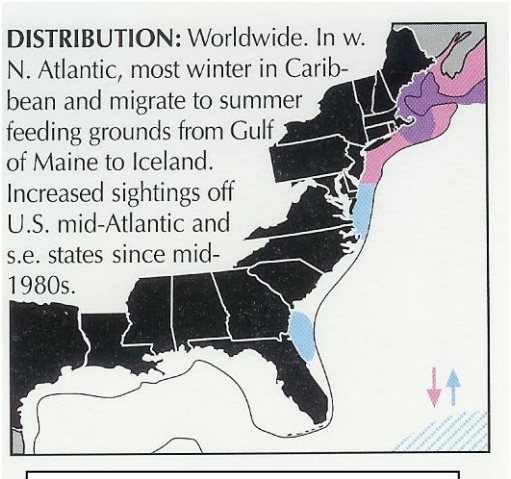
DESCRIPTION

Taxonomy and Basic Description

Illustration from Wynne & Schwartz



The humpback whale is a moderately large baleen whale. First described by Borowski (1781), the humpback's most distinguishable features include: a robust body with a broad, rounded head; a series of fleshy knobs on the rostrum and lower lip; long flippers (one-third of the body length); broad flukes with an irregular trailing edge; ventral throat grooves (12 to 36) extending to the navel; black with white coloring on the throat and belly with variable amounts of white on the undersides of flukes and both sides of the flippers; and a broad and bushy blow hole. Adults reach 11 to 16 m (36 to 52 ft.) in length and a weight of 36 metric tons (40 tons); females are slightly larger than males (Wynne & Schwartz 1999).

Status

All humpback whale populations are federally listed as endangered under the Endangered Species Act. However, The US Atlantic stock (Gulf of Maine stock) is defined as "not-depleted" because it does not coincide with any ESA-listed Distinct Population Segments (DPS) under the Marine Mammal Protection Act and because the average annual fishery-related mortality and serious injury did not exceed its Potential Biological Removal (PBR) level of 22 whales (Hayes et al. 2020).

POPULATION SIZE AND DISTRIBUTION

The humpback whale is worldwide in its distribution. In the western North Atlantic, most winter in the West Indies, where they mate and calve. These whales then migrate to summer feeding grounds from the Gulf of Maine to Iceland. However, a notable number of humpbacks do not undertake this extensive seasonal migration but instead overwinter in mid- and high-latitude regions (Clapham et al. 1993; Swingle et al. 1993). There have been increased sightings of this species off the US mid-Atlantic and southeastern

Map from Wynne and Schwartz, 1999

states since the mid-1980s (Swingle et al. 1993; Wiley et al. 1995). In this region, sightings have been reported in all seasons but are more predominant from January to March (Barco et al. 2002). Whether these increased sightings represent a distributional change or are simply due to an increase in sighting effort and/or whale abundance, is currently unknown (Waring et al. 2004).

The best available estimate of the population size for the US Atlantic waters (Gulf of Maine stock) is 1,396 (Hayes et al. 2020). The most recent estimates indicate continued population growth; however, the size of the humpback stock in the US Atlantic Exclusive Economic Zone (EEZ) may be below its Optimum Sustainable Population (OSP).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The humpback is considered a pelagic and coastal species. These whales are typically encountered over shallow banks and in shelf waters while feeding or breeding but may traverse open ocean during migration (Leatherwood and Reeves 1983; Wynne and Schwartz 1999). Feeding occurs in the cold, nutrient-rich waters of high latitudes. In the western North Atlantic, several discrete feeding grounds exist extending from the Gulf of Maine to off Iceland and northern Norway. Humpbacks exhibit strong fidelity to a particular feeding ground. Calves will typically return to the same feeding ground as their mother. Off the U.S. Atlantic coast, the primary feeding ground for humpbacks is the Gulf of Maine. Humpbacks begin to arrive in the waters off New England in early spring and remain through the fall. Their distribution in this area has been largely correlated to prey species and abundance, although behavior and bottom topography are also factors in foraging strategy (Payne et al. 1986, 1990). Humpbacks are generally piscivorus but krill are also frequently taken in the northern Gulf of Maine (Paquet et al. 1997).

Humpbacks fast while on breeding and calving grounds. During this time, these whales live off their vast reserve of blubber. Individuals from different feeding grounds mix while on the breeding grounds. Such mixing is also recorded within the group of humpback whales that winter off the U.S. mid-Atlantic coast. Most identified individuals from this group belong to the Gulf of Maine stock, but a few animals from stocks off Newfoundland and in the Gulf of St. Lawrence have been identified on the US mid-Atlantic coast wintering grounds as well (Barco et al. 2001). This population, composed of mostly first-year animals and a smaller number of juveniles and adults, is thought to use the mid-Atlantic/southeast region as a supplemental winter feeding ground. Some individuals have been observed over multiple years indicating repeated use of this area.

CHALLENGES

Although hunting previously caused a major decline in all humpback whale populations, these animals are no longer endangered by that activity. Ship collisions and entanglements in fixed fishing gear are the greatest causes of non-natural mortality in humpback whales. Other factors that may affect the recovery of humpback whales include disturbance or displacement caused by noise and other activities associated with shipping, recreational boating, whale watching or air traffic; pollutants from waste disposal; activities associated with mineral exploration and

extraction; habitat degradation associated with coastal development; and competition with fisheries for prey species. These factors could affect reproductive success in individual whales, alter survival, and impact habitat (NMFS 1991).

CONSERVATION ACCOMPLISHMENTS

SCDNR and SAFMC (South Atlantic Fishery Management Council) personnel serve as members of the Atlantic Large Whale Take Reduction Team (ALWTRT). The ALWTRT works with National Oceanic and Atmospheric Administration (NOAA) Fisheries to develop and amend the Atlantic Large Whale Take Reduction Plan. The goal of the plan is to reduce the incidental take of finback, humpback and right whales in commercial fishing operations so that they can reach or maintain their optimum sustainable population size.

To reduce the incidence of ship strikes, especially in the area of shipping lanes, NOAA Fisheries, in collaboration with other Federal agencies, state agencies including SCDNR, environmental groups, citizen groups and the shipping industry have been working to develop ship strike reduction measures along the US Atlantic coast. Currently, the focus of this effort is on the northern right whale given its highly endangered status; however, such measures are also expected to benefit the humpback.

SCDNR conducted a marine mammals stranding program from 1991 to 2005 to obtain data on marine mammals that strand along the South Carolina coast. NOAA National Ocean Service in Charleston managed the stranding network from 2006-2007. From 2008-2018, Coastal Carolina University managed the volunteer SC Marine Mammal Stranding Network in collaboration with NOAA National Ocean Service in Charleston, SC. Since 2018, the non-profit Lowcountry Marine Mammal Network has assumed stranding response activities. SCDNR continues to provide logistical support to the stranding program. Sightings of humpback whales are fairly common in SC waters. Since 1993 there have been seven humpback whale strandings in SC: one in 1993; one in Myrtle Beach in 2001; three in 2006 on Myrtle Beach, Cape Island, and off of Hilton Head Island; one off of Myrtle Beach in 2009; and one on North Island in 2016.

A take reduction plan has been developed for Atlantic large whales, including the humpback whale, to reduce the incidental take of animals in commercial fishing operations to below the Potential Biological Removal (PBR) level. PBR is an estimate of the maximum number of animals, not including natural mortalities, which may be removed from a marine mammal stock while allowing that stock to reach or maintain its Optimum Sustainable Population (OSP). The minimum annual rate of human-caused mortality and serious injury to the Gulf of Maine stock from 2013-2017 averaged 12.5 whales (Hayes et al. 2020). Therefore, despite efforts of the plan to reduce large whale entanglements and other activities to reduce ship strikes, annual mortalities are still exceeding PBR for this stock (22 whales) (Hayes et al. 2020). SCDNR personnel will continue to serve on the ALWTRT in order to help develop and implement programs and activities designed to reduce humpback whale non-natural mortalities to insignificant levels approaching the Zero Mortality Rate Goal (ZMRG). The ZMRG (currently defined as 10% of PBR) for humpback whales is 0.37 animals.

Numerous individuals from scientific, management and conservation communities have been working for some time to improve the status of the humpback whale. One of the outcomes of these efforts has been development of the humpback whale recovery plan. Another was a major research initiative known as the Years of the North Atlantic Humpback (YONAH) (Smith et al. 1999) conducted from 1992 through 1993. This project was a large-scale intensive study of humpback whales throughout most of their entire North Atlantic range, from the West Indies to the Arctic. It addressed large-scale issues, such as size and structure of the population, vital population rates, migratory movement, and structure of the mating system. Information resulting from this study will serve a baseline against which to evaluate, among other things, whether the population is increasing or decreasing over time.

CONSERVATION RECOMMENDATIONS

- Identify essential/critical humpback whale habitat in US waters.
- Identify and minimize possible adverse impacts of human activities and pollution on important habitat by commenting on such things as proposed offshore drilling activities and other energy development activities which could impact important humpback habitat such as offshore wind farms or proposed changes to ocean dumping laws.
- Reduce mortality and injury from entanglement in fishing gear and ship strikes by working with commercial fishermen and the maritime industry to modify fishing gear and harbor approach routes, vessel operational procedures and speeds, and by improving early warning systems to notify vessel traffic of whales in the area.
- Within South Carolina's waters, identify and implement seasonal and/or geographic regulations for fishing gear that may kill or injure humpback whales. Collaborate with other jurisdictions to implement similar fishing gear recommendations.
- Evaluate cumulative impacts of vessel collisions on humpback whale populations.
- Continue photo-identification studies of humpback whales.
- Continue biological studies on stranded humpback whales.
- Develop a standardized protocol for sampling tissues of humpback whales using strandings and biopsies.
- Identify and evaluate feeding competition between humpback whales and fish species and the impacts of prey abundance on whale populations.
- Employ radio tags, underwater listening stations and genetic techniques to define migration routes and transit times for humpback whales.
- Continue assessment of mortality levels and population structure of the wintering aggregation of humpback whales in the mid-Atlantic/southeast region.
- Develop a protocol for monitoring physical and chemical factors that could decrease habitat suitability for humpback whales.
- Assist in defining measurable criteria for monitoring the success of implemented management measures within the ALWTRP.
- Educate fishermen on the importance of reporting entangled whales to improve such counts.
- Improve coordination with federal, state and non-governmental agencies/groups involved in education, outreach and cooperative efforts by supporting regional meetings and workshops to facilitate the exchange of information on whale strandings and ship strikes and to develop and implement procedures to reduce fishing gear entanglements and ship

strikes. Examples would include such things as educational brochures for fishermen and maritime interests informing them about regulatory changes in regards to fishing gear modifications or vessel operating procedures in critical whale habitat areas.
- Develop educational materials in support of humpback whale recovery plan objectives.
- Collaborate with other research, monitoring, and outreach groups to combine efforts to protect the humpback whale.

MEASURES OF SUCCESS

SCDNR personnel will continue to serve on the ALWTRT in order to help develop and implement programs and activities designed to reduce humpback whale non-natural mortalities to insignificant levels approaching the Zero Mortality Rate Goal (ZMRG). The ZMRG (currently defined as 10 percent of PBR) for humpback whales is 0.37 animals. Success of any individual program will be measured according to its apparent contribution toward this goal. Additionally, information resulting from the YONAH study will serve a baseline against which to evaluate whether the population is increasing or decreasing over time.

North Atlantic Right Whale

Eubalaena glacialis

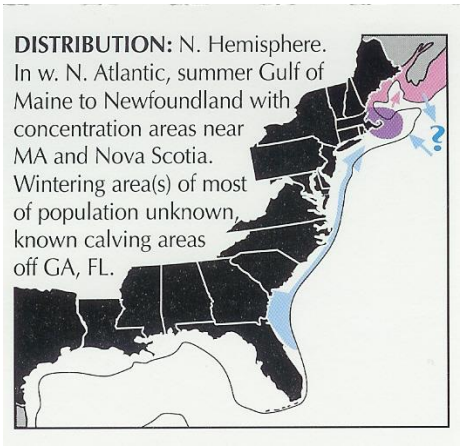
Contributors (2005): David Cupka (SCDNR) and Margaret Murphy (SCDNR)
Reviewed and Edited (2024): Wayne McFee (NOAA)

DESCRIPTION

Illustration from Wynne & Schwartz 1999

Taxonomy and Basic Description

The North Atlantic right whale was first described by Müller (1776). Not built for speed, the northern right whale has a rotund body with a large head (one-third of its total body length) and a narrow, arching rostrum. Its baleen can reach up to 3 m (8 ft.) with the fringe along the inside edge fine enough to allow right whales to filter very small food items from the water. Right whales have a broad, smooth back absent a dorsal fin. Callus-like patches of skin are found on the rostrum, lower lip, and around the eyes. These patches are called callosities and offer a secure holding place for cyamids, (whale lice) which give the callosities an orange or whitish-yellow color. Right whales also have broad, paddle-like flippers and large flukes with smooth concave margins. These whales are predominately black in color, are often mottled, and have a variable amount of white on the belly. Their spout is V-shaped. Adults reach 13 to 18 m (43 to 59 ft.) in length and a weight of 55 metric tons (60 tons) (Wynne & Schwartz 1999).



Status

The North Atlantic right whale is federally listed as an endangered species. It is among the rarest of all large whale species and, indeed, of all marine mammal species. Population size is at a critical level with an estimated 338 animals remaining in western North Atlantic waters as of 2022 (Hayes et al. 2023). The North Atlantic right whale is defined as Endangered under the Endangered Species Act (ESA) due to its endangered status and because the average annual fishery-related mortality and serious injury exceeds its Potential Biological Removal (PBR) level, which is 0.7 individuals (Hayes et al. 2023).

POPULATION SIZE AND DISTRIBUTION

The seasonal movements of the North Atlantic right whale are still poorly understood. Individuals in the western North Atlantic population range from winter calving and nursery areas off the southeastern United States to summer feeding grounds off New England and north to the Bay of Fundy and Scotian Shelf. These northern waters are also important mating and nursery habitats. Analyses based on both genetics and sighting histories of photographically identified individuals suggest that not all reproductively active females return to calving and nursery

grounds each year (Waring et al. 2004). In addition, other than calving females and a few juveniles that winter off the coasts of Georgia and Florida, the wintering location of the remaining individuals in the population is unknown. Therefore, it appears that one or more additional wintering and summering grounds may exist in unsurveyed locations. However, it is possible that the "missing" animals simply disperse over a wide area at these times (Waring et al. 2004).

Map from Wynne & Schwartz, 1999

The right whale was routinely harvested in U.S. waters from 1650 through 1924, with a peak in the early 1700s (Wynne & Schwartz 1999). An estimate of pre-exploitation population size is not available. Population trajectories, based on historical data and estimated present population size, indicate that there may have been 1,000 right whales in the population during the mid 1600s (Waring et al. 2004). During this time period, the population size has been greatly reduced to the point where today there are an estimated 361 animals remaining. It is currently unclear whether the population is stationary, undergoing modest growth, or in decline. Recent examination of the minimum number alive population index suggests a decline in population size with a decline of 23.5% estimated from 2011-2020 (Hayes et al. 2023). The size of this stock is considered to be extremely low relative to its Optimum Sustainable Population (OSP) level in the U.S. Atlantic Exclusive Economic Zone (EEZ).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

There are five well-known habitats used annually by western North Atlantic right whales: 1) coastal Florida and Georgia, 2) Great South Channel east of Cape Cod, 3) Cape Cod and Massachusetts Bays, 4) the Bay of Fundy, and 5) Browns and Baccaro Banks south of Nova Scotia (NMFS 2005). Movements within and between these habitats are believed to be more extensive than originally considered (Waring et al. 2004).

Important feeding areas occur in the Bay of Fundy, Cape Cod Bay, Great South Channel and the Scotian Shelf. Right whales are frequently found in coastal and shelf waters and, for much of the year, their distribution is strongly correlated to the distribution of their prey, calanoid copepods (NMFS 2005). Individuals are generally found in Cape Cod Bay and adjacent waters from January through early May. In late spring, mothers with their newborn calves appear. In summer, right whales make their way northward to feeding grounds off Maine, New Brunswick, and Nova Scotia. As mentioned earlier, these northern waters are also important mating and nursery habitats. In October, a portion of the population—mostly pregnant females—migrates southward to waters off southern Georgia and northern Florida to calve. At present, the southeastern United States is the only known calving ground for the western North Atlantic right whale.

Depending on the time of the year, right whales will spend much of their time near bays and peninsulas and in shallow, coastal waters. These areas provide shelter, food abundance, and security for females rearing young or avoiding the mating efforts of males. Four important habitat areas, used as both feeding and nursery grounds for northern right whales, are the

Browns-Baccaro Bank, Bay of Fundy, Great South Channel and the Cape Cod Bay. Each of these areas is distinguished by high densities of copepod populations. The first three have deep basins (150 m) flanked by relatively shallow water. Copepods are concentrated here because of convergences and upwellings driven by tidal currents. This also occurs in the Cape Cod Bay even though a deep basin isn't present (Cummings 1985; Katona 1999). A fifth important habitat area is found off southern Georgia and northern Florida in nearshore waters; this area serves as a nursery ground and is characterized by large shallow embayments that provide safe areas for females to calve in the winter.

Right whales are known to occur in waters off South Carolina during the winter but the duration of their residency and the extent to which they utilize this area of habitat is currently unknown. There have been three strandings reported: one off Murrels Inlet in 2001, one off Charleston in 2011, and one on Cape Island in March of 2011; the latter two died (Wayne McFee, NOAA, pers. comm.).

Four areas have been designated under the Endangered Species Act as critical habitat for this species (81 FR 4837, 26 February 2016). Three include feeding and nursery areas off the northeastern United States in the Gulf of Maine, Cape Cod/Massachusetts Bay and the Great South Channel; the fourth is the winter calving and nursery area in waters off the southeastern United States south of Cape Fear, North Carolina.

CHALLENGES

The two most common anthropogenic causes of right whale mortalities in the western North Atlantic are ship strikes and entanglement in fishing gear. While entanglements were more common during the period 2016-2020 (n=30), less incidents resulted in documented mortality (36.7%) than did ship strikes (91.7%; 11/12) (Hayes et al. 2023). In the instances where mortality from entanglement does not initially occur, such events probably weaken the entangled individuals making them more susceptible to other direct causes of mortality (Kenney and Kraus 1993). Entanglement-related stress may also decrease reproductive success or reduce the life span of an individual and may adversely affect the growth of the population. Fishing gear commonly implicated in right whale entanglements are gillnets, lobster pots, seine nets and fish weirs (NMFS 1991). Based on scarification, Moore et al. (2021) found that between 1980-2017, 86.1% individual whales identified had evidence of entanglement, some multiple times, suggesting that whales were able to shed gear over time in a number of cases.

The relatively low incidence of photographically identified whales showing scars/wounds attributed to ship propellers when compared to the high rate of such wounds on stranded carcasses indicates that a high proportion of ship/whale interactions are fatal to the whale (Kraus 1990). Ship speed has been argued as an important factor regarding the frequency of ship strike occurrence in large whale species including the right whale (Laist et al. 2001).

Other potential challenges include habitat degradation, noise, contaminants and climate and ecosystem change (NMFS 2005). A continued impact to the coastal habitat of the right whale in the North Atlantic is the undersea exploration and extraction of mineral deposits, as well as

dredging of major shipping channels. Offshore wind turbines could also be a threat as they influence primary production and copepod distribution, as well as increase noise (Hayes et al. 2023). Right whales also frequent coastal waters where dredging and its associated disposal operations occur on a regular basis, such as along the southeastern U.S. It is unknown to what extent mineral extraction and dredging activities may impact right whales.

CONSERVATION ACCOMPLISHMENTS

SCDNR and South Atlantic Fishery Management Council (SAFMC) personnel serve as members of the Atlantic Large Whale Take Reduction Team (ALWTRT). National Oceanic and Atmospheric Administration (NOAA) Fisheries established the ALWTRT, comprised of stakeholder groups, to determine ways to reduce serious injury and mortality of northern right, fin and humpback stocks that interact with Category I or II fisheries. Category I Fisheries are those that have a serious injury/mortality rate of 50 percent or more of a marine mammal stock's PBR. Category II Fisheries are those that are expected to have a serious injury/mortality rate of more than 1 percent but less than 50 percent of a marine mammal stock's PBR. The final plan was implemented in 1999; however, despite the measures put forth in the plan, annual mortalities and serious injury are still exceeding PBR for right whales (0.7 whales). Consequently, the ALWTRT is currently working with NOAA Fisheries to amend the Atlantic Large Whale Take Reduction Plan in order to meet the goals of the MMPA which mandate reducing incidental mortality or serious injury to below each stock's PBR level within six months of the plan's implementation. The long-term goal is to reduce serious injuries and mortality to an insignificant level approaching a Zero Mortality Rate Goal (ZMRG) in order that they can reach or maintain their optimum sustainable population size. To date, despite efforts of the plan to reduce large whale entanglements and other activities to reduce ship strikes, annual mortalities attributed to fishery interactions and ship strikes are still exceeding PBR for right whales (PBR = 0.7 whales, from 2016 – 2020 the minimum rate of annual human-caused mortality and serious injury averaged 8.1 per year). SCDNR personnel will continue to serve on the ALWTRT in order to help develop and implement programs and activities designed to reduce North Atlantic right whale non-natural mortalities to insignificant levels approaching the ZMRG, which is 0.07 right whales.

South Carolina also has representatives on the Southeastern Right Whale Recovery Plan Implementation Team (SEIT). Since its inception in August 1993, the SEIT has met regularly and has been active in a number of areas. Among other things, the SEIT has coordinated a number of efforts to educate mariners about the threat of ship strikes in right whale habitat. Particularly, the SEIT has been instrumental in developing a system of aircraft surveys and communication systems that alert mariners to the presence of right whales in the southeastern US on a real time basis. In addition, the team has addressed and/or provided recommendations to NOAA Fisheries regarding right whale research in the southeastern US, additional measures to reduce the possibility of ship strikes, development of safe operating procedures for large vessels transiting right whale habitat, minimum vessel approach distances, and restrictions on hazardous fishing gear in right whale calving areas (NMFS 2005).

SCDNR conducted a marine mammals stranding program from 1991 to 2005 to obtain data on marine mammals that strand along the South Carolina coast. NOAA National Ocean Service in

Charleston managed the stranding network from 2006-2007. Coastal Carolina University managed the volunteer SC marine mammal stranding network in collaboration with NOAA National Ocean Service in Charleston, SC from 2008-2018. The non-profit Lowcountry Marine Mammal Network has managed stranding response since 2018. SCDNR continues to provide logistical support to the stranding program.

CONSERVATION RECOMMENDATIONS

- Analyze available data and collect additional whale sighting data to assess expanding or modifying the critical habitat boundaries.
- Assess the utility and feasibility of voluntary and mandatory ship routing measures and vessel speed restrictions in right whale habitat.
- Develop and implement programs and regulations to incorporate gear modifications and fishing practices that reduce entanglements of right whales in South Carolina waters.
- Conduct studies of gear modifications that result in reduced right whale entanglements.
- Assess right whale population size, survival rate, and trends on a regular basis. Determine right whale foraging ecology.
- Continue and expand annual winter surveys for right whales off the southeastern US coast.
- Compile or collect relevant physical, chemical, biological, oceanographic, fishery, and other data to characterize features of important right whale habitats and potential sources of anthropogenic destruction and degradation of critical right whale habitats.
- Use acoustic detection technology to monitor right whale occurrence and distribution.
- Continue to maintain a database of right whale sightings and photo-identifications.
- Conduct studies to determine the direct and indirect effects of coastal development, mineral extraction, and dredging activities on the distribution, behavior, and productivity of right whales.
- Continue and improve seasonal aircraft surveillance of right whale habitats and other elements of the “Sighting Advisory System.”
- Continue and improve the mandatory ship reporting system for right-whale sightings.
- Continue and improve the stranding network for right whales.
- Continue and expand efforts to educate mariners and the shipping industry, and fishermen and the fishing industry, about right whale vulnerability to ship strikes and fishing gear entanglements.
- Provide right whale sighting locations to mariners through broadcasts and other appropriate media.
- Encourage reports of right whale entanglements to the disentanglement network.

MEASURES OF SUCCESS

SCDNR personnel will continue to serve on the ALWTRT and the SEIT in order to help develop and implement programs and activities designed to reduce North Atlantic right whale non-natural mortalities to insignificant levels approaching the ZMRG.

Short-finned Pilot Whale

Globicephala macrorhynchus

Contributor (2024): Wayne McFee (NOAA)

DESCRIPTION

Taxonomy and Basic Description

The short-finned pilot whale was first described by Gray in 1846. It is one of two species in the *Globicephala* genus, the other being *G. melas* (long-finned pilot whale). Both are in the family Delphinidae.

At sea, these two species are virtually indistinguishable and overlap geographically along the continental shelf break from Delaware and southern Georges Bank (Rone and Pace 2012), with most sightings of short-finned pilot whales occurring south of Cape Hatteras, NC through the greater Caribbean and into the northern Gulf of Mexico (Maze-Foley and Mullin 2006). Both species are black dorsally with a bulbous head and broad falcate dorsal fin. As the name suggest, short-finned pilot whales have shorter fins that measure about 1/6th of the body length, than long-finned pilot whales, and short-finned pilot whales have fewer teeth (7-9 in reach row) and a shorter and broader rostrum (Olson 2008).

Short-finned pilot whales can attain lengths up to 7.2 m (24 ft.) and weigh upwards of 4,000 kg (8,800 lbs.) (Wursig et al. 2017). Newborns are between 1.4 m to 1.9 m (4’7”ft to 6’3”ft) in length weighing 60 kg (130 lb). Females mature at 7-12 years of age and produce a calf every five to eight years. They can live between 40-60 years.

Short-finned pilot whales are highly social living in large groups of 10-30 animals though sightings and mass strandings of groups of several hundred have been noted. They are deep divers and feed primarily on squid, but will also feed on fish species and octopus (Mintzer at al. 2008).

Status

The status for short-finned pilot whales is neither listed as threatened or endangered under the Endangered Species Act and is not a Strategic Stock under the MMPA (Hayes et al. 2022). Potential Biological Removal (PBR) is 236 animals.

POPULATION SIZE AND DISTRIBUTION

The best population estimate of short-finned pilot whales in the western North Atlantic 28,924 (Hayes et al. 2022). Short-finned pilot whales appear to occur worldwide in tropical and temperate latitudes. They tend to occur over the continental shelf break primarily south of Cape Hatteras, NC through the greater Caribbean and into the norther Gulf of Mexico.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Based on ship-board surveys and genetic analysis through biopsy sampling short-finned pilot whales live in deep water on the continental shelf break and deeper offshore waters of the Gulf Stream east of Cape Hatteras, feeding on cephalopods (squid) and, less frequently, crustaceans and fish (Thorne et al. 2017).

CHALLENGES

The greatest challenge to short-finned pilot whales appears to be fisheries interactions, in particular the pelagic longline fisheries. The estimated mean annual fishery-related mortality and serious injury between 2015-2019 due to the pelagic longline fishery was 136 animals (Hayes et al. 2022). Other threats include marine debris ingestion (plastics, bags, etc.), hook and line fisheries, contaminants (PCBs, DDT, DDE, toxic metals), and increased anthropogenic sound.

From 2013-2023 there have been 9 short-finned pilot whales stranded in South Carolina, five of which stranded alive during a mass stranding event in 2019.

CONSERVATION ACCOMPLISHMENTS

A Prescott Grant through the NMFS to Coastal Carolina University (2008-2020) and the Lowcountry Marine Mammal Network (2021-2024) has funded responses to marine mammal strandings, data collection, training of volunteers, and timely collection of tissues for research since 2008. These funds have allowed the recovery and collection of tissues by the National Ocean Services (NOS), Hollings Marine laboratory (HML) for research on short-finned pilot whales and the supply of tissues to the National Institute of Standards and Technology National Marine Mammal Tissue Bank (Charleston, SC).

CONSERVATION RECOMMENDATIONS

- Continue monitoring short-finned pilot whale strandings to:
    - develop predictive models of stranding rates, especially seasonally, to better prepare network volunteers for increased strandings of these species;
    - increase information on mortality rates and cause of mortalities to obtain a better understanding on the stressors these species face; and
    - develop a better understanding of the distribution of this species.
- Develop outreach material to educate the public about the harm plastics and other marine debris can cause to marine life.
- Engage SC pelagic longline fishers on the potential interaction with long-finned pilot whales
- Conduct collaborative research with partners to determine the cause(s) mortality in short-finned pilot whales. Basic life history parameters such as age analysis using teeth and reproductive status are also essential in determining longevity, population status, and fecundity.

MEASURES OF SUCCESS

As more data are accumulated and a better understanding of the status and life history of short-finned pilot whale species emerges, further management recommendations will be developed. Reduction of interactions with the pelagic longline fisheries and marine debris could have a substantial impact on the survival of this species.

Sperm Whales Guild

Dwarf sperm whale (*Kogia sima*)
Pygmy sperm whale (*Kogia breviceps*)

Illustration by Pieter A. Folkens

Contributor (2005): Wayne McFee (NOAA)
Reviewed and Edited (2012; 2024): Wayne McFee (NOAA)

DESCRIPTION

Taxonomy and Basic Description

The pygmy sperm whale was first described by de Blainville in 1838. The dwarf sperm whale was first described by Owen in 1866. Both were considered a single species until 1966. These are the only two species in the family Kogiidae. The species name for the dwarf sperm whale was changed in 1998 from '*simus'* to '*sima*.' Neither the pygmy nor dwarf sperm whale are kin to the true sperm whale (*Physeter macrocephalus*).

At sea, these two species are virtually indistinguishable. Both species are black dorsally with a white underside. They possess a shark-like head with a narrow under-slung lower jaw and a light colored "false gill" that runs between the eye and the flipper. Small flippers are positioned far forward on the body.

Pygmy sperm whales generally have between 12 and 16 (occasionally 10 to 11) pairs of needle-like teeth in the lower jaw. They can attain lengths up to 3.5 m (11.5 ft.) and weigh upwards of 410 kg (904 lbs.). A diagnostic character of this species is the low, falcate dorsal fin (less than 5% of the body length) positioned behind the midpoint on the back.

Dwarf sperm whales generally have 8 to 11 (rarely up to 13) pairs of teeth in the lower jaw and can have up to 3 pairs of teeth in the upper jaw. They can attain lengths up to 2.7 m (8.9 ft.) and weigh upwards of 210 kg (463 lbs.). A diagnostic character of this species is the high, dolphin-like dorsal fin (greater than 5% of the body length) positioned in the middle of the back. This species usually has a pair of short grooves on the throat.

Status

The status for both species is unknown; and neither is listed as threatened or endangered under the Endangered Species Act (Hayes et al. 2020). The western North Atlantic stock of *Kogia* sp. is not strategic under the MMPA. Potential Biological Removal (PBR) is 46 animals. An unusual mortality event (UME) of pygmy sperm whales in the southeastern United States was declared in 2003 by NMFS, prompting the need for more research on mortality of both species.

POPULATION SIZE AND DISTRIBUTION

Because both species are difficult to distinguish apart from ship board surveys, the population in the western North Atlantic of 7,750 is a combined estimate of both *Kogia* species (Hayes et al. 2020). Both species appear to occur worldwide in tropical and temperate latitudes. They tend to occur over the continental slope with the pygmy sperm whale possibly venturing over the limits of the continental shelf more often than the dwarf sperm whale. Stable isotope research suggests that the species may be separated by vertical niche partitioning, occurring in similar locations (Barros et al. 1998).

Because of their shy behavior and avoidance of research vessels at sea, population estimates in the Western North Atlantic Ocean are unreliable. Nearly all the information obtained on either of these species is from stranded animals.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Based largely on stomach content analyses from stranded specimens, pygmy and dwarf sperm whales live in deep water on the continental slope and occasionally the continental shelf, feeding on cephalopods (squid) and, less frequently, crustaceans and fish. The species of squid found in stomachs suggests that these animals require deep water up to 1,500 m (4,921 ft.). Benthic fish and crabs found in stomachs also suggest that these species forage on the ocean bottom (Reeves et al. 2002).

CHALLENGES

The greatest challenge to both species appears to be marine debris (plastics, bags, balloons). Numerous stranded specimens have been documented with plastic bags and other marine debris in the stomachs. The reasons for this remain speculative but could be the result of mistaking the debris for a potential food source. NMFS observer programs have not documented any mortality in fisheries operations except for one take in the pelagic longline fishery in 2000 (Waring et al. 2002; Hayes et al. 2020).

Cardiomyopathy (enlargement of the heart muscle) appears to be very common in pygmy sperm whales. The etiology of this disease to the heart is unknown, but is observed in nearly 50% of the stranded animals (Bossart et al. 2007). Research on this disease has occurred at a few institutions in the southeastern US (Bryan et al. 2012; Viricel and Rosel 2017). From 2013-2023 there have been 33 *K. breviceps*, 8 *K. sima*, and 3 *Kogia* spp. stranded in South Carolina.

CONSERVATION ACCOMPLISHMENTS

A Prescott Grant through the NMFS to Coastal Carolina University (2008-2020) and the Lowcountry Marine Mammal Network (2021-2024) has funded responses to marine mammal strandings, data collection, training of volunteers, and timely collection of tissues for research since 2008. These funds have allowed the recovery and collection of tissues by the National Ocean Services (NOS), Hollings Marine laboratory (HML) for research on pygmy and dwarf sperm whales.

CONSERVATION RECOMMENDATIONS

- Continue monitoring sperm whale strandings to:
  - develop predictive models of stranding rates, especially seasonally, to better prepare network volunteers for increased strandings of these species;
  - increase information on mortality rates and cause of mortalities to obtain a better understanding on the stressors these species face; and
  - develop a better understanding of the distribution of these species.
- Develop outreach material to educate the public about the harm plastics and other marine debris can cause to marine life.
- Conduct collaborative research with partners to determine the cause(s) of cardiomyopathy in sperm whales. Basic life history parameters such as age analysis using teeth and reproductive status are also essential in determining longevity, population status, and fecundity.

MEASURES OF SUCCESS

As more data are accumulated and a better understanding of the status and life history of the two sperm whale species emerges, further management recommendations will be developed. Reduction of marine debris could have a substantial impact on the survival of these species.

Tamanend's bottlenose dolphin (coastal)

Tursiops erebennus

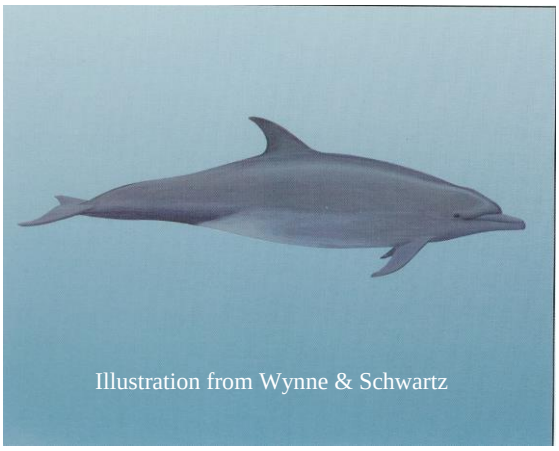

Illustration from Wynne & Schwartz

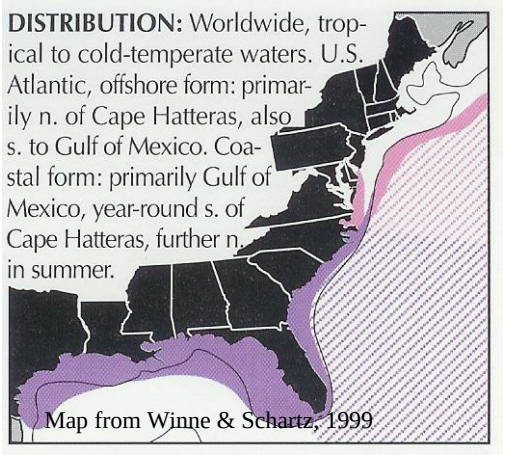
Contributors (2024): Wayne McFee (NOAA) and Todd Speakman (NMMF)

DESCRIPTION

Taxonomy and Basic Description



The bottlenose dolphin, *Tursiops truncatus*, was first described by Montagu in 1821. The body and head are robust with a short, thick, well-defined beak. Based on distribution, genetics, morphology, parasites and prey items, two distinct species are now recognized; the "coastal form" (*Tursiops erebennus*) is shorter and slimmer than the larger "offshore form", *Tursiops truncatus* (Costa et al. 2022). The flippers are pointed with deeply notched flukes. The teeth are small and conical and number between 40 to 52 in the upper jaw and 36 to 48 in the lower jaw. The dorsal fin, located mid-back, is tall and falcate with a broad base. Adult size varies considerably, ranging from 1.9 to 3.6 m (6 to 12 ft.) (Wynne & Schwartz 1999). The bottlenose dolphin has been reported to weigh up to 650 kg (1,432 lb) (Minasian et al. 1984).

Status

The bottlenose dolphin is not listed as threatened or endangered under the Endangered Species Act (ESA). In 1993, the National Oceanic and Atmospheric Administration (NOAA) Fisheries Service (National Marine Fisheries Service or NMFS), treating the coastal population as a single migratory stock, designated the stock as "strategic" under the Marine Mammal Protection Act (MMPA). The action was due to a massive die-off of coastal bottlenose dolphins between 1987 and 1988 (Waring et al. 2002). From 1995 through 2001, the NMFS recognized only a single migratory stock of coastal bottlenose dolphins in the western North Atlantic; therefore, the entire stock was listed as depleted. Current stock assessments have identified 5 coastal stocks of bottlenose dolphins based on genetic studies (Rosel et al. 2009), photo-id (Zolman 2002), strandings (McLellan et al. 2003), and satellite telemetry data (Southeast Fisheries Science Center, NMFS, unpublished data): the Northern Migratory and Southern Migratory stocks, South Carolina/Georgia Coastal stock, Northern Florida Coastal stock, and the Central Florida Coastal stock (Hayes et al. 2022). A second UME from 2013-15 occurred along the Atlantic coast from New York to Florida resulting in over 1,600 bottlenose dolphins stranded (Morris et al. 2015; Hayes et al. 2022). Further, there are at least 10 recognized Estuarine Stocks on the east coast of the US: a Northern NC Estuarine System stock, a Southern NC Estuarine System stock, a Northern South Carolina Estuarine System stock, a Charleston Estuarine System stock, a Northern Georgia/Southern SC Estuarine System stock, a Central Georgia Estuarine System stock, a Southern Georgia Estuarine System stock, a Jacksonville Estuarine System stock, an Indian River Lagoon Estuarine System stock, and a Biscayne Bay Estuarine System stock (Hayes et al. 2022). Because one or more of the stocks may be depleted, all stocks retain the depleted designation.

The western North Atlantic offshore bottlenose dolphin (offshore ecotype; *T. truncatus*) is also not listed as threatened or endangered under the ESA. Potential Biological Removal level or PBR is an estimate of the maximum number of animals, not including natural mortalities, which may be removed from a marine mammal stock while allowing that stock to reach or maintain its Optimum Sustainable Population (OSP). PBR's are established under the MMPA. The average annual fishery-related mortality and serious injury for western North Atlantic offshore bottlenose dolphin from 1996 to 2000 is unknown and the PBR is 519 animals; therefore, the status of this stock is unknown (Hayes et al. 2022).

POPULATION SIZE AND DISTRIBUTION

Two bottlenose dolphin ecotypes inhabit waters in the western North Atlantic Ocean: a shallow water or nearshore/coastal ecotype and a deep water or offshore ecotype (Curry and Smith 1997).

The coastal ecotype is continuously distributed along the Atlantic coast south of Long Island, around peninsula Florida, and along the Gulf of Mexico coast. However, based on genetic studies, Curry (1997) concluded that the nearshore animals in the northern Gulf of Mexico and the western North Atlantic are separate stocks. Within the western North Atlantic, the stock structure of coastal bottlenose dolphins is complex. Efforts to distinguish stocks are complicated by the fact that animals from different stocks cannot be separated on the basis of appearance and by the fact that different stocks sometimes have geographic ranges that overlap temporally and spatially (MMC 2004). Preliminary results from studies involving genetics, photo-identification, telemetry and stable isotopes suggest the existence of at least 5 coastal ecotype stocks in the western North Atlantic and ten estuarine ecotype stocks (Harris et al. 2022). Estimates of abundance for each stock of western North Atlantic coastal bottlenose dolphins are as follows: Northern migratory (6,639); Southern Migratory (3,751); SC/GA (6,027); Northern Florida (877); and Central Florida (1,218). Estimates of abundance for the Estuarine stocks are: Northern NC Estuarine System stock (823); Southern NC Estuarine System stock (unknown); Northern SC Estuarine System stock (453), Indian River Lagoon (1,032). Estimates are unknown (because estimates are greater than 8 years old) for the Charleston, Northern GA/Southern SC, Central Georgia, Southern Georgia, Jacksonville, and Biscayne Bay Estuarine System Stocks.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Bottlenose dolphins are both a coastal and an oceanic species, with the coastal ecotype preferring waters of less than 30 m (98 ft.) in depth. The habitats they occupy are diverse, ranging from rocky reefs to calm lagoons and open waters. The coastal ecotype is adapted for warm shallow waters. Its smaller body and larger flippers suggest increased maneuverability and heat dissipation. These dolphins occur along the outer coastline and in bays, sounds, inlets, estuaries and other inland waters (Hersh and Duffield 1990).

CHALLENGES

A variety of factors, both natural and human-related, can affect bottlenose dolphins. Natural factors include predation by large sharks, disease, parasites, exposure to naturally occurring biotoxins, changes in prey availability, and reduction or loss of habitat due to environmental variation. Human-related causes of mortality and injury to this species include loss of habitat due to coastal development, exposure to pollutants, vessel strikes, entanglement in debris, as well as noise and pollution related to oil and gas development. Bottlenose dolphins have also increasingly become the target of dolphin watching and wild dolphin interaction programs. There is growing concern that these activities may result in altered behavioral patterns, especially where people enter the water with dolphins and where they are fed. In the latter case, behavioral patterns are altered significantly and increased aggression may occur (Bryant 1994).

In addition, recreational and commercial fisheries directly and indirectly affect bottlenose dolphins. Coastal bottlenose dolphins are taken as bycatch in various kinds of fishing gear including gillnets, seines, longlines, shrimp trawls and crab pots (Waring et al. 2002). In South Carolina, the commercial Atlantic blue crab fishery is the most common cause of fishery-related mortality of *T. erebennus* (Krzewinski et al. 2024). Bycatch of offshore bottlenose dolphins has been observed in the pelagic drift gillnet, pelagic pair trawl, New England multispecies sink gillnet, North Atlantic bottom trawl, mid-Atlantic coastal gillnet and pelagic longline fisheries. The pelagic drift gillnets and pelagic pair trawl fisheries no longer exist. Mortalities of bottlenose dolphins due to ingestion of hooks and/or line have also been documented (Gorzelany 1998; Well et al. 1998). The gear most likely had been discarded or was consumed by the dolphin by eating a fish that had been hooked then broke away with the gear. Estimates of fishery-attributed interactions suggest that mortality exceeds the PBR of several coastal stocks considered depleted by the 1987-1988 and 2013-15 die-offs and, thus, may be impeding their recovery.

CONSERVATION ACCOMPLISHMENTS

SCDNR and South Atlantic Fishery Management Council (SAFMC) personnel serve as members of the Bottlenose Dolphin Take Reduction Team (BDTRT), which was convened in 2001. The BDTRT works with NOAA Fisheries to develop the Bottlenose Dolphin Take Reduction Plan (BDTRP) for coastal stocks. The short-term goal of the plan is to reduce, within 6 months of its implementation, the incidental mortality or serious injury of western North Atlantic coastal bottlenose dolphins incidentally taken in commercial fishing operations to levels less than the potential biological removal (PBR) level. The long-term goal of the take reduction plan is to reduce, within five years of plan implementation, incidental mortality and serious injury of coastal bottlenose dolphins incidentally taken in the course of commercial fishing operations to insignificant levels approaching a zero mortality rate goal (ZMRG). The BDTRT has developed a number of recommendations to achieve these goals and to be incorporated into the BDTRP. The BDTRP was amended in December of 2008 (73 FR 77531) with an effective date of January 20, 2009.

The BDTRT has made a number of recommendations to be incorporated into the BDTRP for coastal stocks including regulatory suggestions, based on management units, which apply to specific fisheries. Generally, these recommendations seek to reduce soak times, the amount of

fishing gear in the water at any given time, or to modify practices in order to limit interactions with and the take of bottlenose dolphins. The BDTRT also adopted non-regulatory recommendations for all management units including education and outreach, as well as improved research, monitoring, collection of strandings data, and observer coverage. The finalized specific recommendations were published on April 26, 2006 (FR 50CFR Parts 223 and 229) and SCDNR will continue to explore avenues to implement these recommendations, working together with members of the BDTRT as funding opportunities become available.

SCDNR conducted a marine mammal stranding program from 1991 to 2005 in order to obtain data on marine mammals that strand along the South Carolina coast. Data from the program are used to further our knowledge regarding these animals and the extent to which anthropogenic factors are responsible for or contribute to their stranding. From 2006-2008, the NOAA National Centers for Coastal Ocean Science in Charleston, SC assumed responsibility of the network, Coastal Carolina University administered the program from 2009-2021, and the Lowcountry Marine Mammal Network has assumed responsibility of the Network since 2021, having received grant awards from the Prescott Grant.

CONSERVATION RECOMMENDATIONS

- Improve understanding of stock structure and population trends in order to assess the greatest threats to bottlenose dolphins.
- Determine the significance of periodic die-offs, especially to relatively small, isolated populations of bottlenose dolphins.
- Assess the impact of contaminants on marine mammals, particularly the repercussions of high contaminant loads in individual bottlenose dolphins as well as their offspring.
- Measure the effects of interactions between humans and dolphins in the wild, including behavioral disruption, habituation, injury and death.
- Mitigate threats to bottlenose dolphins posed by entanglement in fishing gear through support of methods proposed by the BDTRT.
- Continue to explore avenues to partner in implementation of recommendations to be published by the BDTRT.

MEASURES OF SUCCESS

A take reduction plan has been developed for coastal bottlenose dolphins to reduce the incidental take of animals in commercial fishing operations to below the Potential Biological Removal (PBR) level. SCDNR personnel will continue to serve on the BDTRT in order to help develop and implement programs and activities designed to reduce bottlenose dolphin non-natural mortalities to insignificant levels approaching a zero mortality and serious injury rate (the Zero Mortality Rate Goal or ZMRG).

Contributors (2005): Jay Butfiloski and Buddy Baker [SCDNR]
Reviewed and Edited (2013): Jay Butfiloski (SCDNR)

DESCRIPTION

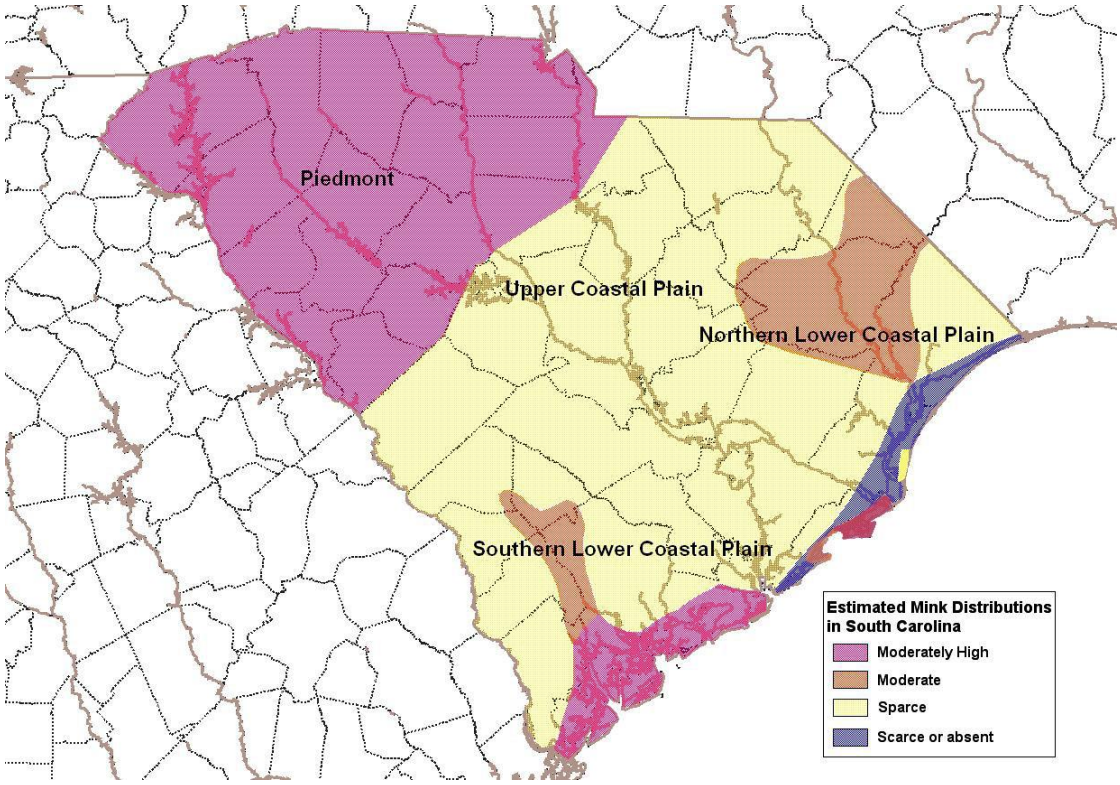
Taxonomy and basic description

The American mink, *Mustela vison* was first described by Schreber in 1777. Mink are classified in the order Carnivora, family Mustelidae, and further categorized into the subfamily Mustelinae.

The mink is characteristic of other members of the weasel family with its short legs and long cylindrical body. Body mass ranges from 0.55 - 1.25 kg (1.2 - 2.75 lbs.) with an overall length of 470 - 700 mm (18.5 - 27.5 in.). Males are approximately 10% larger than females. Pelage is typically dark brown with white markings on the throat, chest, and belly. The tip of the tail is markedly darker than the rest of the body (Jackson 1961).

Mink have two anal glands that produce a strong odor. When stressed, mink can release secretions from these glands, potentially as a defense mechanism (Brinck et al. 1978). Feces are usually deposited in prominent places as territorial markers.

Mink are polygamous, and thus courtship and mating in mink can often be aggressive. Mating usually occurs from January through March, and because of delayed implantation, the gestation period ranges from 40 - 75 days. Birth of the young occurs 30 days after implantation. Young are typically born from April to June. Weaning occurs at 8 - 9 weeks, though the young may remain with the female as a family group until fall.



Status

In South Carolina, the rank for American mink is S3, and the population is considered to be in decline statewide. The global status is listed as secure (G5) (NatureServe 2025).

POPULATION SIZE AND DISTRIBUTION

The mink's range extends throughout Canada and much of the United States except the southwest and a great deal of the northwest. Historically, mink occurred throughout South Carolina. Mink occur in varying densities; the Piedmont region and southern coastal marsh areas have had relatively abundant populations while much of the Upper and Lower Coastal Plain regions have sparse densities, with moderately higher concentrations in the Lynches/Pee Dee and Salkahatchie/Combahee River corridors. Mink are scarce or absent in the northern coastal marshes. Survey data, however,

indicates mink are essentially absent in the northern coastal marshes where population restoration by SCDNR has not taken place, and possibly declining throughout the remainder of the State (Baker 1999). Annual commercial fur harvest data indicated a 38-year average harvest of 86 animals per year by commercial trappers and hunters. However, this average does not adequately reveal the decline in harvest data. From the 1974 - 75 season to 1988 - 89, the average mink harvest was 197. Since the 1989 - 1990 fur harvest season, the average take was only 14 mink (SCDNR 2004 unpublished data).

Map by Jay Butfiloski, SCDNR; modified from Baker 1999.

A considerable amount of anecdotal information has been received from older trappers have reported declining mink numbers. Numerous experienced mink trappers have noted that the species is rare or absent from areas of former abundance, although the habitat is seemingly intact. One trapper from Lancaster County reported that he had not caught a mink in over 20 years from a trap line that once produced as many as 30 mink per year. Furbearer biologists from the Georgia Department of Natural Resources and the North Carolina Wildlife Resources Commission reported similar comments from trappers about declines in mink numbers in their states (Greg Waters, GADNR; Perry Sumner, NCWRC, pers. comm.).

In a mail survey of South Carolina sportsmen who caught mink during the 1987 - 88 trapping season, over 40% of the respondents perceived the mink population to be declining (SC Wildlife and Marine Resources Department, unpublished data).

HABITAT / NATURAL COMMUNITY REQUIREMENTS

Mink are typically associated with habitats that have some type of water component. These areas include swamps, rivers, streams, ponds, and saltwater marshes. Mink typically live in dens located in rock piles, under tree roots, bridge crossings, and stream bank holes. Mink in saltwater marsh habitat may rarely utilize dens because of tidal fluctuations. Instead, young are often birthed on tide rack rafts.

Mink are carnivorous and their diet often reflects prey availability, opportunity, and location. Statewide, fish may make up 40% of the mink's diet. However, mink will also consume small rodents, rabbits, muskrats, squirrels, crabs, crayfish, insects, snails, frogs, snakes, and waterfowl (Baker 1999).

CHALLENGES

A. Habitat Degradation

Because of the lack of historic data on habitat conditions in South Carolina, it is difficult to evaluate quantitatively how mink habitat has changed over time. While the integrity of some streams has clearly been altered, others appear reasonably pristine. There has been no attempt thus far to correlate mink densities with habitat alteration. Future studies should compare mink densities with existing habitat suitability index models.

While habitat alterations may be a contributing factor in South Carolina mink population declines, it is doubtful that habitat conditions alone are responsible. Elsewhere throughout the mink's range, the species is reported to be adaptable in its use of habitats, tolerating both human activity and habitat changes (Allen 1984). Additionally, some of the areas in South Carolina where mink have declined are in stream drainages, which appear to be intact.

B. Environmental Contaminants

Environmental pollution has long been recognized as a biological hazard to wildlife and to man. Industrial pollutants, pesticides, and heavy metals are known to exhibit biomagnification as they pass up the food chain. The mink occupies a niche at or near the top of the food chain and would therefore be especially vulnerable to these environmental contaminants. Mink population declines in other regions of North America, most notably in the Great Lakes Region, have been associated with environmental contaminants. Numerous studies have demonstrated the mink's high level of sensitivity to pollutants, particularly organic mercury compounds (Aulerich et al. 1974; Woberser et al. 1976) and polychlorinated biphenyl (PCBs) (Platonow and Karastad 1973; O'Shea et al. 1981).

In 1987 the Furbearer Project initiated studies to evaluate contaminant levels in trapper - harvested mink carcasses from South Carolina (Carmichael and Baker 1989). The University of Georgia Riverbend Research Center performed chemical analyses under

contract. Mink samples were screened for a total of 21 chlorinated hydrocarbon pesticides plus PCBs. Tests for 10 heavy metals were also conducted.

Residues of DDE, PCBs and mercury were detected in mink tissue samples from South Carolina. Residue levels were generally lower than those reported for other wild mustelid populations and did not approach levels published for mink that suffered mortality in laboratory studies. However, the effect of low levels of these contaminants on reproduction and survivability in wild mink is still questionable. Ringer (1981) stated that reproduction in mink would normally not be impaired by chlorinated hydrocarbon pesticides such as DDT at levels typically encountered in the environment. However, small doses of PCBs and mercury, singly or in combination, are of concern. Fish in most rivers and lakes throughout the country are now contaminated with PCBs (Jacknow et al. 1986), and dietary levels as low as 0.64 ppm have been shown to seriously impair reproduction (Platonow and Karstad 1973). In our studies, 43% of the mink sampled had detectible residues of PCBs with a mean level of 0.56 ppm. Likewise, mercury is widespread in the environment due to man's activities as well as natural processes, and 1 ppm mercury in the mink diet for as little as 2 months is known to be lethal (Kirk 1971). Smaller doses would likely have sublethal effects on reproduction and behavior.

Health advisories posted by the South Carolina Department of Health and Environmental Control in January of 1995 indicated that mercury contamination of fish in 18 rivers and 9 lakes in South Carolina were high enough to prompt warnings about human consumption of fish. The advisory covered all of the stream drainages of the Coastal Plain and reported mercury levels in many drainages which are above the levels known to be lethal to mink. Mercury levels for some fish species in the Black River and Pee Dee River were nearly 3 times higher than known lethal dietary levels for mink.

While the mean levels of mercury detected in mink from the Piedmont Ecoregion of South Carolina (0.53 ppm) were below levels expected to cause direct mortality, a small sample of Coastal Plain mink (n = 3) exhibited levels considered to be greater than normal background levels (mean = 6.01 ppm).

The current Environmental Protection Agency (EPA) limit for fish deemed safe to consume by humans is 2 ppm for PCBs and 1 ppm for mercury. Wild mink eating fish containing PCBs or mercury at these levels, or even less, are at risk. The situation becomes very complex when synergistic or combined effects of environmental contaminants are considered. Lab studies with mink have shown reduced survival in kits born to mink that received both PCBs and mercury simultaneously (Wren et al. 1987). Over 40% of mink sampled in South Carolina contained residues of both PCBs and mercury. If other conditions such as food shortages, extreme climatic conditions such as cold weather or drought, or parasite burdens are added, tolerance levels for these contaminants may be very low for a species like the mink (Wren et al. 1986; Wren et al. 1987).

In 1990 the Furbearer Project continued its investigations into the impact of environmental toxicants on mink by expanding the sample in the Coastal Plain (Osowski et al. 1995). This study was expanded further to include samples from Georgia and North

Carolina because of similar concerns of mink population declines by the wildlife agencies in those states. The Clemson University Institute of Wildlife and Environmental Toxicology conducted chemical analyses for the tri-state study.

Of the organochlorine pesticides tested, only dieldrin was detected at significantly higher levels in South Carolina's Coastal Plain than in the Piedmont. Liver PCB concentrations were also found to be significantly higher than the Piedmont reference group, and many samples were higher than those known to cause mink reproductive dysfunctions.

This study also revealed mercury concentrations from mink kidney tissue to be elevated in the Georgia, North Carolina, and South Carolina Coastal Plain compared to the Piedmont reference. The concentrations detected were high enough, according to Wren et al. (1986), to cause sub-lethal effects on most physiological functions, including reproduction, growth, and behavior. Of the 3 states, South Carolina had the highest mean level of detectable mercury (3.51 ppm).

CONSERVATION ACCOMPLISHMENTS

The Furbearer Project spent a number of years determining the status of mink populations in South Carolina and the causes of their decline. Our research revealed that one of the areas where mink populations had been lost entirely was the tidal marshes from Charleston Harbor north to the SC/NC line. Beginning in 1999, the Furbearer project initiated restoration efforts with South Carolina's coastal mink population. Fortunately, mink remain abundant in the marshes along our state's southern coast. The marshes in the North Edisto River, the ACE Basin, and in the vicinity of Hilton Head Island have served as mink population sources for our capture efforts. Our first restoration effort in the Cape Romain NWR in 1999 and 2000 was hugely successful, thanks in part to the hard work of then Clemson graduate student Jason Peeples and to Dr. Tim Fendley of Clemson University. Based upon the success of our first effort, we moved up the coast with our mink restoration project.

2002 Restoration

In 2002, our goal was to complete a stocking of mink at North Inlet in Georgetown County. Thanks to many of our cooperators, our trapping efficiency was so good in 2002 that we were able to complete stocking efforts in North Inlet and move on to our next target area which was Murrells Inlet. All totaled, we stocked 17 adults and 35 kits in North Inlet and 25 adults in Murrells Inlet.

Population Indexing

In 2002 we were also able to test a new mink indexing technique for measuring marsh mink populations. The work was conducted by Lisa Vandiver who was working with us on a work study contract with the College of Charleston. The Kiawah Island Natural Habitat Conservancy provided funding for the studies. We are very grateful to Barbara Winslow of Kiawah Island for getting the project off of the ground and for her willingness to get her hands dirty with marsh mud throughout the project. Lisa's research focused on the testing of a floating track board design. Overall visitation rates by mink

were 42%, revealing this technique to have great value as a population monitoring device. Our current technique of monitoring marsh mink involves spotlight flood tide surveys. The shortcoming of the flood tide surveys is that we are limited to employing this technique to several days per season. Additionally, these are the same days (during flood tides) that we need to be trapping mink. The track board technique could allow us greater latitude in population monitoring. No flood tide surveys are currently being done.

Population Health Check
We were fortunate to have the cooperation of the Southeastern Cooperative Wildlife Disease Study in performing a population health check on mink from the ACE Basin. A final report is forthcoming, but preliminary reports reveal some surprising virus antibodies.

Toxicology
Because earlier research suggested that the decline in mink populations from South Carolina's northern coastal region was related to environmental contaminants, we wanted to determine if similar problems exist in mink populations of the southern coastal areas. SCDNR partnered with the Clemson University Department of Environmental Toxicology to answer this question. While this research did reveal concentrations of mercury, organochlorine pesticides, PCBs, dioxins, and furans in tissues of mink at levels that may have some adverse effect on individual animals, the overall levels were not considered to be high enough to have adverse effects on the mink population.

Age Structure
Age structure work on ACE Basin mink suggests good survival rates and good recruitment rates within this population.

Food Habits
The Furbearer Project was able to enlist the assistance of Marine Division scientist David Knott to conduct food habits studies of mink in the ACE Basin. We utilized David's expertise to identify marine organisms in mink scats and stomach contents collected throughout other studies. This data allows us to evaluate prey abundance in prospective restoration sites to test for environmental contaminant uptake in prey without sacrificing mink. It also allows us to better explain mink population fluctuations, which may be tied to changes in food availability. Results of the studies revealed that mink are very opportunistic. Some general observations of the common food items in their diet include; small fish, blue crabs, fiddler crabs, insects, mud minnows, marsh hens, and marsh rice rats.

2002 Restoration Evaluation
During the May flood tides in 2003, we conducted follow-up surveys in North Inlet and in Murrells Inlet to evaluate the success of the 2002 stockings. Our observations in North Inlet were very encouraging. In the course of a 2-hour flood tide we counted 5 adult mink. Three of these were females with young. For mink to survive the stress of relocation and still be fit enough to reproduce the first year indicates good environmental conditions. Results from the Murrells Inlet surveys were disappointing. We conducted 2

evening surveys without spotting any mink. Conditions were less than ideal, as the survey crew made it into the marsh late on the first night and it rained on the second night. While we failed to document survival of the released mink, two incomplete surveys are not sufficient to demonstrate absence of mink. A mink sighting report from staff from Huntington Beach State Park in the Summer of 2004 does give some encouragement that the released mink may still be present in the area.

2003 Restoration
Pre-release surveys in the vicinity of Dewees and Capers Islands support our belief that mink are absent in that area. This area of marsh was enrolled as our next restoration site. Assisting us with the logistics of that release were Arla Jessen, Environmental Education Coordinator at Dewees Island, and SCDNR Law Enforcement officers from District 9.

2004 Restoration
A total of 12 mink (females with young) were released into the marshes of Dewees Island during the June flood tides. One of the adult females was predated by a marsh hawk which was witnessed by staff. The remaining young were taken to a rehabilitator, and one survived and was released later that year. We also plan to supplement the number of released animals in the future at Murrells Inlet unless surveys indicate that it is not warranted.

2008 - 2009 Survey Work
Clemson Graduate Student Michael Waller worked to implement track board surveys in an effort to reduce survey manpower. However, many of the same issues that plagued track board work previously—such as tidal fluctuations and other environmental factors—again hampered track board implementation. Thus, emphasis was placed on perfecting spotlight survey work in an effort to evaluate which environmental factors were most significant in surveying mink. Waller's work determined that tide heights 6.05' above Mean Lower Low Water (MLLW) level as measured at the Charleston station and adjusted for local areas was the best predictor for when to use spotlight surveys (Waller 2010).

2010-2011 Mink Impacts and Ecology Study
As the reintroduced mink into Cape Romain National Wildlife Refuge (CRNWR) began to thrive, concerns from staff at the refuge centered on the impacts mink may be having on nesting shorebirds. Clemson Graduate Student Caroline Gorga began looking at that potential impact (Gorga 2012). Refuge staff have implemented a mink removal program along Cape Island in conjunction with other predator removal prior to nesting seasons. Diet analysis from mink taken from the CRNWR in an effort to increase shorebird nesting success found that out of 45 mink stomachs collected, 7.4 % contained avian material of unknown species. A bioenergetics model developed from this estimated that an individual mink consumed 8.5 avian prey items per month based on the sampled diet. Unfortunately mink are being blamed for much of the lack of nesting success of several species of nesting shorebirds for which only anecdotal or isolated data exists. Previous studies in the area have shown that habitat loss from erosion and overwash from tides and boat wakes to be significant factors in loss of coastal nesting birds (Thibault 2008, Brooks 2011). Because the natural loss of habitat and overwash is not controllable,

predator control remains one of the management strategies of the refuge. In fact, the CRNWR Comprehensive Conservation Plan states one of the goals is to "remove mink from the refuge" (USFWS 2010).

CONSERVATION RECOMMENDATIONS

- The protection of river corridors, streams, and marsh habitat are necessary for reestablishment of mink populations. Any efforts to improve water quality attributes would benefit mink. Large-scale conservation easements and focus areas such as those in the ACE Basin area, as well as outright purchases of important riparian properties, should benefit mink populations. Such areas would need to be identified and prioritized.

- Continued monitoring through the use of flood tide surveys are needed to assess the success of reintroduction projects in the northern coastal marshes of South Carolina.

- Further research will be needed to fully support the contention that environmental contaminants are associated with the decline in mink populations in South Carolina. From the results of the studies conducted thus far, the list of suspected contaminants can be narrowed to mercury, PCBs, DDE, and dieldrin, with the greatest level of concern assigned to mercury.

- Assess the impacts of predation on nesting shorebirds. Find strategies to limit mink predation where necessary yet discourage prophylactic trapping and shooting of mink where it isn’t warranted.

- Surveys should be run in the northern coastal marshes to assess the ability of mink to persist in reintroduced areas.

MEASURES OF SUCCESS

A definitive determination of what has caused mink declines in the State would be considered a measure of success with the ultimate goal being to correct the problem(s) and bring mink levels back up to the 1970s or 1980s population count.

Silver-haired Bat

Lasionycteris noctivagans

Contributors (2012): Mary Bunch (SCDNR), Susan Loeb (US Forest Service), Mary K. Clark (Private consultant), Austin Trousdale (Lander University), Travis Perry (Furman University), and Jeff Magniez (US Forest Service)
Revised and Updated (2025): Jennifer Kindel (SCDNR)

DESCRIPTION

Taxonomy and basic description

The silver-haired bat was described by Le Conte in 1831. It is monotypic. A medium sized insectivorous bat, the silver-haired bat weighs 8.1 - 11 g (0.28 - 0.38 oz.) as an adult and has a total length of 92 - 115 mm (3.62 - 4.53 in.). The forearm measures 42 - 44 mm (1.65 - 1.73 in.) and the foot measures 7 - 11 mm (0.27 - 0.43 in.). The fur is dark brown or black with distinct white or silver tips. Older bats have a less frosted appearance. The ears are rounded and the tragus is broad. Litter size is 1 - 2 young in a single birth per year, with 2 being typical.

Silver-haired bat

This bat is often grouped as a tree bat because roosting habitat includes tree features such as foliage, lightening scars and loose bark and they are frequently found roosting alone. Other times it is lumped with colonial cavity or crevice-roosting bat species because they have been found in small groups in tree features and man-made structures. The silver-haired bat is best described as a migratory, often solitary, crevice-roosting bat, with exceptions to each.

Status

In South Carolina the silver-haired bat is ranked as Vulnerable (S3). They are ranked Apparently Secure (S4) in North Carolina and Tennessee, and Secure (S5) in Georgia. Silver-haired bats are not ranked in Alabama and Florida (they are not typically found in Florida), and their designation in West Virginia is Imperiled (S2). The silver-haired bat has a global status of Vulnerable (G3).

POPULATION SIZE AND DISTRIBUTION

The distribution of the silver-haired bat is thought to be widespread in the United States. It is migratory, although in some regions, such as British Columbia, they can be found year-round. They migrate south in the fall, where they overwinter, and north in the spring

where they give birth and raise their young. The silver-haired bat is a long-distance migrant, traveling distances of more than 1600 km (994 mi.) between winter sites and summer sites. Evidence suggests that females of the species migrate farther than males. Summer records for silver-haired bats in South Carolina are lacking. Density estimates are likewise not available. When found in groups, the groups tend to be of a dozen individuals or less. However, they are often found as singles. Nothing is known about their social structure or why they sometimes form small colonies that tend to re-form when the group changes roosts. When small colonies switch summer (maternity) roosts, they do not all switch at the same time but do switch roosts the same night so as to remain together. Studies of relatedness of individuals in summer and winter colonies have not been done.

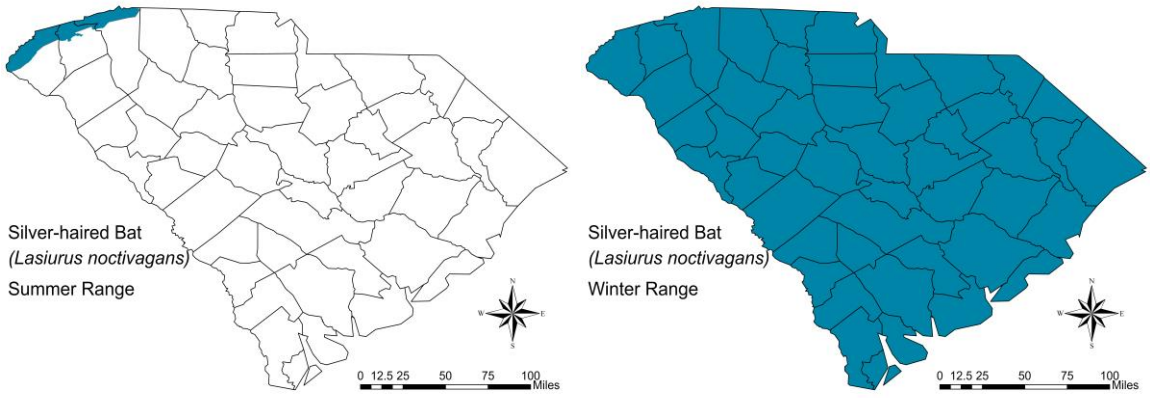

Figure 1: Summer and winter distribution of the silver-haired bat in South Carolina

The silver-haired bat is distributed statewide in South Carolina in the winter; they are not typically found outside of the Blue Ridge ecoregion in the summer. During a study from 1996-2001, silver-haired bats were not detected at the Savannah River Site in the Inner Coastal Plain of South Carolina during summer. Acoustic survey of sites along the shores of Keowee and Jocassee Lakes in 2012 did detect silver-haired bats in July. Significant silver-haired bat mortality has been documented at wind energy facilities in the eastern United States, particularly during fall migration.

Human deaths from rabies have been linked to tri-colored bat (*Perimyotis subflavus*) and silver-haired bat strains of the rabies virus at a greater rate than the bats' abundance would suggest. The silver-haired bat strain is more virulent than other bat strains, but it is not known if silver-haired bats succumb to rabies at a higher rate than other North American bats.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In summer, silver-haired bats are often captured over or near water. Documented summer roosts include tree cavities, under loose bark, under tree foliage, and occasionally in buildings. They engage in frequent roost site switching when using trees. The average distance recorded for summer roost switching noted in British Columbia is 194 m (636 ft.).

Winter roosts include rock crevices, stacks of firewood, caves, tree crevices created by lightning strikes, under loose bark, buildings, bird nest boxes, and in tree cavities, including those created by woodpeckers. In Arkansas, winter roosts are frequently on canopy trees, most often shortleaf pines (under loose bark) and less frequently in cavities in white oak (*Quercus alba*), northern red oak (*Quercus rubra*) and black gum (*Nyssa sylvatica*). However, they are also found in rock crevices (reused over multiple years), and during colder weather, under a tree root or in a hole at the base of a tree. Winter roosts in Arkansas are most often on the south-facing aspect of terrain, and the average height in trees is slightly over 5 m (16.4 ft.). Spring migratory season roosts in Canada are typically 2.5-3 m (8.2-9.8 ft.) above ground in trees. The optimal temperature for hibernating silver-haired bats in Missouri is 5°C (41°F) and is consistent with that for red bats (*Lasiurus borealis*) in the same area.

The silver-haired bat may forage above a cluttered environment. They do not avoid gaps in canopy cover and seem to select larger woodland seasonal pools, in open canopy, over small pools, and in closed canopy. Most foraging is done in openings, but they have been documented using low (near 5 meters above ground) open areas below very high canopy trees with little vertical structure below the canopy. They often use pine or mixed pine-hardwood forests for foraging and roosting. Their flight speed has been described as slow, 4 - 8 m/sec (10.7 - 11.2 mph). Prey consists of Lepidopterans, Homopterans, Dipterans, Hymenopterans, Hemipterans, Coleopterans and Neuropterans. In the southeast some foraging activity of silver-haired bats has been noted in winter during warm spells.

Silver-haired bats may delay foraging periods, when big brown bats (*Eptesicus fuscus*) are abundant in the same area, and forage earlier when the big brown bat is not prevalent.

CHALLENGES

- Loss of roost habitat due to development and forestry practices (man-made alterations and anthropogenic changes).
- Loss of habitat and direct mortality from natural causes such as hurricanes.
- Collisions with wind turbines or injury from active turbines (currently not in SC).
- Collisions with towers.
- Possible vulnerability to heavy metal contamination because they often forage over water.
- It is not known if white-nose syndrome, a fungal disease of hibernating bats, will afflict silver-haired bats.

CONSERVATION ACCOMPLISHMENTS

None of the experts contacted in the mammal review process had knowledge of any funded projects dealing specifically with the silver-haired bat in South Carolina. These bats are detected sporadically but are poorly understood.

CONSERVATION RECOMMENDATIONS

Management

- In timber harvest projects, retain a snag density of >21 snags/hectare.
- Work with wind energy development companies to mitigate impacts of wind turbines (e.g. increasing the cut-in speed of turbines to reduce mortalities).
- Only flashing lights should be used on towers, rather than constant on lights; this is now regarded as acceptable by the FAA and can reduce bird and bat mortality.

Priority research and survey needs

- Research the migration routes, timing and patterns of the silver-haired bat.
- Determine where South Carolina's over-wintering population goes for the summer (perhaps by using stable isotopes from hair or nail samples).
- Study potential impacts from wind farms and develop strategies to reduce silver-bat mortality.
- Determine winter roost site and habitat requirements.
- Determine if silver-haired bats are threatened by pesticide and/or heavy metal contamination.
- Examine the impacts of winter burns during cold weather on silver-haired bats (particularly on south-facing burn units).

Monitoring

- Maintain capture and location information for silver-haired bats.
- Use vehicular acoustic surveys to monitor silver-haired bats occupancy rates on a seasonal and annual basis.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized by those with the greatest conservation applicability. Surveys and density estimates in the southern region should provide some population estimations that will be used to more accurately rank the species and prioritize future management needs. It is important to determine important roost site locations to provide long-term habitat for the species. Currently, very little is known about silver-haired bats in South Carolina.

DESCRIPTION

Taxonomy and basic description

Colonial bats are those which gather in groups, forming maternity and/or hibernation colonies. The colony size can vary from 3 to 4 individuals to thousands. Cavity roosting bats use cavities or crevices for shelter. Most species of South Carolina bats are colonial cavity or crevice roosting. They include big brown bat (*Eptescicus fuscus*), brazilian free-tailed bat (*Tadarida brasiliensis*), eastern small-footed myotis (*Myotis leibii*), evening bat (*Nycticeius humeralis*), gray bat (*Myotis grisescens*), little brown bat (*Myotis lucifugus*), northern long-eared bat (*Myotis septentrionalis*), Rafinesque's big-eared bat (*Corynorhinus rafinesquii*), southeastern myotis (*Myotis austroriparius*), and tricolored bat (*Perimyotis subflavus)*. Eight of these species are of conservation concern and are discussed in this SWAP Plan; big brown, eastern small-footed, gray, little brown, northern long-eared, Rafinesque's big-eared, southeastern, and tricolored bat.

All South Carolina bats are nocturnal, feed on insects, and navigate or locate prey by ultrasonic echolocation. Echolocation is the use of reflected sound waves to locate objects. Ultrasonic echolocation means the sound waves used are typically above the human hearing range. Fecundity in these species is low, with bats producing 1-2 young (pups) annually in the summer. Eastern small-footed, gray, little brown, northern long-eared and Rafinesque's big eared bats produce only a single pup while southeastern, big brown, and tricolored bats typically give birth to up to 2 young per year.

Big brown bats

Big brown bats are large bats weighing 13-18 g (0.4 - 0.6 oz.) with a body length of 10.3 -13.0 cm (4.1 - 5.1 in) and a forearm measurement of 4 cm (1.57 in) or more. They have dark brown glossy fur, with a dark muzzle that has an inflated appearance. This species was first described in 1796 by Palisot de Beauvois.

Eastern small-footed myotis © MerlinTuttle.org

The eastern small-footed myotis (*Myotis leibii*) is a monotypic species and is South Carolina's smallest bat. Adults typically weigh only 3 - 6 g (0.1 - 0.2 oz) and have a wingspan of 21 - 25 cm (8.3 - 9.7 in). They have distinctively small feet only 6 - 8 mm (0.2 - 0.3 in) long, a dark mask at the eyes, and black ears. Their fur is shiny brown on back and whitish or buff on the belly. Wing and tail membranes as well as the muzzle, are a dark chocolate color. The eastern small-footed myotis was first described by Audubon and Bachman in 1842.

Gray bat © MerlinTuttle.org

The gray bat (*Myotis grisescens*) is the largest *Myotis* species in the eastern United States weighing ~7 - 10 g (0.25 - 0.35 oz) with a wingspan of 22 - 27 cm (10 - 12 in). While many southeastern bat species have bi- or tri-colored hairs, gray bats are known for their monochromic smoky brown or mouse gray dorsal fur colored from base to tip, though the belly may have whitish or buff tipped hairs. Unlike most other *Myotis* species, the plagiopatagium of the gray bat attaches at the ankle or base of the foot rather than at the base of the toes. The southeastern myotis may present a similar attachment, but gray bats are further distinguished by the unique presence of a notch in the thumb claw. The gray bat was first described by A.H. Howell in 1909.

Little brown bat ©MerlinTuttle.org

Little brown bats can be difficult to tell from northern long-eared bats. Both are small bats with brown fur. Little brown bats tend to have dark brown fur on the back that appears glossy. The little brown bat typically weighs 7 - 14 g (0.24 - 0.49 oz) and is 8 - 9.5 cm (3.1 - 3.7 in) long. The hairs on the feet of the little brown bat extend beyond the nail, unlike those of the northern long-eared bat. Northern long-eared bats are also 8 - 9.5 cm (3.1 - 3.7 in) long and their average weight is 7.4 g (0.26 oz).

The tragus (a structure within the ear) is straight on both the little brown bat and the northern long-eared bat, but it is more pointed in the northern long-eared bat. The ears of a northern long-eared bat, if folded toward the nose, would extend slightly beyond the tip of the nose. The little brown bat was first described in 1831 by LeConte, and the northern long-eared bat by Trouessart in 1897.

Northern long-eared bat

Rafinesque's big-eared bats

Rafinesque's big-eared bats (*Corynorhinus rafinesquii*) have enormous ears, 27 - 37 mm (1.1 - 1.5 in) which they fold up (deflate) while resting or hibernating. These bats have hairy toes, relatively large feet (9 - 13 mm or 0.4 - 0.5 in), and two distinct fleshy protuberances, on either side of the nose. They weigh 7 - 10 g (0.24 - 0.35 oz). Fur color in adults is a dark brown on back with dark rooted whitish hairs on the underside of the animal. Juveniles appear dark gray. The first upper incisor tooth has two cusps or points. The Rafinesque's big-eared bat was first described by Lesson in 1827.

Previously accepted designations for this species were *Corynorhinus macrotis* and *Plecotus rafinesquii*. The current accepted scientific name, *Corynorhinus rafinesquii*, is based on chromosomal variation and morphometric measurements. Two subspecies of Rafinesque's big-eared bats are recognized within South Carolina. *Corynorhinus rafinesquii rafinesquii* is the subspecies found in the mountains of South Carolina and into North Carolina, Georgia and beyond along the Appalachian Mountains. The disjunct Coastal Plain populations are recognized as *C. r. macrotis*.

Southeastern myotis (*Myotis austroriparius*) have a pinkish face or muzzle. The fur of the southeastern myotis has a wooly texture and is generally a dull-grayish brown. Fur color may vary with season, with some individuals having a bright reddish-orange appearance in the summer. These bats weigh 5 - 12 g (0.17 - 0.42 oz). The hindfoot is hairy and averages 10 mm (0.39 in) long. The southeastern myotis was first described by Rhoads in 1897.

Southeastern myotis (red phase)

The tricolored bat is small, weighing an average of 6 g (0.2 oz). For their size they have large feet, 7.3 - 9.9 mm (0.29 - 0.39 in). They are not as colorful as the term “tricolored” implies. Tricolor refers to the banding on the hairs; from the base to tip each hair appears dark, light and dark. Most tricolored bats are buff-yellowish but can appear brown. The radius bone visible through the skin appears pink. The face and ears also have a pinkish color. The tricolored bat was described by F. Cuvier in 1832 and renamed to their current Genus in 2006 by Hooper, Van Den Bussche and Horacek.

Tricolored bat

Status

In South Carolina, the big brown bat is considered Apparently Secure (S4) and globally ranked as Secure (G5). Most surrounding states rank this species as Secure (S5), but big brown bats are known to suffer from White-nose Syndrome (WNS).

Eastern small-footed myotis have a global rank of Apparently Secure (G4). In South Carolina small-footed myotis are Imperiled (S2) and are designated as “in need of management” which equates to State Threatened. North Carolina, Georgia, Virginia, Tennessee, and Kentucky also rank this species as Imperiled (S2). In North Carolina, the eastern small-footed bat is considered a species of state special concern. In 2013, USFWS determined that the eastern small-footed myotis did not warrant listing under the ESA.

The gray bat is Critically Imperiled (S1) in South Carolina, as well as in Georgia, Florida, North Carolina, and Virginia. It is considered Imperiled (S2) in Alabama, Tennessee, and Kentucky. The rounded global status of the gray bat is considered Vulnerable (G3) and has been federally endangered since 1976. This species is vulnerable due to being highly sensitive to human disturbance and having large numbers limited to a small number of caves across their range.

Little brown bats are globally ranked as Vulnerable (G3). In South Carolina, they are considered Imperiled (S2). North Carolina, Virginia, West Virginia, and Kentucky share the Imperiled rank for little brown bats. In Georgia they’re considered Critically Imperiled (S1) while in Alabama and Tennessee they are ranked as Vulnerable (S3). In North Carolina, this species is considered state endangered. The little brown bat is currently under review by the US Fish and Wildlife Service for listing on the Endangered Species Act due to threats from WNS.

Northern long-eared bats in South Carolina are considered Critically Imperiled (S1). They are ranked as Critically Imperiled in Georgia, Tennessee, and Kentucky, and as Imperiled (S2) in North Carolina, Alabama, and Virginia. In North Carolina, this species

is considered state endangered. The US Fish and Wildlife Service listed northern long-eared bats as endangered under the ESA in 2024 due to threats from WNS. This species has global rounded rank of Imperiled (G2).

The Rafinesque's big-eared bat is Imperiled (S2) in South Carolina and is listed as State Endangered. In North Carolina, *C. r. rafinesquii* is state threatened and *C. r. macrotis* is of state special concern. Georgia, Tennessee, and Kentucky rank Rafinesque's as Vulnerable (S3), while Virginia and Alabama rank them as Imperiled (S2). West Virginia and Florida consider the species to be Critically Imperiled (S1). This species has a rounded global status of Vulnerable (G3).

The southeastern myotis is Vulnerable in South Carolina (S3) and is designated as "in need of management." It has the same designation in Georgia, Florida, and Tennessee. In Virginia, North Carolina and Alabama the species is ranked as Imperiled (S2). In North Carolina, this is a state special concern species. The global status of southeastern myotis is ranked as Apparently Secure (G4).

In South Carolina, tricolored bats are ranked as Vulnerable (S3) as they are in North Carolina and Alabama as well. However, Florida, Georgia, Tennessee, Kentucky, West Virginia and Virginia rank this species a Imperiled (S2). In North Carolina, this species is considered state endangered. Globally, the tricolored bat has a rounded rank of Vulnerable (G3).

WNS is a fungal disease of hibernating bats. The fungus, *Pseudogymnoascus destructans*, attacks the dermis of bats while their immune systems are not active during hibernation. The fungus prefers cool, humid conditions such as those bats seek for winter hibernation in caves and mines. The fungus is difficult to detect on bats during the warm summer months when their body temperature is high and their immune systems launch effective attacks on the fungus. However an individual's past affliction with WNS may manifest as damage to wing membranes post-hibernation. By summer much of the damage from the previous winter is not evident. Over 7 million bats are estimated to have been killed by WNS in the Northeast since the discovery of WNS in 2006.

Although winters in South Carolina are warmer and shorter than those in the northeast, hibernaculum temperatures in the northeastern section are in the optimal growth range of the fungus. Consequently, WNS has had a significant impact on tricolored bat, northern long-eared bat, and little brown bat populations in the northwestern part of the state. However, big brown bat populations do not appear to have been significantly impacted by WNS.

In February 2013, a tricolored bat was found dead at Table Rock State Park. Testing by the Southeastern Cooperative Wildlife Disease Study in Athens, GA confirmed that the bat had WNS, the first case in SC. Since then, there have been three confirmed counties with bats found to suffer from WNS (Oconee, Pickens and Richland counties) and seven others confirmed with fungus *Pseudogymnoascus destructans* (Cherokee, Greenville, Lancaster, Laurens, Spartanburg, Union, and York). Unfortunately, tricolored bat

populations in two major Upstate hibernacula had declined at an alarming rate (up to 97 percent) since WNS arrived in South Carolina. However, tricolored bats populations in those hibernacula have stopped declining and begun to slowly increase in recent years.

POPULATION SIZE AND DISTRIBUTION

Big brown bats are common in South Carolina and occur throughout the state. These bats will use T-beam bridges, buildings, mines, tunnels, caves, and hollow trees for roosts. They are sometimes deemed a nuisance by homeowners. These bats use T-beam bridges, buildings, mines, tunnels, caves, and hollow trees for roosts. They are sometimes deemed a nuisance by homeowners. Tricolored bats also occur throughout the state. While populations have declined precipitously in the northwestern part of the state, they are still relatively common in the lower part of the state.

The range of the eastern small-footed myotis extends from the mountains of South Carolina (Figure 1) and Georgia, northward along the Appalachian Mountains into Virginia, West Virginia, Pennsylvania and southern New England and Canada. Populations extend westward into Kentucky, Tennessee, Alabama, and into Oklahoma. Population trends for this species are largely unknown and this species has never been regarded as abundant anywhere.

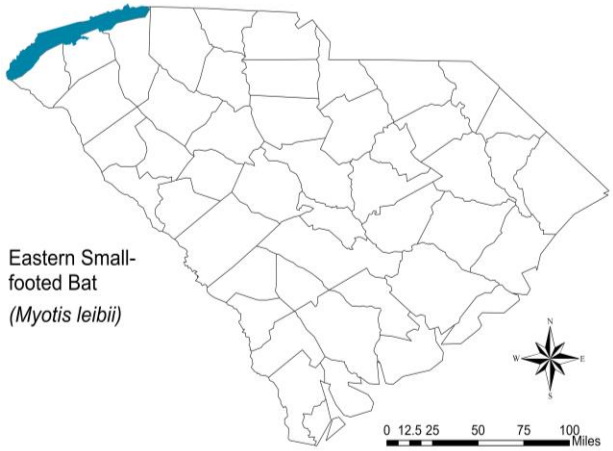

Figure 1. Distribution of the eastern small-footed bat in South Carolina

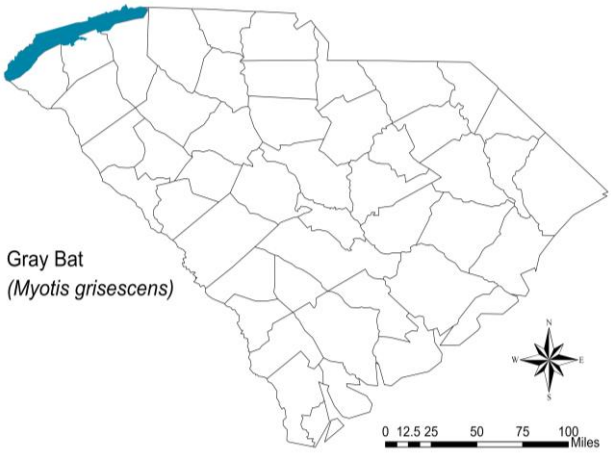

Figure 2. Distribution of the gray bat in South Carolina

Gray bats are restricted to cave regions of the midwestern and southeastern parts of the United States. Ninety-five percent of all gray bats hibernate in nine main winter caves located in Tennessee, Missouri, Kentucky, Alabama, Arkansas, and North Carolina. In August 2023, four gray bats were first recorded in South Carolina in Greenville and Oconee counties in crevices of bridges. Thus, we anticipate the range of this species to be in the Blue Ridge ecoregion of South Carolina (Figure 2).

Historically, both little brown and northern long-eared bats were found primarily in the mountains of South Carolina. However, their populations have declined significantly in this part of the state. Little brown bats range from central Alaska and southern Canada into the southeastern and southwestern US and are widely distributed. The southern limit of this species is in northern portions of South Carolina, Georgia, Alabama, and Mississippi, and little brown bats have been found in every ecoregion of South Carolina. In summer, little brown bats are found primarily in the Blue Ridge mountains, though there have also been infrequent reports of this species in the Piedmont, Sandhills and Coastal Plain regions (Figure 3). However, it is unknown where most of South Carolina's summer populations overwinter.

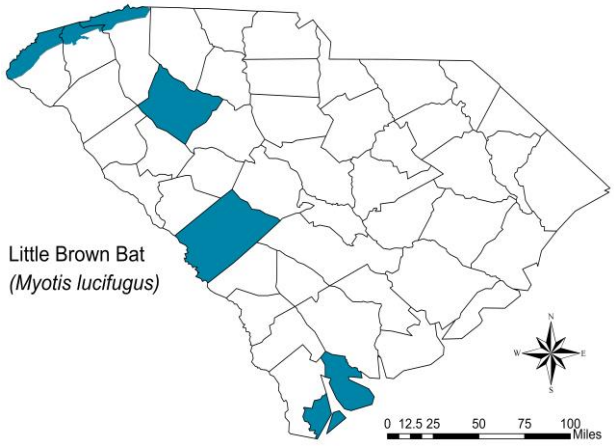

Figure 3. Distribution of the little brown bat in South Carolina.

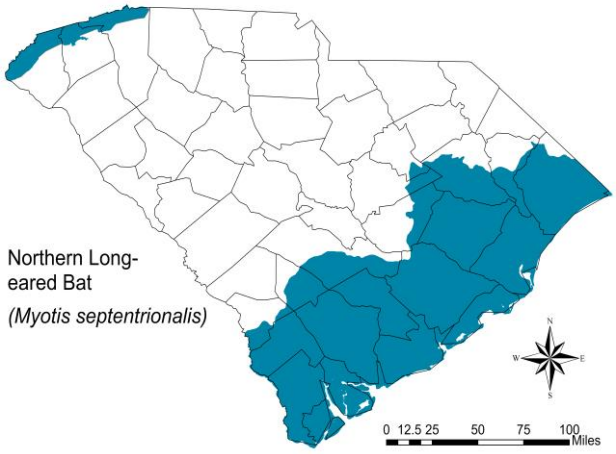

Figure 4. Distribution of the northern long-eared bat in South Carolina.

Northern long-eared bats are widely but patchily distributed across eastern North America ranging from southern Canada and the central and eastern US, northwest to the Dakotas, west through the central states, and south to northern Florida. No individuals from the SC mountain populations of this species have been captured in recent years. However, northern long-eared bats have been found in the Coastal Plain in many areas, although their numbers do not appear to be high (Figure 4).

Rafinesque's big-eared bats are found in all SC ecoregions except the Piedmont (Figure 5). *C. r. rafinesquii* are distributed within the Southern Appalachian Ecoregion from West Virginia southward into South Carolina, Georgia, and into Alabama. *C. r. macrotis* range from North Carolina, southward along the entire coastal plain and into the Sandhills of South Carolina. They extend southward through Georgia and into Florida. Rafinesque's big-eared bats have never been considered abundant. Colony sizes are larger in the northern end of their range where the species often inhabits caves and

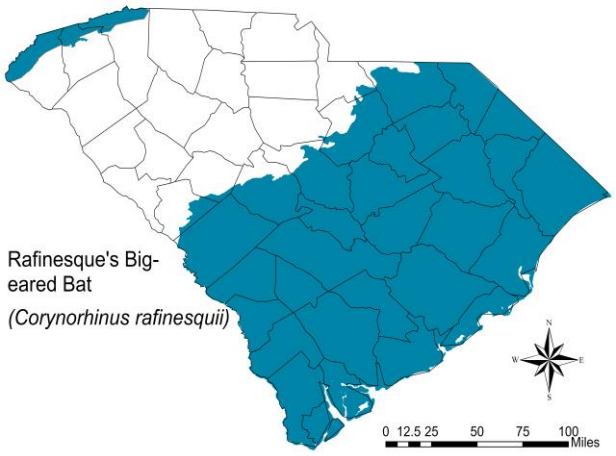

Figure 5. Distribution of the Rafinesque's big-eared bat in South Carolina.

mines but tend to be smaller in the southern portions of the range where caves and mines are less abundant. Southern roosts tend to be in tree cavities and man-made structures. Colony sizes are often less than 30 (usually 5-12) and seldom over 100. Population trend information is sparse, but most states suspect declines. Size of home range varies, averaging 93.2 ha (230.3 acres) in the Inner Coastal Plain Ecoregion, and ranges from 64-89 ha (158-220 acres) in a forested old growth swamp on the Outer Coastal Plain.

The southeastern myotis occurs from Florida northward mostly in the Coastal Plain through South Carolina (Figure 6), North Carolina and into the Southern Coastal Plain of Virginia. The distribution extends westward along the Coastal Plain of Georgia, Alabama, Louisiana, and Mississippi and northward along the Mississippi River into western Tennessee, Kentucky, southern Illinois and Indiana. Individuals have recently been documented in Piedmont counties in South Carolina, but state population trends are not known.

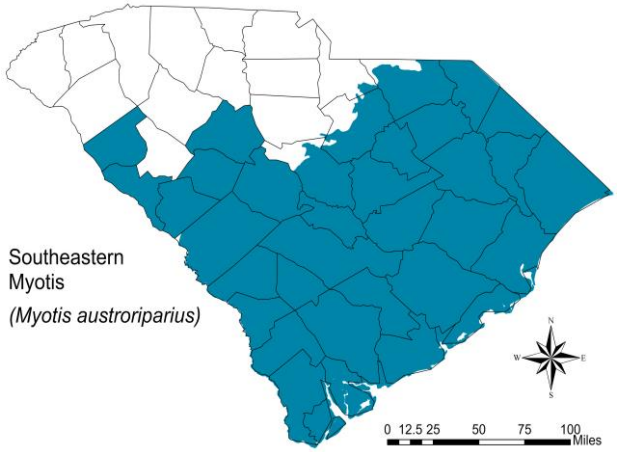

Figure 6. Distribution of the southeastern myotis in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Big Brown Bat

Big brown bats are ubiquitous. They are frequently found in buildings, cavity trees, under bridges and in bat boxes. They are infrequently found in tunnels and caves. Typically, they do not move to underground structures until extremely cold temperatures arrive and they are often the first species to leave the hibernaculum. They are frequently excluded from homes by wildlife control operators.

Big brown bats usually forage in open areas such as fields and wildlife openings or large gaps within forests. In the eastern United States, their diet consists primarily of Coleoptera. Lepidoptera are also an important part of their diet in some areas.

Eastern Small-footed Myotis

These small bats are known to use caves, mines, abandoned buildings, rock crevices and shelters, and crevices within bridges in wooded areas of the Southern Appalachian Ecoregion. In South Carolina, only few eastern small-footed myotis roosts have been found. They included a crevice in a rock outcrop in mature hardwoods (also suitable for green salamanders, *Aneides aeneus*), loose tarpaper on an abandoned log cabin, a wood pile on a porch, a fish hatchery building, and a picnic shelter.

Hardwood and evergreen forests, mixed hardwood-conifer stands, bottomland, and floodplains are reported as important habitat for the eastern small-footed myotis. They appear to prefer to forage over streams and ponds. For example, in South Carolina, they have been observed foraging over Reedy Cove Creek >100 m (328 ft.) downstream from the waterfalls. These bats are slow fliers with a fluttery flight pattern. It is likely they require forested corridors between roosts and foraging areas. The winter and summer roosting requirements and foraging habitats are poorly understood for this species.

Several species of colonial bats are sometimes nuisances or unwanted residents of homes, businesses, stadiums, and other man-made structures. Most often, nuisance colonies in South Carolina can be attributed to four species: big brown, free-tailed, evening bats, and tricolored bats. While all three colonial species of conservation concern do sometimes use buildings, those buildings are usually unoccupied; it is very uncommon for them to use sites frequented by humans.

Gray Bat

Although gray bats are nearly exclusively cave dwellers, they have been found using storm sewers/box culverts, abandoned mines, and bridges during the summer. Maternity caves have high humidity, are often wet, and have high domed rooms that serve as heat traps. Gray bats have been observed roosting with southeastern bats in Florida and Indiana bats in Arkansas and Missouri. At maternity sites farther from water, females and juveniles sometimes move to alternative caves closer to water post-volancy. In the winter, 95% of all gray bats hibernate in nine main winter caves located in Tennessee, Missouri, Kentucky, Alabama, Arkansas, and North Carolina. Gray bats were only recently discovered in South Carolina, but four separate individuals found were roosting in expansion joint crevices on bridges over water in Oconee and Greenville counties in August 2023. Gray bat calls have also been detected in those counties in mid-July as part of South Carolina's North American Bat Monitoring Program (NABat).

Little Brown Bat

In South Carolina, maternity colonies are known to use buildings and picnic shelters. They also are likely to use cavity trees. Only one hibernaculum is known from a single cave in Pickens County, South Carolina. It is unknown where most of South Carolina's little brown bats overwinter.

Northern Long-eared Bat

Habitat requirements of northern long-eared bats are still not well known in South Carolina. A northern long-eared bat was tracked to a dead pine; the bat was under loose

bark on National Forest land near Oconee State Park. In the Coastal Plain of South Carolina, northern long-eared bats primarily use longleaf pines (*Pinus palustris*). Studies of their roosting habits in North Carolina, Kentucky, Arkansas, and West Virginia show they use a variety of tree species. Oaks were the primary roost in one study in North Carolina, where pines were the primary roost in another. Shortleaf pine (*Pinus echinata*) has been shown to be used in Arkansas and Kentucky, and in West Virginia black locust was used for roosting. Northern long-eared bats tend to prefer crevices and cavities in dead or live-damaged trees, but they sometimes roost between loose bark and the bole of dead trees. Females prefer larger diameter trees than those used by males.

Northern long-eared bats are clutter-adapted species; meaning that they often forage in densely forested areas. In South Carolina, they are most likely to forage in mature stands. Northern long-eared bats often glean their prey from the surface of vegetation although they also forage by aerial hawking.

Rafinesque's Big-eared Bat

In South Carolina, some Coastal Plains' and Sandhills' populations use T-beam and I-beam bridges, abandoned buildings, old bunkers and tunnels, and cavity trees. The mountain populations apparently do not use bridges for roosts but use cavity trees, typically large hollow tulip poplars (*Liriodendron tulipifera*), abandoned buildings, cave or cave-like structures called rock shelters, and abandoned mines and tunnels. Rafinesque's big-eared bats are non-migratory. Movement is described as localized, not far-ranging from the roost; and distribution is patchy.

Habitat in the Blue Ridge Mountains for *C. r. rafinesquii* includes rock outcrops (for roosting), mesic and cove hardwood forests, forested bottomlands, bottomland agricultural fields, dry deciduous forest, pine woodlands, and forested riparian areas. Coastal Zone and Sandhills habitat of *C. r. macrotis* for roosting and foraging include black gum (*Nyssa sylvatica*) and water tupelo (*Nyssa aquatic*) stands, bald cypress (*Taxodium distichum*) swamp forests, maritime forests, and mature forested bottomlands (hardwood or mixed). They require very large tree cavities, frequently found in gum (*Nyssa sp*.) trees. Foraging was documented in a young pine plantation in a study with a small sample size. The best way to locate colonies is to examine cavities of large trees in appropriate areas.

Rafinesque's big-eared bats are reported to be moth specialists, although other insects are also consumed. Studies have shown that consumption of moths varied, with 48-100% of samples containing moths (Lepidoptera).

Southeastern Myotis

Caves (including limestone sinks), mines, abandoned buildings, log piles, and large hollow trees are used for roosting, maternity colonies and hibernation sites. In addition, they use forested bottomlands, forested swamps, Carolina bays, mesic deciduous and mixed forests. This bat forages and prefers to roost over or near water.

In Florida studies show that food habits vary with season. In summer Coleoptera and Lepidoptera were primary prey. Winter consumption included Coleoptera, Lipidoptera, Diptera, and especially Culicidae.

Tricolored Bat

The small-bodied tricolored bat is often one of the first species to move into a mine or cave for hibernation and is often the last to leave in the spring. In winter these bats often use abandoned mines and caves in the northwestern part of the state. Although considered colonial bats, individuals are often not physically clumped together. While hibernating in these caves, mines, and tunnels, tricolored bats hang singly but can be near conspecifics. Frequently they are covered in condensation while hibernating. In the lower part of the state, tricolored use a variety of structures including culverts, bridges, tree hollows, and tree foliage. During cold periods they go into deep torpor with torpor bouts lasting as long as 15 days. However, during warm periods they often switch roosts and possibly forage.

During summer tricolored bats can be found under certain bridges and in buildings in the summer. They are sometimes regarded as a nuisance by homeowners. In South Carolina and Indiana, females often form small maternity colonies (3-5 individuals) in clusters of live or dead leaves in trees. Male tricolored bats in North Carolina use large diameter oaks and hickories for roosts. In the Coastal Plain of South Carolina they use hardwood trees and often roost in Spanish moss (*Tilandsia usneoides*). Tricolored bats switch roost sites frequently in summer but their roosts are typically close together.

South Carolina data shows that tricolored bat activity does not seem to be influenced by thinning forest stands or by conducting controlled burns. In Illinois the diet of tricolored bats consisted mainly of Trichopterans (caddisflies) and consist of Coleoptera and Hymenoptera and in bottomland forests of east Texas it consists mainly of Coleoptera, Diptera, and Lepidoptera.

CHALLENGES

Threats to these bat species are summarized as follows:

All colonial bats in South Carolina[1]:

White-nose syndrome threatens all these species, although Rafinesque's big-eared bats have not suffered mortality due to WNS. An eastern small-footed myotis and a tricolored bat were discovered at Table Rock in 2013 suffering from WNS. The population of tricolored bats in Stumphouse Main Tunnel dropped 90 percent between 2014 (321 individuals) and 2018 (31 individuals) but has slowly begun to recover with 123 individuals detected in 2024. As of March 2024, there have been three confirmed counties with bats found to suffer from WNS (Oconee, Pickens and Richland) and seven others confirmed with the fungus that causes WNS, *Pseudogymnoascus destructans* (Cherokee, Greenville, Lancaster, Laurens, Spartanburg, Union, and York).

- Disturbance/destruction of natural roost structures (caves, rock shelters, trees).
- Global climate change may make southern hibernation sites unsuitable (too warm).

- Increased development and urbanization reduces habitat and forces bats into direct contact with humans.
- Increased predation by natural predators due to habitat alterations that either make the bats more vulnerable to predation or increase the density of predators.
- Destruction and disturbance of artificial roost structures (girder type bridges, abandoned houses and barns, mines, and tunnels).

Rafinesque's big-eared bat and Southeastern myotis:

- Destruction of natural roosts, particularly large hollow trees in the Coastal Plain.
- Destruction and fragmentation of bottomland hardwood forests that are used for roosting and foraging.
- Pesticide and heavy metal contamination.
- Unnatural predation at roosts by feral cats.
- Alteration of natural flood regimes may affect the regeneration of important forest community types such as cypress-gum, thus preventing recruitment of future roost trees.
- Alteration of local hydrology can increase flooding of natural roosts.
- Genetic isolation of populations.
- Abundant invasive exotic vegetation, such as some privet species, may prevent regeneration of forest species and impair recruitment of suitable roost trees.

Rafinesque's big-eared bat:

- Destruction and fragmentation of mature forests in the mountains and Coastal Plain.

Southeastern myotis:

- Flooding / inundation of natural roost sites.

Other threats (not species-specific) on the horizon:

- Wind turbines erected near roosts, and colony sites, and along migratory routes kill bats. Significant mortality of tricolored bats was noted at one wind power facility.

CONSERVATION ACCOMPLISHMENTS

Currently nearly 80,000 ha (197,684 ac.) of mountain habitat in South Carolina is protected by state, federal, or nonprofit conservation organizations. Many of those tracts protect Rafinesque's big-eared bat and eastern small-footed myotis roosts or foraging areas. Examples are Ashmore Heritage Preserve, the Greenville Water System's South Saluda watershed that is held in a conservation easement, and the Andrew Pickens District of the Sumter National Forest.

Several important roost and/or foraging sites in the Coastal Plain are in public ownership. An excellent example of old growth forest with Rafinesque's big-eared bats and Southeastern myotis is the Francis Beidler Swamp, also known as Four Holes Swamp, owned by the Audubon Society. Congaree National Park, which is the largest intact expanse of old growth bottomland hardwood forest remaining in the southeast and is

10,802 ha (26,692 ac), provides important roosting and foraging habitat for big-eared bats and southeastern myotis.

These activities have benefited bats:

- Surveys of mines, tunnels, bunkers and rock shelters/caves and trees along the Savannah River floodplain have located some colonies of Rafinesque's big-eared bats, Southeastern myotis, tricolored bats and occasional records of the other colonial species listed here.
- Contribution to poster, "Bats of the Eastern United States" used for educational outreach and provided free to the public.
- Completed a survey of Pest Control and Wildlife Control Operators in 1991 to evaluate the use of chemicals / pesticides vs. exclusion on nuisance bat colonies and reported findings at the South Carolina 33rd Annual Pest Control Operators School (38% had been using pesticides/chemicals on bats).
- Provided several training sessions on exclusion techniques and bat identification to Wildlife Control operators (WCOs) and Clemson University students.
- Posted WNS information and important links on the SCDNR website.
- Conducted numerous information and education programs on South Carolina's bats.
- Gated 12 tunnels to reduce human disturbance to Rafinesque's big-eared bat and tricolored bat colonies and modified 5 to improve air traps for Rafinesque's big-eared bats and big browns.
- Completed state-wide survey of bridges (2002-2003) to determine distribution of Rafinesque's big-eared bats; 52 bridges were used by Rafinesque's big-eared bats and of those 24 were used by maternity colonies. That work also located several big brown colonies and one tricolored bat colony.
- Completed studies of tricolored bats roosting and foraging habitat use throughout the state and throughout the year and conducted annual censuses of Stumphouse Main Tunnel 2014-2024.
- Good baseline data on the use of natural roosts and foraging areas by Rafinesque's big eared bat and the southeastern myotis are available for the Francis Beidler Forest in the Outer Coastal Plain, Congaree National Park in the Inner Coastal Plain, the Savannah River Site, Webb Wildlife Center and Groton Plantation.
- Some baseline data on the use of natural roosts by coastal northern long-eared bat populations are available for Francis Marion National Forest and Santee Coastal Reserve Wildlife Management area.
- Various agencies and NGOs have erected artificial roost structures (concrete bat towers and/or wooden bat boxes) at Silver Bluff Audubon Sanctuary, Hamilton Ridge WMA, Oconee, Devils Fork, Kings Mountain, and Table Rock State Park, Clemson Experimental Forest, Sumter National Forest, South Carolina National Guard McCrady Training Site, Jocassee Gorges, Ashmore Heritage Preserve and Hampton Plantation State Historic Site.
- WNS information was posted at the main Stumphouse Tunnel owned by Clemson University.
- Acoustic survey routes have provided baseline population and diversity information within the Andrew Pickens and Long Cane and Enoree Districts of the Sumter

National Forest, the Savannah River Site, and Carolina Sandhills National Wildlife Refuge.
- Statewide acoustic surveys (stationary and mobile) following the North American Bat Monitoring (NABat) protocol have been running annually since 2015, providing over 10 years of long-term bat data across South Carolina.
- A citizen science project and online form called SC Bat Watch! was created to monitor bat roost sites across the state and can be found here: https://www.dnr.sc.gov/wildlife/bats/batwatch.html

CONSERVATION RECOMMENDATIONS

Habitat protection
- Efforts should be made to protect foraging areas and migration corridors in addition to protecting known roosts. Protections could vary including landowner incentive programs, conservation easements, lease agreements, or purchases.
- Some formal agreement, such as a Memorandum of Understanding, between SCDNR and SCDOT regarding adaptations to new, long bridges over water in the Sandhills and Inner and Outer Coastal Plain is desirable. Currently, some of this work is handled though discussions with environmental consultants working on bridge projects with wetlands impacts.
- The protection of mature bottomland hardwood forests and connecting corridors in the Inner and Outer Coastal Plain is important for *C. rafinesquii* and *M. austroriparius*. Recruitment of younger stages of high-quality bottomland habitat for growth into future roost trees is needed.

Management
- Control human access to important mines, tunnels, caves, and rock shelter formations by signage or other restrictions, and do not create trails or roads to these sites.
- Designate buffers (no-cut zones) around known roosts.
- Provide forested corridors between any harvested units and retain large snags.
- Retain and recruit cypress-gum swamp forests containing large cavity trees.
- Regarding roosts in buildings: Measures should be taken to provide alternate roost structures at each significant site, or repairs should be made to the structure to ensure roost longevity. Typical bat box structures will not suffice for species that prefer large open cavities (Rafinesque's big-eared bats), not crevices. Structures which mimic large hollow trees may be suitable alternative roosts (similar to artificial chimney structures now used for chimney swifts) for Rafinesque's big-eared bats and southeastern myotis. Multi-chamber nursery boxes should be erected for significant little brown bat, northern long-eared, and small-footed myotis colonies. Alternatively, large bat towers for Rafinesque's big-eared bats can be modified to accommodate these species.

Priority research and survey needs
These research and survey needs are not restricted to South Carolina and could involve partnerships with other states in the respective ecoregions.

All colonial bats:

- Because we are at the southernmost range to find bats hibernating, evaluation of roost availability along with roost temperature and the availability of appropriate food (insects high in polyunsaturated fats) should be compared to winter survival.

Eastern small-footed and southeastern myotis:

- Determine summer and winter roost site requirements.

Gray bat:

- Determine seasonal distribution in South Carolina through capture and tracking surveys.
- Continue surveys of transportation structures where gray bats are likely to roost.
- Determine roosting habitat requirements including landscape factors that influence roost habitat quality.

Rafinesque's big-eared bat and eastern small-footed myotis and southeastern myotis:

- Determine if prescribed fire represents any threat, and what the acceptable distance of fire, smoke and fire lines from roosts.

Rafinesque's big-eared bat and southeastern myotis:

- Determine the genetic structure of selected colonies and test whether populations are experiencing adverse genetic consequences from isolation and fragmentation.
- Survey and map mines, tunnels, wells and cave-like structures not surveyed in previous efforts.
- Obtain long-term demographic data including reproductive success, sex ratios, survival, immigration and emigration facilitated by dispersal, and determine the effects of biotic and abiotic factors on these parameters.
- Determine if unnatural predation at roosts by feral cats is occurring. The study sites should include the southeastern myotis roost at Orangeburg State Park.
- Develop suitable man-made roosts specific to these species.
- Use existing data on habitat preferences to identify the availability of natural roost habitat and to determine the amount of protected versus unprotected habitat.

Rafinesque's big-eared bat:

- Determine alternate roost sites for bridge roosting individuals.
- Locate and map roost trees by physical searches where possible.
- Determine foraging habitat requirements (habitat types, size, and distance from roosts).
- Determine the effects of habitat fragmentation and roads on foraging behavior of Rafinesque's big-eared bats.
- Study the feeding ecology requirements in the mountains and coastal plain.

Southeastern myotis:

- Determine roosting habitat requirements including landscape factors that influence roost habitat quality.
- Obtain basic information on colony size, composition, dynamics, and how these vary with roost site characteristics.
- Little brown, northern long-eared bat:
- Locate any hibernacula of South Carolina bats.
- Conduct demographic studies on little brown bats to measure the effects of WNS if it occurs.

Monitoring

- Identify colonies of eastern small-footed myotis and southeastern myotis and begin long-term monitoring on colony size, persistence, and roost sites.
- Identify more of gray bat locations and monitor those individuals or colonies.
- Monitor any winter colonies of little brown bats, if found and continue monitoring of hibernacula of other species where access is permitted.
- Monitor the little brown bat maternity colony at the SCDNR Fish Hatchery in Oconee County.
- Continue long-term monitoring of bridges in the Coastal Plain for Rafinesque's big-eared bats.
- Continue long-term monitoring of Rafinesque's big-eared bat roosts in the mountains.

Education, public outreach and cooperative efforts

- Currently, bats are gaining recognition and popularity largely due to efforts of conservation organizations such as Bat Conservation International. Development of brochures, interactive websites and study plans should benefit the public and the species.
- Incorporate bats, particularly those of conservation concern, into forest plans, and other land management plans.
- Require certification of WCOs that includes exclusion training, restrictions or recommendations on appropriate timing of exclusion, and mandatory notification of SCDNR if any of the bat species in this document are involved. Clemson University's Pesticide Regulation and Control, Clemson Extension, and SCDNR could partner in training and administering this program.
- If suitable designs for man-made alternate roosts prove effective, those plans should become mainstreamed by making the plans and placement guides available as a pdf document to be shared with organizations such as the South Carolina Wildlife Federation (SCWF).

MEASURES OF SUCCESS

Initiating, funding, managing, and continuing to run a long-term statewide acoustic bat project has been an efficient use of grant funds and hugely successful for providing data to determine bat species distribution and abundance across South Carolina. Statewide bat monitoring through winter hibernacula counts and summer mist-netting and tracking have

provided critical information such as survivorship from WNS, northern long-eared bat maternity roosts, and pup season timing. Any significant bat roost that is protected or created from these actions can be interpreted as success. Not all threats can be abated, though, such as flooding of natural roosts. Surveys and density estimates in the southern region should provide some population estimations, which will be used to more accurately rank the species and prioritize future management needs. It is important to determine important roost site locations to provide long-term habitat for the species.

DESCRIPTION

Taxonomy and basic description

Foliage roosting bats (also called tree bats) roost by hanging under leaves and branches, or often in the case of northern yellow bats (*Lasiurus intermedius*), under Spanish moss (*Tillandsia usneoides*). Tree bats rarely, if ever, roost in caves although they have sometimes been captured with colonial bats during fall swarming at cave entrances. These species have been documented roosting on the outside of buildings and behind shutters. The Genus name Lasiurus refers to the fact that these bats have hairy tail membranes (the membrane between the hind legs encompassing the tail). These are South Carolina's more colorful bat species. In addition to the northern yellow bat, South Carolina has the eastern red bat (*Lasiurus borealis*), the Seminole (*Lasiurus seminolus*) bat and the hoary bat (*Lasiurus cinereus*). These latter three species have fur to the tip of the tail membrane. The northern yellow bat tail membrane is not well furred entirely to the tip and the ears are somewhat pointed, not rounded like those of eastern red, Seminole and hoary bats. All these bats typically have 2-4 young in a single birth per year. These bats exhibit sexual dimorphism; the females are larger than the males, and females tend to have a frosted appearance to their fur.

The northern yellow bat was described by H. Allen in 1862, and the subspecies recognized in South Carolina is *Lasiurus intermedius floridanus*. The eastern red bat was described by Gray in 1831, and the closely related Seminole bat was first described in 1895 by Rhoads. Palisot de Beauvois described the hoary bat in 1796.

Northern yellow bat

The second largest bat in South Carolina, the northern yellow bat weighs 14 - 20 g (0.49 - 0.7 oz.) and has a total length of 127.6 mm (5 in.). The forearm measures 51 - 53 mm (2 - 2.1 in.) and foot measures 8 - 12 mm (0.3 - 0.47 in.). The fur is a silky yellow-orange with a faint wash of brown or gray on the tips.

Female eastern red bats have a light red base color with hairs frosted at the tips so their general appearance is lighter and have a more chestnut appearance than that of males who tend to be a brick red color. Both sexes have a crisp white patch at the wrist and shoulder. Individuals have an average weight of 15 g (0.53 oz.), and a body length of 13 cm (5.1 in). Ears are rounded and furred. The coloration of eastern red bats and Seminole bats gives them the appearance of dead leaves.

Eastern red bat, female

Seminole bat

Male Seminole bats are a rich mahogany and the larger females also have a mahogany base color but with frosted hairs. Like eastern red bats they have distinct white patches at the wrist and shoulder. Sizes vary from 8.8 - 12.1 cm (3.5 - 4.8 in.) body length and weighing 9 - 14 g (0.3 - 0.5 oz.). They have furry rounded ears.

Hoary bats are the largest bat in South Carolina weighing 25 g (0.9 oz.) on average, and their wingspan approaches 40 cm (16 in.). They are very attractive with distinct black ear margins and a dark muzzle, contrasted by yellow on the head and under the chin. The rest of the bat is a rich mahogany base color with light frosted tips. Females are larger than males but are not colored differently. This coloration allows a hoary bat to visually blend in with tree bark. The species is the most well-furred bat in South Carolina. Like the red and the Seminole bat, the hoary bat has white wrist and shoulder patches.

Status

The status of the northern yellow bat in South Carolina and Georgia is Vulnerable (S3). Mississippi regards the species as Imperiled (S2). Alabama and North Carolina rank the northern yellow bat as Critically Imperiled (S1) and of state special concern. The species has a global status of Apparently Secure (G5).

Eastern red, Seminole, and hoary bats are ranked as Vulnerable to Apparently Secure (G3G4). However, recent models suggest that hoary bat populations may become endangered due to mortality associated with wind energy developments. In South Carolina the state rank for hoary bats is Imperiled (S2). Georgia ranks hoary bats as Apparently Secure (S4), whereas North Carolina lists them as Vulnerable to Apparently Secure (S3S4). Seminole bats are ranked as Vulnerable (S3) in South Carolina and North Carolina, whereas in Georgia they are ranked Secure (S5). Eastern red bats are ranked as Vulnerable (S3) in South Carolina, but Secure (S5) in Georgia, Alabama, and North Carolina.

POPULATION SIZE AND DISTRIBUTION

The distribution of northern yellow bats is poorly known. They have been found in coastal New Jersey and Virginia, but the accepted range is typically farther south. They occur in the Outer Coastal Plain of South Carolina and into the Inner Coastal Plain along the Savannah River, and southward in the Coastal Plain of Georgia and Alabama and into Florida (Figure 1). North Carolina reports two records near South Carolina from New Hanover and Brunswick Counties.

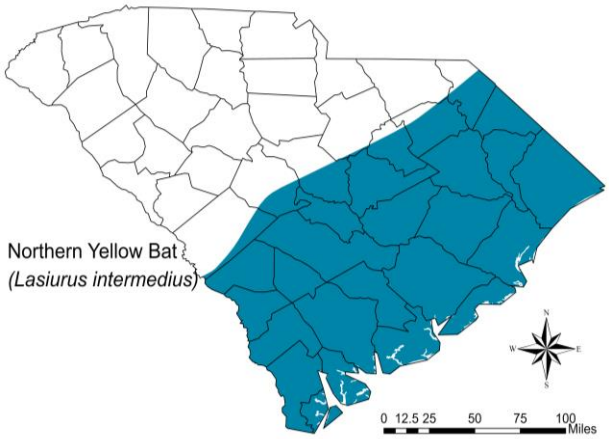

Figure 1. Distribution of the northern yellow bat in South Carolina.

Northern yellow bat density estimates are not available. In some locations in Florida, the northern yellow bat is the predominant species. There, feeding aggregations of more than 100 individuals, (mostly females) have been reported in mid to late summer. Males may congregate in the winter in Florida; the behavior in the Carolinas is unknown. The home range of an individual northern yellow bat in Georgia was reported as 10.5 ha (25.9 acres) in oak and pine habitat. The species is not known to be migratory.

Eastern red bats are distributed statewide and are considered year-round residents, but their numbers increase in the late fall and winter due to the arrival of winter migrants from the north. Hoary bats are distributed statewide in winter, but they are probably rare in the state during summer due to their likely migratory patterns. Hoary bats are more difficult to detect than eastern red bats because they typically forage higher than most net

and harp trap sets, but they have been detected in breeding condition in summer in the mountains. An adult hoary bat was found in the Piedmont, July 3, 2012. Little is known about eastern red bat and hoary bat migration. High mortality is seen in eastern red and hoary bats at wind energy facilities, particularly in spring and fall in forested regions of the Eastern United States.

Seminole bats have been found statewide, though only a few summer and fall records of Seminole bats in the upper Piedmont and Blueridge ecoregion exist. Seminole bats are more common in South Carolina's pine-dominated Inner and Outer Coastal Plains and lower Piedmont. They are non-migratory. Like northern yellow bats, Seminole bats will roost in clumps of Spanish moss. These bats can also roost behind loose bark. Roosts are typically 1- 4.5 meters above the ground.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Northern yellow bats are one of the least understood mammalian species in South Carolina. They occur in the Coastal Plains of South Carolina. Most of what is known about the species was derived from Florida. These bats forage over open areas such as fields, pastures, golf courses, marshes, and along lake and forest edges. Roosting habitat includes oak forests, long-leaf pine stands (*Pinus palustris*) in Florida sandhills, and live oak (*Quercus virginiana*) hammocks. Roosting sites are usually in clumps of Spanish moss or under old palm fronds. In South Carolina they roost in dead fronds of the Sabal palm (*Sabal palmetto*) or Spanish moss in hardwood forests. During summer they forage in open areas near water such as salt marshes, ponds, and fields but in winter they forage in bottomland hardwood forests, fields, and ponds.

Seminole and eastern red bat calls are too similar to differentiate using acoustic detectors so it is difficult to estimate relative abundance or habitat use where the species overlap without using radio telemetry. Eastern red bats prefer foraging in uncluttered stands (those which have been thinned). They roost on smaller branches or twigs, often in the hardwood tree canopy. Eastern red bats often prefer the dominant or co-dominant live hardwoods, and they may not use trees near forest margins. However, in North Carolina, males select roosts that are close to forest roads. Eastern red bats sometimes roost in the leaf litter, particularly during very cold periods, with their furry tail membrane pulled around their body up to their face. Thus, they may be vulnerable to predation and any activity involving disturbance of the leaf litter during winter periods.

Seminole bats roost in pine-dominated stands in summer. Preferred roost trees tend to be large pines located near forested corridors. Reproductive females choose the largest trees. Non-reproductive bats will use smaller trees (they are not limited to use of large pines only). During winter, Seminole bats are more likely to use both hardwood and pine stands for roosting. Like eastern red bats, Seminole bats use the leaf litter of the forest floor for winter roosting as well as overstory and understory trees.

Both Seminole and eastern red bats exhibit low roost site fidelity (i.e. they frequently switch trees) but have high site fidelity (they roost among different trees located within the same general area).

Seminole bats typically do not use hardwood forested streamside corridors for foraging but use upland forested corridors which typically have a pine component. Eastern red bats in managed forests in Mississippi show no preference for habitat types. Although eastern red bats are often in urban areas, at the landscape level they avoid areas with greater development.

Hoary bats typically roost 3-5 m (10 - 16 ft.) above the ground and will use tree cavities, trunks, tree foliage, squirrel nests, and Spanish moss. They inhabit coniferous and deciduous forests near clearings.

Studies on habitat use of these bats have not been abundant and evenly spread among physiographic regions or habitat types. Therefore, one cannot presume the information herein to be comprehensive and typical to all areas.

CHALLENGES

- Loss of habitat due to development (man-made alterations and anthropogenic changes).
- Loss of roost sites in the form of removal of old palm fronds (for cosmetic reasons) and harvest of Spanish moss.
- Loss of habitat and direct mortality from natural causes such as hurricanes.
- Collisions with wind turbines or injury from active turbines.
- Collisions with towers.

CONSERVATION ACCOMPLISHMENTS

A two-year study of northern yellow bat foraging ecology during summer and winter and summer roosting ecology was conducted at the Palmetto Bluff Conservancy, Pinckey Island National Wildlife Refuge, and Victoria Bluff Heritage Preserve. They were not detected in several bat surveys on coastal military installations but have been detected at Waccamaw National Wildlife Refuge and in several Coastal Plain counties through SC NABat acoustic surveys.

CONSERVATION RECOMMENDATIONS

Management

- Retain Spanish moss and old palm fronds on public lands to benefit northern yellow bats.
- Encourage retention of Spanish moss and old palm fronds on private lands to benefit northern yellow bats.
- Retain upland forest corridors to prevent isolation of Seminole bats.

- In the Piedmont region, timber management that creates uncluttered forest, such as pine thinning or controlled burns may benefit foraging bats.
- Work with wind energy development companies to mitigate impacts of wind turbines (e.g. increasing the cut-in speed of turbines to reduce mortalities).
- Advise forestry professionals to conduct controlled burns when minimum night temperatures are >4°C (39°F) and temperatures at the time of ignition are >10°C (50°F).

Priority research and survey needs

- Identify priority areas for field surveys for northern yellow bats.
- Determine northern yellow bat distribution, via surveys, in the Carolinas.
- Determine summer and winter roost site and habitat requirements for all lasiurine species.
- Gather migration information for red and hoary bats.
- Determine the extent of off-shore foraging and commuting and its seasonality to assess vulnerability of lasiurine bats to off-shore wind development.
- Determine vulnerability of lasiurine bats to coastal wind energy development, particularly during fall migration.
- Conduct molecular research to determine the validity of the yellow bat subspecies designation and the variation within the species across its known distribution.
- Determine if northern yellow bats are threatened by pesticide and / or heavy metal contamination.

Monitoring

- Monitor significant northern yellow bat roost sites, located by survey efforts, for continued usage.
- Maintain capture and location information for all lasiurine bats.
- Use NABat surveys to monitor lasiurine bats occupancy rates on a seasonal and annual basis.

Education, public outreach and cooperative efforts

- Educate home and landowners about the importance of northern yellow and other bats and discourage the practice of removing roosting habitat such as old palm fronds and large amounts of Spanish moss from trees.
- Create demonstration areas on publicly owned site(s), leaving old fronds uncut on palms in a highly visible area with prominent signage explaining that old fronds provide important roosting habitat for northern yellow bats.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized by those with the greatest conservation applicability. Surveys and density

estimates in the southern region should provide some population estimations that will be used to more accurately rank the species and prioritize future management needs. It is imperative to determine important roost site locations to provide long-term habitat for the species. Currently, very little is known about northern yellow bats in South Carolina.

Moles Guild

Hairy-tailed Mole (*Parascalops breweri*)
Star-nosed Mole (*Condylura cristata*)

Contributors (2005): Mary Bunch (SCDNR), Mark Ford (VA Tech),
and David Webster (UNC-W)
Reviewed and Edited (2012): Steve Fields (Culture and Heritage Museums)
and David Webster (UNC-W)
Reviewed and Edited (2024): Ben Cooper (SCDNR) and Jennifer Kindel (SCDNR)

TAXONOMY AND BASIC DESCRIPTION

Three species of moles occur in South Carolina. These include the eastern mole (*Scalopus aquaticus*), which is widely distributed and common. The other 2 species, the star-nosed mole (*Condylura cristata*) and hairy-tailed mole (*Parascalops breweri*), are less commonly encountered in South Carolina. All 3 possess velvety fur; eyes that are small and concealed in the fur; and large well-developed forelimbs with backward facing palms and long claws. They also lack external ear structures.

Star-nosed Mole Photo courtesy of ATBI

The star-nosed mole was first described by Linnaeus in 1758. Two subspecies are recognized for the star-nosed mole: *Condylura cristata cristata* and *Condylura cristata parva*. Star-nosed moles in South Carolina are considered to be *C. c. parva* (Peterson and Yates 1980). As the name implies, the rostrum of the star-nosed mole is star-like and consists of 22 fleshy appendages. Total length of this species ranges from 153 to 238 mm (6.24 to 9.3 in.). The moderately haired tail is approximately one-third to one-half the body length. The fur is black or a black-brown on the back (Peterson and Yates 1980; Webster et al. 1985; Laerm et al. 2005a).

Hairy-tailed Mole Photo by E.B. Pivorun

The hairy-tailed mole, first described by Bachman in 1842, is the smallest of South Carolina's moles, ranging from 139 to 174 mm (5.4 to 6.8 in.). The name suggests its identifying attribute, a densely furred tail. The tail is less than one-quarter of the body length. The fur is black to a gray-black on top and slightly paler underneath (Hallett 1978; Laerm et al. 2005b). Both mole species use their tail for fat storage; therefore, tail width varies with season and condition.

STATUS

Both species are of special concern in South Carolina. The state rank for the hairy-tailed mole is imperiled (S2) (NatureServe 2024). The star-nosed mole is ranked state-wide as vulnerable (S3) (NatureServe 2024). Both species have a global rank of secure (G5) (NatureServe 2024). The hairy-tailed mole is common in Pennsylvania (Merritt 1987) and appears to be secure (S5) in Virginia and apparently secure (S4) in Kentucky and North Carolina but is considered vulnerable (S3) in Tennessee and critically imperiled in Georgia (S1) (Lamer et al. 2005b; NatureServe 2024). The star-nosed mole, ranked as uncommon in South Carolina, is imperiled (S2) in Georgia and Tennessee and is considered apparently secure (S4) in North Carolina and Virginia (Laerm et al. 2005a; NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

There are no population estimates available in the southern end of the range (Southern Appalachians) for either the hairy-tailed or star-nosed moles. Laerm et al. (2005a, 2005b) reports both species as "uncommon" and the hairy-tailed mole as "rarely reported in appropriate habitat."

The hairy-tailed mole is restricted to the high elevation mountains of South Carolina within the Southern Appalachian Ecoregion (Figure 1).

The range for hairy-tailed moles extends from the mountains in South Carolina northward into southern Maine and extreme southern Canada (Hallett 1978).

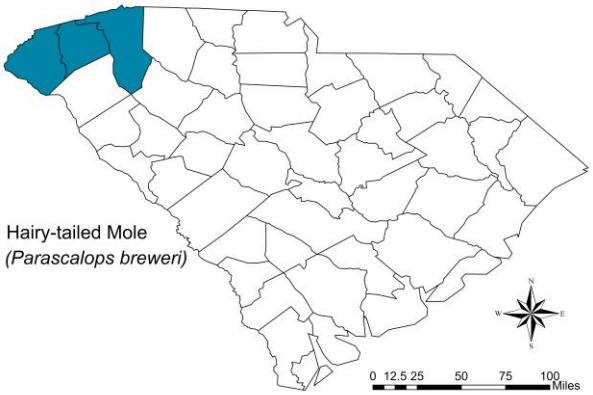

Figure 1. Distribution of the hairy-tailed mole in South Carolina.

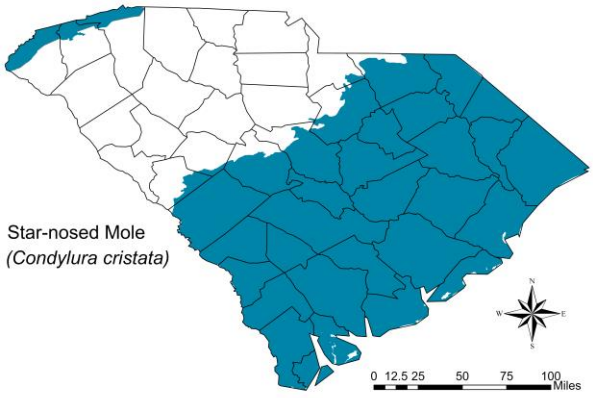

Figure 2. Distribution of the star-nosed mole in South Carolina.

The star-nosed mole extends both into South Carolina's mountains and the Outer and Inner Coastal Plains and Sandhills Ecoregions (Figure 2). There appears to be a gap in the distribution of star-nosed moles in the piedmont of South Carolina and most of the piedmont of North Carolina (Beane 1995).

The North American distribution for the star-nosed mole extends from Canada, down to and across New England and the Great Lakes states, southward along the Appalachians into Georgia and South Carolina. Additionally, it is found coastally through Georgia and extreme northern Florida (Peterson and Yates 1980).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Both the star-nosed and hairy-tailed moles are found in the southern Appalachian Mountains. Within that ecoregion, they show some overlap in habitat; both species use mesic mixed forest, mesic deciduous hardwood, and bottomland or floodplain forests. The latter habitat is extremely uncommon in the mountain ecoregion in South Carolina (Griffith et al. 2002).

Hairy-tailed moles are usually found in areas with elevations above 427 m (1400 ft.). Habitats for this species include fields and pastures, deciduous (including dry deciduous) needle-leaved evergreen forest, and mixed evergreen-hardwood forest. Often the habitat includes loose, easily drained, and excavated soil with cover. Soils are not typically wet or of high clay content. In the southern Appalachians, associated species that can occur in the same habitats as the hairy-tailed mole include several other South Carolina species of concern: the southern red-backed vole (*Myodes gapperi*), woodland jumping mouse (*Napaeozapus insignis*), star-nosed mole (*Condylura cristata*) and masked shrew (*Sorex cinereus*).

Star-nosed moles in the Southern Appalachian Ecoregion tend to be found in wetter sites than hairy-tailed moles, often found in sites such as swamps, marshes and bogs. Star-nosed moles are the most aquatic of our moles and construct tunnels that sometimes lead into water (Webster et al. 1985). Forested floodplains, forested and early successional bottomlands, mesic hardwood sites, and streamside areas typify habitats used by this species in the mountains. Additionally, star-nosed moles are found in sites with dense leaf litter.

The coastal and sandhills habitats for star-nosed moles include pocosins, wetlands, saturated bottomlands, and long-leaf pine habitat. Neither forest age nor successional stage has been reported as a critical factor determining habitat suitability for the star-nosed mole (Laerm et al. 2005a).

Both the star-nosed mole and the hairy-tailed mole burrow and will create both underground tunnels and surface tunnels. Nests are constructed underground. All moles are vulnerable to inundation; therefore, nests are built above the typical high-water level.

CHALLENGES

Scientists agree that additional surveys for star-nosed moles and hairy-tailed moles are necessary to better understand the distribution and abundance of these species. Additionally, in order to better understand the association with wet soils preferred by star-nosed moles, soil requirements should also be investigated for this species.

Cats, dogs, owls, foxes and snakes can all prey upon both species. Presumably, coyotes will also use star-nosed moles and hairy-tailed moles as a food source. Currently, none of these predators are reported to be major threats to the species' survival (Hallett 1978; Peterson and Yates 1980). Increased predation from cats and dogs is expected as residential development increases.

Increases in eradication from humans that view these species as nuisances can be expected. However, landscaping techniques exist that may reduce problems that result due to mole activity.

One of these techniques is to limit the use of mulch. Mulch favors water retention, which in turn attracts soil invertebrates, the food source for moles. By removing the habitat of these invertebrates, the area becomes inhospitable to moles. Exclusion techniques, such as mole fences or underground barriers, may also limit mole damage (Henderson 1994).

As the urban interface grows, increased impacts from development will occur. Development impacts can be measured by quantifying creation of impermeable surfaces, such as roads, buildings and parking lots (Laerm et al. 2005a). Direct loss of habitat is a threat, as are changes in hydrology associated with development. Laerm et al. (2005a) suggest that activities that permanently saturate the soil in sites occupied by star-nosed moles and hairy-tailed moles are detrimental. Neither the hairy-tailed nor star-nosed mole seems to be sensitive to seral stage; however, effects of timber harvests on localized, temporal water levels could cause nests to be flooded with ground water.

The recent range expansion of the nine-banded armadillo into the South Carolina Coastal Plain may represent a threat to the star-nosed mole due to competition for food resources. Predation by feral hogs may also present a threat to moles throughout their range.

CONSERVATION ACCOMPLISHMENTS

In South Carolina, the Andrew Pickens Ranger District of the Sumter National Forest, several mountain Heritage Preserves, Jocassee Gorges, several state parks, and some tracts owned or held in easement by various land trusts contain habitat for star-nosed moles and hairy-tailed moles. For example, over 12,141 ha (30,000 ac.) of mountain land is under conservation easement held by The Nature Conservancy. None of those properties were purchased specifically to protect either the star-nosed or hairy-tailed moles; however, both benefit from these acquisitions and the protection offered for their habitat.

SSURGO (Soil Survey Geographic database) level soils have been completed for the State in 2002. The Geological Survey is mapping structural geology for various areas of the state at 1:24,000-scale including the mountains and upper Piedmont (J. Scurry, pers. comm.). This new data may assist in defining mole habitat.

CONSERVATION RECOMMENDATIONS

- Discourage the construction of ponds in known star-nosed mole and hairy-tailed mole habitat and prevent increases in storm water run-off associated with development in known and potential habitats.
- Re-examine current South Carolina state rankings for these mole species as required under the Nongame and Endangered Species Conservation Act, in Chapter 15 under Title 50 of the Code of Law of South Carolina.
- Conduct ecoregion-wide surveys for distribution and density of both the star-nosed mole and the hairy-tailed mole in order to better understand their conservation status. Survey techniques should be standardized throughout the southeast so that results and data are readily comparable. All capture data should be made available to the most current

statewide Heritage Trust database. That information should also be shared with neighboring states.
- Complete a thorough identification of mountain bogs and seeps and their interface with upland sites to prioritize site surveys for the star-nosed mole and the hairy-tailed mole.
- Investigate specific limiting factors associated with habitats for both the star-nosed mole and the hairy-tailed mole.
- Investigate the effects of timber harvest on temporal water table levels and associated impacts to star-nosed mole distribution.
- Educate landowners and other members of the public about the ecological role and benefits of star-nosed moles and hairy-tailed moles.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized by those with the greatest conservation applicability. Surveys and density estimates in the southern region should provide some population estimations, which will be used to more accurately rank the species and prioritize future management needs.

Woodland Jumping Mouse

Napaeozapus insignis

Contributors (2005): Mary Bunch (SCDNR), Travis Perry (Furman University), Edward Pivorun (Clemson University), and Stanlee Miller (Campbell Museum, Clemson University)

DESCRIPTION

Taxonomy and basic description

The woodland jumping mouse (*Napaeozapus insignis*) was first named by Miller in 1891. The subspecies recognized in the southern Appalachians, based entirely on morphometric measurements, is *Napaeozapus insignis roanensis* (Whitaker and Wrigley 1972). Adults of this subspecies are 204 to 256 mm (8.0 to 10.1 in.) long, including the tail. The tail, which is longer than the body, is often white-tipped and bicolored; it is brown-gray on the top and whitish underneath and ranges in length from 115 to 160 mm (4.5 to 6.3 in.). Woodland jumping mice have large hind feet, 28 to 34 mm (1.1 to 1.3 in.), which are appropriate for jumping. The woodland jumping mouse is a colorful mammal: the fur on the sides is a yellow-orange and a dark wide stripe down the back is a red-orange-brown hue. The belly is white. Adults weigh 15 to 30 g (0.53 to 1.06 oz.) (Whitaker and Wrigley 1972; Webster et al. 1985).

Status

Woodland jumping mice are ranked as imperiled (S2) in South Carolina, as secure (S5) in Virginia, as apparently secure (S4) in North Carolina, Tennessee, and Kentucky, and as vulnerable (S3) in Georgia (NatureServe 2024). Their global rank is secure (G5) (NatureServe 2024). They are not listed on the IUCN Red list as a species of concern and their populations are considered stable (Cassola 2016).

POPULATION SIZE AND DISTRIBUTION

Woodland jumping mice range from Manitoba, Canada, eastward through Ontario, Quebec, Labrador, Nova Scotia and New Brunswick, and south through the Great Lakes region, New England, and the Mid Atlantic. As the range extends southward, it narrows to the confines of the Appalachian Mountains, ending in northern Georgia and northwestern South Carolina (Linzey 1995; Whitaker and Wrigley 1972; Webster et al. 1985; NatureServe 2024). See Figure 1.

Density estimates from the north vary at 0.64, 5.2, and 6.7 animals per hectare (0.26, 2.7, and 5.2 per acre, respectively), and home ranges are about 0.4 to 3.6 hectares (1 to 9 acres) (Whitaker and Wrigley 1972). It is not considered abnormal to have widely varying densities due to short life expectancies, high reproductive outputs, and a life cycle prone to fluctuation with seasons, weather, and predation cycles. No density estimates are available for the Southeast.

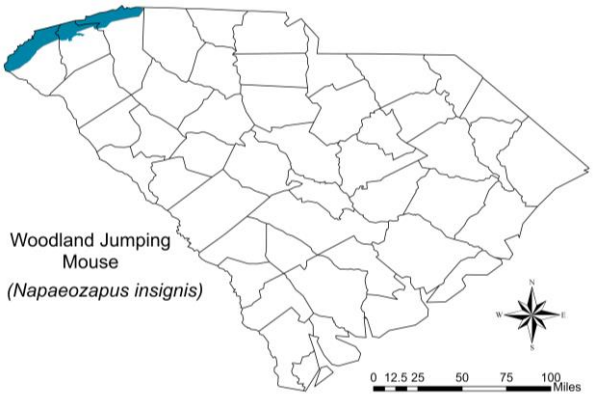

Figure 1. Distribution of the woodland jumping mouse in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Within the Southern Appalachian Ecoregion, woodland jumping mice are restricted to high elevation sites in cool moist habitats such as hemlock stands, sheltered cove hardwood stands with northern species, and Rhododendron draped streamside zones (Ford et al. 1994). In South Carolina, these animals have been found at elevations of 427 m (1,400 ft.) and above. Woodland jumping mice are true hibernators in the north (Merritt 1987); however, this behavior has not been studied or confirmed in the southeast. Hibernation requires reliably cold temperatures; this fact might explain their range restriction in the southeast.

The effects of logging or canopy removal on the habitat selection of woodland jumping mice is not clearly understood, but there are indications that these mice prefer moist habitats with abundant herbaceous cover rather than thick woody regeneration (Ford et al. 2000). South Carolina priority listed species that are sometimes associated with these same habitat characteristics in the southern Appalachians include the southern red-backed vole (*Clethrionomys gapperi*), eastern pygmy shrew (*Sorex hoyi*), star-nosed mole (*Condylura cristata*), and masked shrew (*Sorex cinereus*).

Woodland jumping mice have a varying diet of fungi, insect larvae, berries, seeds, nuts, and vegetation (Whitaker and Wrigley 1972). Studies indicate that woodland jumping mice consume significant amounts of the *Endogone* spp. and *Glomus* spp. fungi in both mixed mesic forest and eastern hemlock habitats (Williams and Finney 1964; Orrock et al. 2003). The presence or abundance of deer mice (*Peromyscus maniculatus*) is negatively correlated with consumption of the *Endogone* spp. fungi; in those situations, the jumping mice consume other fungal species (Orrock et al. 2003).

CHALLENGES

Challenges to the woodland jumping mouse include habitat fragmentation due to development and barriers created by associated structures such as 4-lane divided highways (NatureServe 2024). Additionally, hemlock wooly adelgids (*Adelgas tsugae*), an invasive pest, may threaten some suitable habitat sites if the hemlocks and associated fungi are killed or reduced (Evans

2004). Finally, global warming could shift suitable habitat farther north and into higher elevations not found in South Carolina (W. Mark Ford, pers. comm.).

CONSERVATION ACCOMPLISHMENTS

Some woodland jumping mouse habitat is protected on public lands such as the Jocassee Gorges and Caesars Head State Park.

CONSERVATION RECOMMENDATIONS

- Consider land acquisitions or conservation easements that provide linkage of appropriate habitat within the Southern Appalachian Ecoregion. Investigate the possibility of promoting or participating in regional efforts to establish such linkages.
- Encourage land managers to avoid canopy removal of mesic, high elevation sites and provide corridors linking appropriate habitat.
- Estimate woodland jumping mouse density for habitats in the southern part of the species' range.
- Conduct genetic research to determine if southern woodland jumping mice are distinct from northern conspecifics.
- Designate permanent monitoring sites on public land including a high elevation hardwood cove and a hemlock site.
- Work with partners to make information about the woodland jumping mouse available to the general public.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized for the greatest conservation applicability. Surveys and density estimates in the southern region should provide some population estimations, which will be used to more accurately rank the species and prioritize future management needs. Analysis of DNA and mtDNA will reveal the relatedness and genetic diversity of the northern versus southern woodland jumping mice.

Appalachian Cottontail

Sylvilagus obscurus

Contributors (2005): Mary Bunch (SCDNR), Rickie Davis (Clemson University), Stanlee Miller (Campbell Museum, Clemson University), and Rob Harrison (SCDNR)

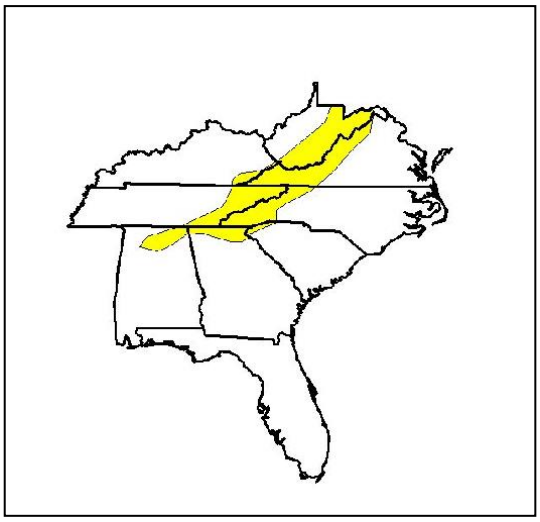
DESCRIPTION

Taxonomy and Basic Description

Photo by SCDNR

Appalachian cottontails were recently described by Chapman, Cramer, Deppenaar, and Robinson in 1992. The species was previously known as New England cottontail (*Sylvilagus transitionalis*) but was reclassified to Appalachian cottontail (*Sylvilagus obscurus*) based on chromosome number and exacting skull measurements. Ruedas et al. (1989) described the southern cytotype, now known as the Appalachian cottontail (Chapman et al. 1992), as having a smaller diploid chromosome compliment than the northern cytotype (the New England cottontail) (46 and 52, respectively). Although analysis of a region of mitochondrial DNA does not support the new species designation (Litvaitis et al. 1997), the Integrated Taxonomic Information System (USDA 2005) recognizes the new designation.



New England and Appalachian cottontails are indistinguishable without cranial examination or karyotyping (Chapman et al. 1992). The two are distinguished in the field by geographical location rather than by external features; those that occur south or west of the Hudson River in New York are Appalachian cottontails.

As with all "cottontails," including the sympatric Eastern cottontail (*Sylvilagus floridanus*), the underside of the Appalachian's tail is white. The fur is rusty-brown with black hairs. There are seldom any white hairs on the forehead and the ears are somewhat rounded (Chapman 1975) and less 'mulish' in appearance than Eastern cottontails. Sometimes the anterior ear margin is black or very dark in sharp contrast to the white hairs inside. Eastern cottontails have a rusty orange patch at the nape of the neck and often have the appearance of a dark saddle across their backs (Chapman 1975); the Appalachian cottontail has a reddish nape patch but is more uniformly dark. Live specimens have a very dark iris relative to Eastern cottontails (Bunch and Dye 1999). Appalachian cottontails have a diffuse gray cheek patch, lacking in the Eastern cottontail. The most reliable characteristic to distinguish Appalachian from Eastern cottontails is the presence of a dark patch between the ears in Appalachian cottontails (Litvaitis et al. 1991; Chapman et al. 1992). These differences between the Eastern and Appalachian cottontails are so subtle that identification usually requires handling of the animal. These two species are easily distinguished by skull characteristics (Chapman 1975).

The Appalachian cottontail is the smallest rabbit species in the southeast; adults weigh 0.8 to 1.1 kg (1.75 to 2.42 lbs.). They range in total length from 386 to 430 mm (15.5 to 17 in.), with an average ear length of about 58 mm (2.3 in.) (Chapman 1975). Weights of South Carolina specimens in the Campbell Museum of Natural History at Clemson University average 1.05 kg (2.32 pounds).

Status

In South Carolina, Appalachian cottontails are considered uncommon or rare and therefore vulnerable (S3). They are also considered rare in Georgia (Ozier 1999), Tennessee and North Carolina (NatureServe 2013). The Appalachian cottontail is still listed as apparently secure globally (G4). The fact that populations that occur in South Carolina are at the limit of the range of the species increases the responsibility of SCDNR to monitor the status of the population. Any changes to the viability of the species might likely occur on the periphery of its range.

POPULATION SIZE AND DISTRIBUTION

Appalachian cottontails occur in mountain habitat and range from the Hudson River in New York, southward through Pennsylvania and Maryland, and continue southward in the Appalachian Mountains into northwestern South Carolina, northern Georgia and Alabama. Appalachian cottontails are better adapted to colder climates than Eastern cottontails (Chapman et al. 1977). The Blue Ridge escarpment represents the extreme southeastern extent of the range for Appalachian cottontails.

The noncontiguous arrangement of Appalachian cottontails in the southeast is described as a mosaic distribution (Chapman et al. 1992). In South Carolina, the species is found only in the mountains of the three northwestern counties at elevations as low as 274 m (900 ft.), but more typically above 487 m (1600 ft.) (Bunch and Dye 1999). The Blue Ridge Mountain province in South Carolina has elevations between 365 and 1066 m (1,200 and 3,500 ft.) above sea level (Myers et al. 1986). Appalachian cottontails are restricted to the southern Appalachian ecoregion in South Carolina, which comprises only 1.7% of the state's total land area (Myers et al. 1986).

Distribution is patchy across the mountains of Oconee, Pickens and Greenville Counties. Suitable habitat is not uniform and continuous throughout the mountains. However, the Appalachian cottontail does not occur in all suitable mountain habitats. Some sites that appear suitable based on cover, forage, and elevation are occupied by Eastern cottontails, both Eastern and Appalachian cottontails, or no rabbits at all. Therefore, estimates of Appalachian cottontail populations cannot be extrapolated using remote sensing such as aerial photographs to identify habitat.

Density estimates have not been made for this rabbit in the southern end of their range; however, densities in South Carolina are expected to be similar to those found in other states. A density estimate from Virginia approximates one rabbit per two hectares in six to seven year-old clearcuts (Blymer 1976). Laseter (1999) estimated a density of 0.8 rabbits per hectare in eastern Tennessee. In western Maryland, home ranges are identified as 2 to 10 hectares (4.9 to 24.7 acres) for females and 4 to 9 hectares (9.9 to 22.2 acres) for males (Sommer 1997).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Ericaceous cover (heath-like plants) is a component of all sites occupied by Appalachian cottontails in the state (Bunch et al. 1997), which is consistent with previous reported requirements (Chapman et al. 1992). The cover varies and includes mountain laurel (*Kalmia latifolia*), blueberries (*Vaccinium* spp.), blackberry vines (*Rubus* spp.), greenbriar (*Smilax* spp.) and cane (*Arundinaria gigantea*). Sites with Appalachian cottontails range from ridgetops of pine-heath communities to mixed pine hardwoods and extend down slopes into riparian sites (Paul and Quay 1963). Forest or stand ages vary and include young clearcuts and pine plantations less than 4 years old; overstocked pine plantations approaching thinning age; and mature pine, pine-hardwood and hardwood forests (Bunch et al. 1997; Bunch and Dye 1999). Appalachian cottontails have not been noted in pastures, orchards or wildlife plots, but have been captured near the edges of linear food plots. Sole (1999) reported captures at reclaimed mine sites.

Good rabbit habitat is not thoroughly understood. Reproduction and rabbit health have been linked to salt availability (McCready and Weeks 1992), stem density and quality (Lochmiller et al. 1995) and availability of cover (Barbour and Litvaitis 1993; Smith and Litvaitis 2001). Appalachian cottontails require dense understory vegetation (Laseter, 1999). Appalachian cottontails consume more forbs and are less dependent on grasses than Eastern cottontails. However, both rabbits eat significant amounts of woody material in the winter (Spencer and Chapman 1986).

CHALLENGES

Due to regional differences between habitats in the southern Appalachian mountains and the New England area, management needs for the Appalachian cottontail are likely very different from management needs for the New England cottontail. Therefore, lack of species-specific makes it difficult to successfully manage for the Appalachian cottontail.

Small patch size (less than 2.5 hectares or 6.1 acres) and habitat fragmentation are known to lead to low survival rates of New England cottontails (Barbour and Litvaitis 1993). Habitat fragmentation, often due to development, may limit Appalachian cottontails to public lands with extensive private inholdings and to areas where large public tracts are separated by private holdings; such areas currently exist in northeastern Greenville County.

Indirect displacement by Eastern cottontails is a possible threat, particularly where both species are found sympatrically and permanent clearing takes place for pastures, lawns, orchards, golf courses and housing developments. Eastern cottontails benefit more from grasses (Spencer and

Chapman 1986) and large grassy areas than Appalachian cottontails; the latter needs more cover (Litvaitis et al. 1985; Barbour and Litvaitis 1993; Sommer 1997). Although Eastern cottontails are not capable of evicting New England cottontails from occupied habitats and vice versa (Probert and Litvaitis 1996), once habitats are modified to favor Eastern cottontails and they move into the site, it is unlikely that New England cottontails will displace them. Because Appalachian cottontails are similar to New England cottontails behaviorally and in cover and habitat requirements (Tefft and Chapman 1987; Probert and Litvaitis 1996), they are expected to respond similarly.

Hunting is not known to adversely affect the species in South Carolina; however, pregnant and lactating rabbits have been captured in February before the end of hunting season on March 1. Species-specific rabbit hunting data are not currently collected, and small game hunting pressure is believed to be light in the mountains. It is currently legal to possess and move all native rabbit species in the state of South Carolina. However, release of Eastern cottontails into habitat of Appalachian cottontails remains a threat of undetermined proportion or likelihood. Historically, moving and releasing rabbits was a common practice (Chapman and Fuller 1975). Once Eastern cottontails are established, they cannot be displaced via interspecific competition. Eastern cottontails can colonize neighboring disturbance patches more quickly than Appalachians because the latter requires dense cover in close proximity while Eastern cottontails are well adapted to foraging in open areas (Smith and Litvaitis 2000). Therefore, the Eastern cottontail more easily accesses new habitat (Probert and Livaitis 1996).

Cottontails are taken by a wide variety of predators including cats, dogs, coyotes, foxes, bobcats, mink, weasels, birds of prey and snakes. Any activity that increases the density of predators, or any changes in habitat that make Appalachian cottontails more vulnerable to predation (Litvaitis and Villafuerte 1996), are a threat.

CONSERVATION ACCOMPLISHMENTS

The species was first documented in South Carolina by a 1940 museum specimen collected by W. Perrygo and J. Hoyt. In the 1980's, the South Carolina Department of Natural Resources (SCDNR), initiated survey work with Check for Wildlife funds to verify the species' presence in South Carolina.

SCDNR tested a discriminate model developed by Litvaitis et al. (1991) for field identification of Appalachian (then known as New England) cottontails. Identifications were confirmed by mtDNA analysis and skull characteristics. The model was 77.7% accurate on southeastern specimens. One consistent external feature was the black spot or strip between the ears in Appalachian cottontails (Bunch and Dye 1999).

A study was conducted in the Sumter National Forest to assess whether Appalachian cottontails would be displaced after timber harvest in a mature pine-hardwood forest. This forest was adjacent to or near two habitats: a young clear cut and an orchard, which were occupied by Eastern cottontails. The mature pine-hardwood stand was cut and burned. Eastern cottontails used the site as it regenerated, and Appalachian cottontails did not reappear at the site until seven years after site regeneration (Bunch and Dye 1999).

In South Carolina, a significant amount of appropriate Appalachian cottontail habitat in the southern Appalachian ecoregion is on public land or is otherwise protected, including the Andrew Pickens Ranger District of the Sumter National Forest, ten Heritage Preserves, and the Jocassee Gorges; the latter is managed by SCDNR. Suitable habitat is also on several large state parks and some tracts owned or held in easement by various land trusts, including over 12,140 ha (30,000 acres) of mountain land under a conservation easement held by The Nature Conservancy. Over 65,559 ha (162,000 acres) of mountain lands are protected in some capacity.

CONSERVATION RECOMMENDATIONS

- Encourage land acquisitions or conservation easements which will provide mountain habitat linkage. Consider regional partnerships for habitat protection in the Blue Ridge Escarpment.
- Discourage or avoid creation of new, permanent, early successional habitat on mountain sites on public lands adjacent to existing populations of Eastern cottontails until the impact of Eastern cottontails on Appalachian cottontails is better understood.
- Evaluate the impact of hunting on Appalachian cottontails. Breeding condition should also be noted in harvested animals to evaluate seasons and bag limits. If rabbit identification by hunters is unreliable, heads and tissue samples can be collected and used to improve accuracy.
- Conduct an ecoregion-wide Appalachian cottontail distributional and density survey using mtDNA analysis of fresh fecal pellets.
- Partner with states throughout the entire range of both Appalachian and New England cottontails to provide materials and samples for expanded mtDNA analysis of these rabbit populations and support nuclear genome analysis for these species.
- Determine best management practices for Appalachian cottontails in the southeast through habitat measurements and manipulations.
- Measure the effectiveness of salt licks and fertilizing sites on Appalachian cottontail condition and reproduction.
- Evaluate prescribed burning as a tool for proper habitat management.
- Periodically survey selected sites for Appalachian and Eastern cottontails.
- Discourage moving and releasing Eastern cottontails.
- A demonstration area for Appalachian cottontails could be developed in the mountains in conjunction with efforts to highlight other species of conservation concern in South Carolina. This demonstration area would also provide research opportunities for new information on management and ecological needs of the species.
- Develop web links and educational materials to help educate the public about wildlife diversity, especially that of rabbits, in the mountain ecosystems.

MEASURES OF SUCCESS

Surveys of distribution and density, paired with long-term monitoring of harvests and use at specific sites will help assign status information to the species and set appropriate harvest limits and seasons. Researching the effects of controlled burns and supplemental salt will help public and private landowners know if those actions will benefit Appalachian cottontails.

DESCRIPTION

Taxonomy and Basic Description

The swamp rabbit, *Sylvilagus aquaticus*, was first described by Bachman in 1837. Swamp rabbits, or "cane-cutters", are the largest species of rabbit in the southeastern United States. These rabbits range in total length from 452 to 552 mm (17.8 to 21.7 in.) and range from 1900 to 2700 g (4.5 to 6 lbs.) in weight (Chapman and Feldhamer 1981; Webster et al. 1985). Weights of South Carolina specimens in the Campbell Museum of Natural History at Clemson University range from 1700 to 2300 g (3.74 to 5.07 lbs.).

Swamp rabbit, © Clayton Bownds (CC BY-NC)

The fur of swamp rabbits is rusty-brown with black hairs, giving the animals a grizzled appearance. Similar to the eastern cottontail (*Sylvilagus floridanus*) and the Appalachian cottontail (*Sylvilagus obscurus*), the underside of the tail is white. This differs from the bluish gray tail of the marsh rabbit (*Sylvilagus palustris*).

Status

In South Carolina, these rabbits are considered vulnerable (S3) due to habitat loss and limited habitat availability. In Alabama and neighboring Georgia, the swamp rabbit is ranked as secure (S5), while in Tennessee the species is apparently secure (S4; NatureServe 2024). The Global Heritage Rank is secure or G5 (NatureServe 2024), yet data from several states, including Arkansas, Missouri and Kentucky, indicate populations are imperiled due to loss of habitat (Platt and Bunch 2000) and range shrinkage (Sealander and Heidt 1990; Schwartz and Schwartz 1981; Sole 1994).

POPULATION SIZE AND DISTRIBUTION

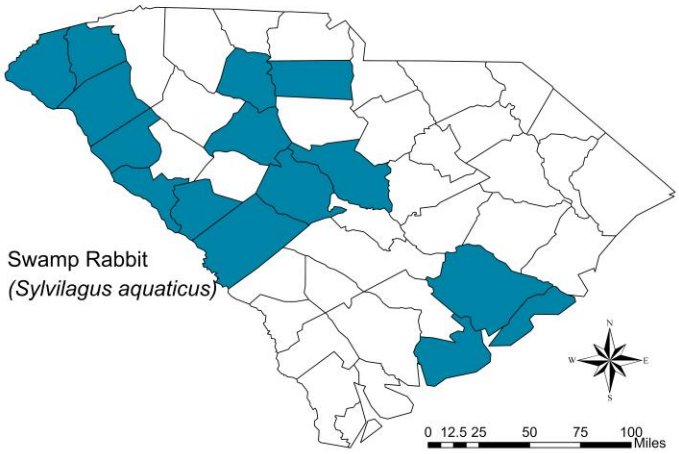

Figure 1: Distribution of the swamp rabbit in South Carolina

Swamp rabbits are distributed from the Gulf of Mexico, northward along the Mississippi River to Illinois and Indiana, eastward to the western Piedmont of South Carolina, and westward to east Texas and Oklahoma (Chapman and Feldhamer 1981). In South Carolina, most occurrences are in Anderson, Oconee, and Pickens Counties in the Savannah River drainage of the western Piedmont region (Platt and Bunch 2000). Recent surveys conducted from 2021–2023 documented swamp rabbits in Abbeville, Aiken, Anderson, Charleston, Edgefield, Lexington, McCormick, Newberry, Oconee, Pickens, Richland, and Union Counties (Figure 1), suggesting a more extensive distribution than previously thought (S.N. Harris, Clemson University, unpub. data, 2024). There is also one confirmed historical record from York County (Platt and Bunch 2000) and unverified reports from Chesterfield, Greenville, Kershaw, Marlboro, and Orangeburg Counties (Golley 1966); M. Hook, SCDNR, unpub. data, 2024). It is unclear whether disjunct records east and south of the bulk of confirmed records represent historically-occurring populations or more recent range expansions.

Swamp rabbit population size and density estimates are unavailable for South Carolina. In a Georgia floodplain, swamp rabbits had an average maximum home range of 7.6 hectares (18.9 acres) and a density of 0.14 animals per hectare (0.05 animals per acre) (Lowe 1958). Home ranges in Missouri average 1.82 to 2.43 hectares (4.5 to 6 acres) (Schwartz and Schwartz 1981). An occupancy probability at potential swamp rabbit locations derived from visual pellet surveys in South Carolina was 0.32 (S.N. Harris, Clemson University, unpub. data, 2024). Results from this study also indicated that swamp rabbits persisted at 83% of sites with previous swamp rabbit records that the researchers were able to visit.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

As indicated by their common name, swamp rabbits tend to be found in close proximity to water. In some parts of its range, the species is considered a bottomland hardwood forest specialist, and thus an indicator species for the quality of this ecosystem (Hilliard et al. 2017). The home range of swamp rabbits in Indiana is limited to within two kilometers (1.24 miles) of water (Terrel 1972); this is likely to hold true throughout the entire range for this species. In South Carolina, habitat varies from swamps and wet scrub/shrub land to forested bottomlands. Swamp rabbits are often associated with, but not restricted to canebrakes dominated by switchcane (*Arundinaria gigantea*) (Platt et al. 2001). A recent study in the state found that swamp rabbit occupancy was positively associated with proximity to emergent herbaceous or woody wetlands and lower percentages of tree canopy cover, the latter potentially highlighting the importance of open,

sunny areas with herbaceous vegetation to the species (S.N. Harris, Clemson University, unpub. data, 2024).

Korte and Fredrickson (1977) reported that viable swamp rabbit populations require contiguous habitat in areas exceeding 100 ha (247.1 acres); however, Sole (1994) suggests that this figure needs to be re-evaluated. Sole found that in Kentucky, about one third of the occupied habitat was in woodlots less than 100 ha in size that were sometimes isolated or connected by narrow bands to other suitable habitat.

Logs, stumps and tree falls are an important component of swamp rabbit habitat. These structures are used for latrine sites, resting cover, and nesting (Zollner et al. 2000a; Platt and Rainwater 2001). Like all of South Carolina's rabbits, swamp rabbits prefer dense thickets that provide suitable cover.

CHALLENGES

Hydrologic changes that result from flooding associated with dam construction and filling, channelization, ditching, and draining of wetlands are well-recognized challenges to swamp rabbit populations throughout their range. In South Carolina, a significant portion of swamp rabbit habitat was inundated by the construction of Lake Hartwell. Habitat is also lost as a result of pond construction, urban development, road construction and land clearing for agricultural activities. Two sites reported by Platt and Bunch (2000) along U.S. 123 have since been destroyed by urban development.

Because swamp rabbits inhabit floodplains and wetlands, they are vulnerable to flooding. Floods during the breeding season can be especially deleterious to populations. Although flooding is a natural phenomenon, urban development tends to alter natural floodplains, resulting in more frequent and, often, more severe flooding than is usually expected (C. Gawne and Lee Mitchell, personal communication, 2004). As stated above, hydrologic changes will result from urban development, and Upstate South Carolina, where the majority of swamp rabbit records come from, is currently experiencing rapid growth in human population (i.e., a 10.7% increase between 2010 and 2020; U.S. Census Bureau 2021). An unpublished study conducted by SCDNR demonstrated a four-fold increase in development for every one-fold increase in population between 1983-1998 (Richard Lacy, personal communication, 2004). For this study, development was measured by impermeable surfaces such as pavement and buildings. This increase in flow to rivers and streams often results in erosion of streambeds. Once this erosion begins, the streams and rivers become vulnerable to flash flooding.

The impact of hunting on swamp rabbits has not been determined. Swamp rabbit populations on small tracts of land and those isolated by development or well-traveled roads tend to preclude the use of hunting dogs, thereby reducing the threat of hunting. Current data collected from rabbit hunting does not require hunters to distinguish the rabbit species that was taken.

Most of the suitable swamp rabbit habitat in South Carolina is on private land. Therefore, the future of the species in South Carolina and throughout much of its range largely depends on the

stewardship of private lands (Sole 1994). It is important that the landscape and local flooding history be a consideration in site protection design (Zollner et al. 2000b).

There is some evidence that swamp rabbits at the periphery of their range occur in a metapopulation of smaller, isolated subpopulations (Roy Nielsen et al. 2008). As South Carolina represents the eastern extent for this species, it is possible that swamp rabbits in the state have a metapopulation structure, meaning naturally-disjunct subpopulations are at greater risk of localized extinction.

Rabbit haemorrhagic disease virus type 2 is an emerging pathogen with a high mortality rate (USDA-APHIS 2024) that has been documented in domestic rabbits and in wild lagomorphs in the western United States (Asin et al. 2022). However, no outbreaks in wild lagomorphs in the eastern United States have yet been reported.

CONSERVATION ACCOMPLISHMENTS

The U.S. Army Corps of Engineers designed and constructed Lake Hartwell. Because their boundary line follows the approximate 204 m (670 ft.) contour around Lake Hartwell, some swamp rabbit habitat along creeks and rivers flowing into the lake was protected during development of the lake. Other public lands that offer protection for the swamp rabbit include U.S. Forest Service, SCDNR, and Clemson University properties.

CONSERVATION RECOMMENDATIONS

- Partner with private and public landowners to maintain swamp rabbit habitat via whatever means are available, including but not limited to acquisitions, conservation easements, designations of green spaces, and encouragement of stewardship by private landowners.
- Partner with federal agencies, such as the Army Corps of Engineers, the Natural Resources Conservation Service, and the U.S. Fish and Wildlife Service, to protect more wetland habitat.
- Evaluate the impact of hunting on swamp rabbit populations and improve collection of harvest data from rabbit hunters.
- Partner with hunters to collect habitat information for the swamp rabbit.
- Estimate the amount of habitat necessary to sustain a viable population of swamp rabbits.
- Conduct surveys of suitable habitat in the Southeastern Plains and Middle Atlantic and Southern Coastal Plain ecoregions to determine how far east and south the swamp rabbit's range extends in the state.
- Determine swamp rabbit density within selected study populations and determine population size estimates based on available habitat.
- Evaluate the genetic makeup and health of swamp rabbit populations in the state (genetic diversity, gene flow, metapopulation status, etc.)
- Communicate with other agencies and engage with new scientific literature to monitor for pathogen outbreaks and epizootics that may adversely affect swamp rabbits in South Carolina.
- Monitor suitable swamp rabbit habitat by aerial photography over regular intervals.

- Produce brochures and web links to better educate South Carolinians on this unique species of rabbit.
- Where possible, restore wetlands that exist within the range of the swamp rabbit. The restoration work could be used for public outreach, giving school groups or community organizations hands-on experience in wetland restoration. A recent successful example of this was conducted at Rocky River Nature Park, a known swamp rabbit site (S.N. Harris, Clemson University, unpub. data, 2024), where a volunteer workday was carried out in March 2024 to remove invasive species. Part of the pretext for this work was that a population of the "rare swamp rabbit" inhabited the park (https://www.upstateforever.org/events/58/volunteer-workday-rocky-river-nature-park-invasives-removal, accessed 2024 May 30).

MEASURES OF SUCCESS

Density estimates, paired with habitat information, will allow evaluation of the amount of potential habitat and remote assessment of habitat levels. The effectiveness of partnerships protecting wetlands and other properties that contain swamp rabbits can be assessed when paired with the monitoring of those populations.

DESCRIPTION

Taxonomy and Basic Description

Masked Shrew. Photo by E.B. Pivorun

All shrews have long pointed snouts, short dense fur, and small eyes. The ears blend in well with the surrounding fur. The masked shrew was first named by Kerr in 1792 (Laerm et al. 2007*a*), the eastern pygmy shrew by Baird in 1858, and the smoky shrew by Kerr in 1792 (Laerm et al. 2007*b*). The eastern pygmy shrew and the masked shrew closely resemble each other; both are small with gray-brown fur on the back and a more faded version underneath. Both have distinctly bicolored tails, dark above and pale underneath, that are more than half the head and body length (Webster et al. 1985). In the summer, the eastern pygmy shrew has a reddish hue to its pelage, whereas the masked shrew has a brown hue. In contrast, the smoky shrew is slightly larger with dark gray to blackish-gray fur in winter and brownish fur in summer with a lighter hue underneath for both coats (Owen 1984). Similar to its congenerics, the smoky shrew also has a bicolored tail more than half the length of its head and body which is dark above and pale underneath (Laerm et al. 2007*b*).

Eastern pygmy shrew. Photo by Roger Barbour/ ATBI Program

Only one subspecies of masked shrew, *Sorex cinereus cinereus*, is found in South Carolina. The total length of this animal ranges from 80 to 111 mm (3.1 to 4.3 in.), including a tail of 34 to 48 mm (1.34 to 1.9 in.). Masked shrews weigh 3 to 5 g (0.10 to 0.17 oz.).

Eastern pygmy shrews are the smallest mammal in South Carolina, weighing only 2 to 4 g (0.07 to 0.14 oz.), about the weight of a dime (Webster et al. 1985). They range in total length from 70 to 96 mm

(2.7 to 3.8 in.; Ford et al. 2007). Tail length is 25 to 34 mm (0.99 to 1.34 in.). The most reliable distinguishing feature is a third upper unicuspid tooth (one with only one point) that is reduced when compared to preceding unicuspids. In shrews found sympatrically with eastern pygmy shrews, such as the masked shrew or the southeastern shrew (*Sorex longirostris*), the third upper unicuspid is similar in size to other unicuspids (Long 1974). *Sorex hoyi winnemana* is the only subspecies of eastern pygmy shrew known from the extreme southern range, including from within South Carolina (Diersing 1980). The eastern pygmy shrew was originally classified as *Microsorex hoyi*. Diersing (1980) subsequently determined that the species was more appropriately classified in the genus *Sorex; microsorex* was reclassified to a subgenus. [Note: North Carolina's Wildlife Action Plan lists the eastern pygmy shrew by subspecies and Georgia's Comprehensive Wildlife Conservation Strategy does not list it at all.]

Relatively large for a shrew, the smoky shrew (*Sorex fumeus)* weighs 6 to 10 g (0.21 to 0.35 oz.) and ranges in total length from 104 to 130 mm (4.09 to 5.11 in.) with a tail length of 37 to 52 mm (1.45 to 2.04 in; Laerm et al. 2007*b*). Their fur in summer is dark gray to brownish, and in winter is blackish gray. Only one subspecies of smoky shrew, *S. f. fumeus*, occurs in South Carolina (Laerm et al. 2007*b*).

Status

The masked shrew, eastern pygmy shrew, and smoky shrew all have a global rank of secure or G5 (NatureServe 2024). This species is considered secure (S5) in the northern part of its range from Virginia north through the continental United States, through Canada and into Alaska (NatureServe 2024). The state rank for the masked shrew is imperiled (S2) in South Carolina and Georgia, and the species is listed as vulnerable (S3) in Kentucky but considered apparently secure (S4) in North Carolina and Tennessee (NatureServe 2024).

The eastern pygmy shrew is ranked as imperiled (S2) in South Carolina, Georgia, and Tennessee, as vulnerable (S3) in North Carolina, and as apparently secure (S4) in Virginia and Kentucky but is designated as critically imperiled (S1) in Alabama (NatureServe 2024).

The smoky shrew is listed as vulnerable (S3) in South Carolina and Georgia, as apparently secure (S4) in North Carolina and Tennessee, and as secure (S5) in Virginia and Kentucky, but is ranked as critically imperiled (S1) in Alabama (NatureServe 2024).

These species are considered of conservation concern in interest of maintaining the biological diversity of the state of South Carolina. Each species is indicative of habitats that are uncommon in the state and, therefore, provides an index of proper management of such habitats.

POPULATION SIZE AND DISTRIBUTION

South Carolina's mountains represent the southeastern most extent of masked, eastern pygmy, and smoky shrew distribution. The masked shrew extends into Alaska and western Canada, ranging into the Rocky Mountains, while all three species occur in eastern Canada and across much of the Great Lakes region, New England, and down the Appalachians to northern Georgia and South Carolina (Figures 1 and 2). The eastern pygmy and smoky shrews' ranges extends

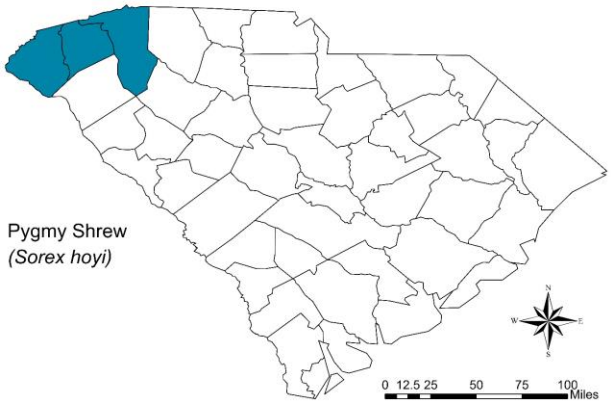

Figure 1. Distribution of the eastern pygmy shrew in South Carolina

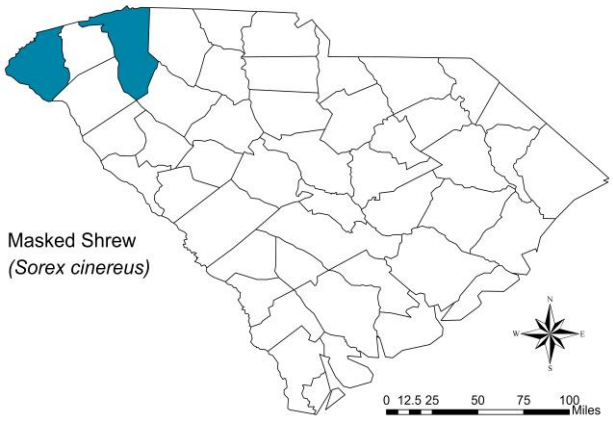

Figure 2. Distribution of the masked shrew in South Carolina

westward into Alabama (NatureServe 2024). Masked shrews are at the extreme edge of their range in Georgia and South Carolina. Here, they are uncommon and found only at high elevations or in sheltered coves (Ford et al. 1994; Laerm et al. 1995).

Though there are no recent records of the smoky shrew in South Carolina, historical records of this species exist in Oconee, Pickens and Greenville Counties (South Carolina Heritage Trust 2024).

There are no population estimates available in the southern Appalachians for the eastern pygmy, masked, or smoky shrew.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Masked, eastern pygmy, and smoky shrews are restricted to the southern Appalachian (Blue Ridge) Ecoregion in South Carolina. Within that ecoregion, masked and eastern pygmy shrews show some overlap in habitat; both species use mesic mixed forest, mesic deciduous hardwood, dry deciduous forest, and eastern hemlock ravine forests. The smoky shrew prefers mesic deciduous hardwood forests and moist coniferous or mixed forests (Laerm et al. 2007*b*). Masked and smoky shrews are more selective in their southern habitats and tend to use more northern-type communities like high elevation sites (Laerm et al. 2007*a*, 2007*b*). The eastern pygmy

shrew is rather prevalent throughout most mountain habitats (Ford et al. 2007; Laerm et al. 2007*c*). Masked shrews use sites with thick understory, high soil moisture, and high organic matter (Brannon 2000, Laerm et al. 2007*a*). Features like logs, stumps, rocks, and dense leaf litter are often components of masked and smoky shrew habitat (Laerm et al. 2007*a*, 2007*b*). Masked, eastern pygmy, and smoky shrews are not sensitive to timber harvest or prescribed burning in the central Appalachians provided that moist conditions with abundant ground structure remain (Ford et al. 2007; Laerm et al. 2007*b*).

Shrews are beneficial mammals in that they eat many grubs and larvae, which are often pest species (Merritt 1987). Predators of the masked, pygmy, and smoky shrew include domestic and feral cats and dogs, hawks, owls, foxes, coyotes, weasels and snakes. None of these predators are currently reported to be major threats to these species' survival.

CHALLENGES

In South Carolina, a large portion of the habitat in the Appalachian ecoregion that is appropriate for masked, eastern pygmy, and smoky shrews is on public land which includes National Forests, State Parks, Nature Conservancy properties, and DNR managed properties. None of these properties were purchased specifically to protect these shrews; however, these species benefited from acquisition and protection of habitat. While these protected areas provide needed habitat, populations on private lands are still threatened by land conversion. Land development in the southern Appalachians represents a major threat to masked, eastern pygmy, and smoky shrews. Land use in this region is rapidly changing from rural/agricultural to urban. An unpublished study conducted by SCDNR showed a 4-fold increase in development to every one-fold increase in population between 1983 and 1998 (Richard Lacy, personal communication). Increased predation from domestic cats and dogs, direct displacement from development, and limited movement across roads that form barriers are expected as development increases in the southern Blue Ridge Mountains.

Shrews and some other rodent species are readily found dead in discarded glass and plastic uncapped bottles; sometimes multiple animals are trapped in a single bottle. Therefore, unnecessary losses associated with refuse entrapment represent one of the challenges that litter poses to the ecosystem.

Destruction of hemlock forests by the exotic hemlock wooly adelgid (*Adelges tsugae*) may also impact local masked shrew populations (Laerm et al. 2007*a*). It is important that entire hemlock-associated communities be sampled and monitored at permanent plots in order to measure effects of hemlock wooly adelgid infestations and to evaluate the effectiveness of recent releases of exotic predatory beetles to control the infestation (Conway and Culin 2004).

CONSERVATION ACCOMPLISHMENTS

As previously mentioned, a large portion of the South Carolina habitat in the Blue Ridge ecoregion that is appropriate for masked, eastern pygmy, and smoky shrews is on public land which includes National Forests, State Parks, Nature Conservancy properties, and DNR managed properties.

CONSERVATION RECOMMENDATIONS

- Re-examine current state rankings for masked, eastern pygmy, and smoky shrews. Adjust those rankings based on any new surveys as appropriate.
- Conduct ecoregion-wide surveys to determine masked, eastern pygmy, and smoky shrew distribution and density. All capture data should be shared with neighboring states.
- Consider partnerships that can help educate the public that litter can be extremely harmful to native wildlife.
- Encourage various groups to increase litter removal.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized by those with the greatest conservation applicability. Surveys and density estimates in the southern region should provide population estimations that will be used to more accurately rank the species and prioritize future management needs. The effectiveness of anti-litter campaigns can be readily verified by the amount of trash removed before and after the projects.

Eastern Spotted Skunk
Spilogale putorius

Contributors (2005): Jay Butfiloski (SCDNR) and Tom Swaygnham (SCDNR)
Reviewed and Edited (2012): Jay Butfiloski (SCDNR)
Reviewed and Edited (2024): Stephen Harris (Clemson), David Jachowski (Clemson)

DESCRIPTION

Taxonomy and Basic Description

Photo by Roger Barbour (ATBI, Smoky Mountains National Park)

The eastern, or Alleghanian, spotted skunk is smaller than the more common striped skunk (*Mephitis mephitis*). The spotted skunk ranges from 0.5 to 1.8 kg (1 to 4 lbs.) in weight and from 250 to 688 mm (10 to 27 in.) in overall length (Crabb 1944; Hall and Kelson 1959; Walker 1964; Patton 1974). Males are approximately 10% larger than females (Van Gelder 1959). Pelage is typically dark black with 4 to 6 broken white stripes, which give the animal the appearance of being spotted. An inverted, white, triangle-shaped nose patch is usually present and is separate of the broken white stripes. The fur is denser and finer than that of the striped skunk (Zeiner 1975).

Spotted skunks breed in late winter or early spring and may delay implantation for up to two weeks. Gestation lasts 45 to 60 days. One litter per year generally produces one to six young. Young are born from April through July and are weaned by about 8 weeks of age; May and June are the peak breeding months for this species (Contantine 1961).

Like other members of the genus, eastern spotted skunks have well-developed scent glands that are often used for defense. The paired anal glands are located in nipples just inside the anus. Musk is discharged after the nipples protrude through the anus as the tail is elevated (Crabb 1948). One of the more curious behaviors displayed by the spotted skunk is a headstand that is used in defensive posturing. The skunk will move towards the threat, balance itself on its forelegs and direct the anal sacs towards the opponent (Johnson 1921).

Status

Eastern spotted skunk populations have declined since at least the mid-1900s (Gompper and Hackett 2005). State NatureServe rankings indicate that the species is not secure in the states it is known to occur in (NatureServe 2024). It is currently ranked as critically imperiled in Maryland and Mississippi (S1) and imperiled (S2) in Pennsylvania, South Carolina, and West Virginia. The species is considered vulnerable and/or imperiled (S2S3) in Alabama and Kentucky).

Additionally, the International Union for Conservation of Nature (IUCN) Red List status for the species is Vulnerable and a decreasing population trend is noted (Gompper and Jachowski 2016).

POPULATION SIZE AND DISTRIBUTION

The eastern spotted skunk's range extends from southern Pennsylvania, down the Appalachian Mountain range and into Florida, with a portion of the eastern edge of its range encompassing the western portion of South Carolina (Figure 1). Unlike the striped skunk, which has a more uniform distribution within its geographic range, the spotted skunk is typically more localized in its distribution (Perry et al. 2021).

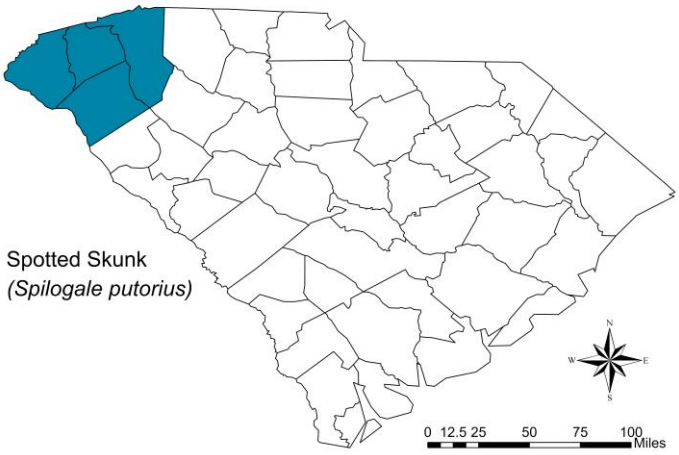

Figure 1: Distribution of the spotted skunk in South Carolina

The eastern spotted skunk is known primarily to persist in the Blue Ridge Mountains of Upstate South Carolina, with a majority of records within the past 10 years coming from Oconee, Pickens, and Greenville Counties. Little is known about its distribution throughout the Piedmont, though there is a recent observation from Anderson County. Historical records (>40 years ago) exist for Aiken, Edgefield, and Richland Counties. No recent observations have occurred in the Coastal Plain, despite the species commonly occurring in coastal environments in Florida (Kinlaw et al. 1995). Little is known about the population size and extent of the spotted skunk's distribution in South Carolina, although the infrequent rates of detection in structured camera surveys suggest they occur at low densities relative to other furbearers.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In the Appalachian Mountains, eastern spotted skunks are found in both young/early-successional forest stands (Eastern Spotted Skunk Cooperative Study Group 2020) as well as mature forest stands at higher elevations (Thorne et al. 2017). Regardless of stand age, they prefer dense understory cover and coarse woody debris (Reed and Kennedy 2000, Diggins et al. 2015, Wilson et al. 2016, Thorne et al. 2017, Eng and Jachowski 2019*a*). A study in the Blue Ridge Mountains of South Carolina showed spotted skunk occupancy probability decreased with increasing elevation, suggesting that lower elevation habitats in the Upstate could be occupied by this species (Eng and Jachowski 2019*a*).

Dens are important requirements for eastern spotted skunks as they are used as protection from weather and predators (Crabb 1948). Multiple studies have demonstrated that cover (e.g., canopy cover, understory cover) and coarse woody debris are important factors in den site selection in the Appalachian Mountains (Sprayberry and Edelman 2018, Eng and Jachowski 2019*b*, Hassler et al. 2021, Thorne and Ford 2022, Siegfried et al. 2023). The presence of rocks (e.g., rock

outcrops; Hassler et al. 2021, Thorne and Ford 2022) and proximity to drainage channels (Eng and Jachowski 2019*b*) have also been positively correlated with skunk den site selection in the Appalachian Mountains.

CHALLENGES

A diverse suite of threats likely limit eastern spotted skunks in South Carolina. Upstate South Carolina is one of the fastest-growing regions in a state that that is currently outpacing the percent change seen in resident human population of the United States as a whole (U.S. Census Bureau), so habitat for spotted skunks will likely continue to be fragmented or entirely lost. As natural areas are transformed to developed areas, skunk populations are expected to decline. Because skunks prefer dense cover and such areas are generally not found in developed areas, habitat loss will lead to these population declines.

Conversion of small-scale farms to larger industrial operations and refinement of agricultural practices have had a negative effect on eastern spotted skunks (Gompper and Hackett 2005, Eastern Spotted Skunk Cooperative Study Group 2019). Similarly, the maturation of early-successional forests has likely led to the species' decline as it loses the dense woody cover associated with these forest stands (Eastern Spotted Skunk Cooperative Study Group 2020). In fact, a 37% decline in suitable area for the species since its decline in the mid-1900s has been suggested (Cheeseman et al. 2021).

Spotted skunks, as one of the smallest carnivores, are also sensitive to the presence of other carnivores in the systems they occupy (Jachowski et al. 2024). As human development changes the abundance of larger carnivores in these systems, it is likely these processes have cascading effects on spotted skunks and deserve future research attention.

Further, humans tend to be very intolerant of skunks due to the animals' defensive behaviors. Skunks that do not attempt to relocate as development occurs are likely to be considered nuisance wildlife and may be removed or destroyed as development continues.

An outbreak of canine distemper that killed half of the study population of eastern spotted skunks in a recent study in western North Carolina (Harris et al. 2021) highlights the possible detrimental effects of cyclical or novel epizootics on small or isolated populations. Spotted skunks are also known to be sensitive to a diversity of other diseases, although the population-level impacts of these diseases is poorly understood (Eastern Spotted Skunk Cooperative Study Group 2020).

Also, anticoagulant rodenticide exposure has not been documented in spotted skunks thus far, but morbidity or mortality due to exposure has been documented in imperiled carnivore species in North America and globally (Keating et al. 2024). More information is needed on the potential threat rodenticides may pose to eastern spotted skunks as rodents are known to be an important food item (Crabb 1941).

CONSERVATION ACCOMPLISHMENTS

In South Carolina, considerable portions of the Blue Ridge ecoregion have been protected for conservation by federal and state agencies including SCDNR and the U.S. Forest Service. While these areas were not designated to further conservation of this species, they are largely dense forest areas that are used by spotted skunks.

The reporting requirements of the annual commercial fur harvest were modified so that trappers were asked to differentiate between striped and spotted skunks. It was hoped that this data would be utilized to evaluate long-term trends, but no one has yet to report spotted skunks in their harvests.

CONSERVATION RECOMMENDATIONS

- Manage forested lands for silvicultural treatments that retain understory vegetation and coarse woody debris.
- Determine population size and viability of resident spotted skunk populations in the Upstate.
- Determine the distribution, abundance, and habitat requirements of spotted skunks in the Piedmont and Coastal Plain of South Carolina.
- Continue camera trap-based monitoring of spotted skunk populations in the Upstate to determine long-term trends in occupancy, colonization and extinction.
- Educate residents that there are 2 different skunk species in South Carolina and there are beneficial aspects of spotted skunks; these animals are not killing poultry, getting into garbage cans, and are indicators of healthy and biodiverse ecosystems.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized by those with the greatest conservation applicability. Within the upstate, research is needed on the abundance and population viability of resident spotted skunks. State-wide surveys and density estimates are needed to provide information on the current distribution of the species and prioritize future management needs.

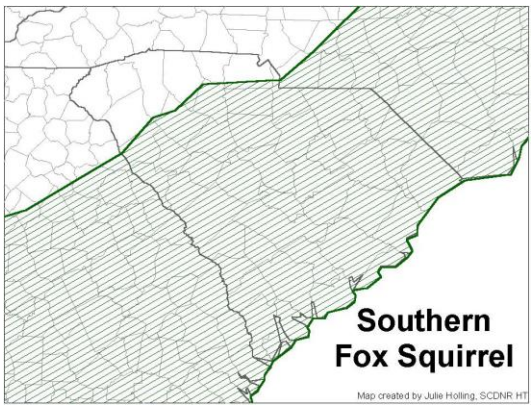
DESCRIPTION

Taxonomy and Basic Description

Photo by Phillip Jones



Fox squirrels (*Sciurus niger*) were first described by Linnaeus (1758); ten recognized subspecies exist throughout the United States. These arboreal mammals range in length from 450 to 698 mm (17 to 27.5 in.) and weigh 0.5 to 1.2 kg (17.6 to 42.3 oz.). Coloration varies greatly, both locally and regionally; this variation has resulted in subdivision into numerous subspecies (Hall 1981). Fox squirrel subspecies can be divided into two distinctive but intergrading coloration groups (Weigl et al. 1989). Six subspecies (*S. n. vulpinus*, *S. n. cinereus*, *S. n. niger*, *S. n. shermani*, *S. n. avicennia* and *S. n. bachmani*) have silver, gray, agouti (grizzled) and/or melanistic (black) pelage with tan, gold or reddish undersides. In this coloration group, animals have black head markings, white or gray noses, and white ears and feet. The other coloration group contains four subspecies (*S. n. vulpinus, S. n. subauratus, S. n. ludovicianus*, and *S. n. limitis*) that are characterized by a distinctly reddish, orange, or tan agouti (grizzled) pelage, a grizzled or black nose, and no white markings on the head or feet. Melanism is common in the southern portions of the range (Lowery 1974; Kiltie 1989; Roe 1994). However, Turner and Laerm (1993) concluded that pelage characteristics are too varied and subjective to permit consistent determination or subspecies in the southeastern portions of the range. The fox squirrel is readily distinguished from the smaller gray squirrel (*S. carolinensis*) by its larger size and presence of only a single pair of premolars in the upper and lower jaws.

Status

The eastern fox squirrel has state rank of apparently secure (S3S4) in South Carolina and a global rank of secure G5 (NatureServe 2024). However, it is listed as vulnerable (S3) in North Carolina and Alabama, as apparently secure (S4) in Virginia, and as secure (S5) in Arkansa, Florida, Georgia, Kentucky, Louisana, Mississippi, Oklahoma, Tennessee, and Texas. The Delmarva Peninsula fox squirrel (*S. n. cinereus*) is federally listed as endangered (US Department of Interior 2003). The fox squirrel is considered a game animal and its harvest seasons are regulated in all states in the southeast (Edwards et al. 2003). Concerns for the

conservation status of the southern fox squirrel are due to the lack of information on the distribution, abundance and ecology of the species.

POPULATION SIZE AND DISTRIBUTION

The southern fox squirrel (*Sciurus niger niger*) is the only fox squirrel native to South Carolina (Edwards et al. 2003). Populations are scattered across the South Carolina Coastal Plain, occur less often in the Piedmont (Wood and Davis 1981; Harrigal 1993), and are rare to absent in the Blue Ridge (Harrigal 1993). According to the 2024 SCDNR Biennial Fox Squirrel Survey Report Southern fox squirrels have been documented in every county in SC except Greenville and York counties. (Hook 2024) In Georgia the species is most common in the Coastal Plain and Piedmont and rare to absent in the Blue Ridge (Hilliard 1979; Turner 1988; Turner and Laerm 1993). Fox squirrels in North Carolina are restricted to the southeastern Coastal Plain south of the Pamlico River (Weigl 1987); although historical records indicate its former occurrence in the Piedmont and Blue Ridge (Lee et al. 1982), the fox squirrel is now rare to absent (Weigl 1987).

Fox squirrel populations east of the Appalachians and along the eastern Gulf Coast have been declining dramatically over the past 100 years (Doutt et al. 1977; Webster et al. 1985; Loeb and Lennartz 1989; Weigl et al. 1989; Humphrey and Jodice 1992, Loeb and Moncrief 1993; Conner et al. 1999). Density estimates in the southeast range from 0.1 to 75 per square km (0.2 to 185 per square acre) (Moore 1957; Hilliard 1979; Humphrey et al. 1985; Weigl et al. 1989; Tappe 1991; Tappe et al.1993; Lee 1999).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Southeastern fox squirrels select more pine-dominated habitats compared to the deciduous habitats selected by the midwestern subspecies (Weigl et al. 1989). In southern Florida, they occur in cypress swamps, tropical hardwood forests, live oak (*Q. virginiana*) forests, and mangrove forests (Humphrey and Jodice 1992). Throughout the lower Coastal Plain, fox squirrels occur in fire-maintained longleaf pine (*P. palustris*) turkey oak (*Q. laevis*) sand hills, pine flatwoods and associated bottomland habitat (Moore 1957; Williams and Humphrey 1979; Kantola 1992; Wooding 1997; Conner et al. 1999). The preferred habitat of fox squirrels in the sandhills and piedmont of the Carolinas, Georgia and elsewhere is mixed stands of longleaf, loblolly (*P. taeda*) and shortleaf pine (*P. echinata*), hardwoods and bottomlands (Taylor 1973; Hilliard 1979; Dueser et al. 1988; Edwards et al. 1989; Loeb and Lennartz 1989; Weigl et al. 1989; Loeb and Moncrief 1993). Throughout its range, parks, golf courses and residential areas may support substantial fox squirrel populations (Jodice and Humphrey 1992).

Fox squirrels use tree cavities and leaf nests both as refugia and for rearing young. Leaf nests occur in a variety of tree species including both hardwoods and pines. Fox squirrels use cavities

in a variety of tree species. Cavity use is greatest during winter and spring (Nixon and Hansen 1987; Edwards et al. 1989; Edwards and Guynn 1995). Hilliard (1979) and Weigl et al. (1989) suggested that the absence of suitable cavity trees might be a critical factor in litter survival and subsequent recruitment of fox squirrels in Georgia and North Carolina. However, others have found no evidence that an absence of cavities was limiting fox squirrels in Florida or Georgia (Kantola 1986; Edwards and Guynn 1995).

Throughout their range, fox squirrels produce two litters per year; breeding is concentrated in late winter/early spring and, to a lesser extent, in summer (Moore 1957; Hoffman and Kirkpatrick 1959; Harnishfeger et al. 1978; Weigl et al. 1989; Larson 1990). Reproductive success is highly variable and dependent on demographic and environmental factors such as availability and timing of food sources, availability of cavities, and weather (Nixon and McClain 1969).

The diet of the fox squirrel is diverse and varies seasonally and by region (Flyger and Gates 1982). Nuts, seeds, buds, and flowers of pines (*Pinus* spp.), oaks (*Quercus* spp.), hickories (*Carya* spp.), beech (*Fagus grandifolia*), walnut (*Juglans* spp.) and other available hardwood species like maple (*Acer* spp.) are major components of the squirrel's diet. Soft mast, such as dogwood (*Cornus* spp.), grape (*Vitis* spp.), persimmon (*Diospyros virginiana*) and cherry (*Prunus* spp.), various fruits, fungi, and insects are also eaten.

CHALLENGES

The widespread loss of preferred habitat, including mature, open pine-oak forests and associated bottomland and swamps is detrimental to fox squirrels throughout the southeast. Practices that have contributed to habitat loss include large-scale monocultural replacement of longleaf pine by loblolly pine, shortened stand rotation, loss of hardwoods, and fire suppression (Weigl 1987; Loeb and Lennartz 1989; Weigl et al. 1989; Dueser and Handley 1991; Humphrey and Jodice 1992; Kantola 1992).

Habitat improvement practices for fox squirrels generally target forest structure and tree species composition. Changes in forest structure affect overstory and understory densities and tree cavity availability. Tree species composition markedly affects mast production. Specific management practices vary among regions. The primary factor in maintaining fox squirrel populations in forest stands after harvest is sustaining adequate levels of winter-storable tree seeds (Nixon et al. 1975). Chamberlain et al. (1999) and Yarrow and Yarrow (1999) provide management guidelines specific to Mississippi and Alabama, respectively. Streamside management zones offer an option for providing high-quality habitat and travel corridors for fox squirrels in areas affected by even-aged forest management. Studies in the southeast suggest that forest management practices that reduce dense understory vegetation and promote retention of mature mast-producing hardwoods will benefit fox squirrels. Such practices include the use of prescribed fire, mowing and retention of hardwood stringers in pine-dominated habitats (Kantola 1986; Edwards et al. 1989; Lee 1999; Chamberlain et al. 1999; Conner et al. 1999).

Fox squirrels also benefit from the promotion and retention of cavity trees. Although cavity trees benefit both fox and gray squirrels, cavities are a more important habitat component for gray squirrels (Sanderson et al. 1980; Flyger and Gates 1982; Edwards and Guynn 1995).

The fox squirrel is a popular small game animal. Hunting mortality is considered compensatory to some extent, and is generally not thought of as a major factor controlling squirrel populations (Conner 2001). However, intensively hunted populations may be particularly vulnerable to overharvest depending on their level of isolation and potential for recolonization from nearby refuges or other lightly hunted areas (Allen 1943; Nixon et al. 1974; Herkert et al. 1992). In South Carolina, no distinction is made between hunting regulations for fox and gray squirrels on private lands, which contain the bulk of suitable fox squirrel habitats. Tappe and Guynn (1998) suggested that it might be more appropriate to manage southern fox squirrels differently than the gray squirrel because the former requires large home ranges and has a lower reproductive rate. Hunting fox squirrels is prohibited on many wildlife management areas in South Carolina.

CONSERVATION ACCOMPLISHMENTS

Fox squirrels have been protected from hunting mortality on over 61% Wildlife Management Areas within South Carolina. Additionally, a sighting survey to determine fox squirrel distribution in South Carolina was performed in 1989 and became a biennial event beginning in 1994. Statewide distribution of fox squirrels appears to be stable based on county distribution of sightings in the fox squirrel sighting survey. The data are not appropriate for estimating abundance as the number of personnel and sighting effort vary greatly between survey periods. A restoration project on St. Phillips and Hall Islands, South Carolina suggests translocation of fox squirrels may be a useful tool in restoring and augmenting fox squirrel populations throughout the Southeast (Senecal 2001). Fifty-two fox squirrels were released on the islands in 1999 and 2000. Annual survival of translocated fox squirrels was similar to reported rates in native populations and reproduction was documented.

Since 2004, successful restoration projects for southern fox squirrels have taken place on Yeamans Hall, Bailey Island, Clemson Sandhills Research and Education Center and Botany Bay Plantation Heritage Preserve and Wildlife Management Area in Charleston County. All squirrels translocated in these projects came from within South Carolina.

CONSERVATION RECOMMENDATIONS

- Consider southern fox squirrel habitat requirements when managing for red-cockaded woodpeckers (*Picoides borealis*) as these two species often occur sympatrically.
- Consider southern fox squirrel habitat when restoring longleaf pine/wiregrass ecosystems.
- Encourage landowners and developers to consider southern fox squirrels when planning and constructing developed areas such as golf courses, parks and residential communities.
- Encourage maintenance of mature (greater than 50 years) loblolly and longleaf pine stands that have open canopies and sparse midstories. When possible, encourage landowners to maintain mature stands on their properties.

- Use prescribed burning to maintain sparse midstories in pine and mixed pine/hardwood stands on SCDNR properties. Encourage other landowners to also use prescribed burning to provide habitat for southern fox squirrels.
- Utilize fox squirrel translocation as a population restoration and conservation tool when suitable unoccupied habitat is identified and fox squirrel donors are available.
- Document the distribution and population status of southern fox squirrels in South Carolina, particularly in the piedmont.
- Conduct studies of dispersal patterns, feeding habits, translocation success, hunting mortality and population dynamics for southern fox squirrels.
- Conduct landscape-scale research studies to determine the effects of anthropogenic-induced habitat fragmentation and loss.
- Establish a survey protocol to periodically monitor southern fox squirrel population trends on WMAs and large SCDNR land holdings.
- Estimate harvest of fox squirrels on game harvest surveys.
- Continue the biennial fox squirrel sighting survey.

MEASUREMENTS OF SUCCESS

The ongoing biennial survey has shown population fluctuations from year to year. At this point, there is not enough data to determine if this is a cyclical pattern of a stable population. Over time, biologists hope that the population in South Carolina can be stabilized or increased. As research and management needs are identified, projects will be initiated to address those needs.

Meadow Vole

Microtus pennsylvanicus

Contributors (2005): Travis Perry (Furman University) and Mary Bunch (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Photo by John White©

The meadow vole was originally described by George Ord in 1815 (*in* Guthrie 1815) from specimens collected "in meadows below Philadelphia" and was named *Microtus pennsylvanicus* (Wilson and Reeder 1993). A single subspecies, *Microtus pennsylvanicus pennsylvanicus*, occurs in South Carolina.

The meadow vole is a small to medium sized rodent and is characterized by relatively small eyes, inconspicuous ears, and a short tail. Meadow voles range in total length from 140 to 196 mm (5.5 to 7.7 in.) and in weight from 33 to 65 g (1.2 to 2.3 oz.) (Hall 1981; Tamarin 1999). The pelage is dark brown above and silvery gray beneath (Brown 1997). Meadow voles are best distinguished from South Carolina's other vole species, the pine or woodland vole (*Microtus pinetorum),* by 4 characteristics: (1) pine vole tails are barely longer than the hind foot whereas meadow vole tails are 2 to 3 times the length of the hind foot; (2) pine voles have elongate fore-claws relative to meadow voles; (3) pine voles (25 to 33 g; 0.88 to 1.16 oz.) are typically much smaller than meadow voles; and (4) the second upper molar in pine voles has four dentine islands; there are five to six dentine islands in the meadow vole.

Status

The meadow vole is a globally secure (G5) species (NatureServe 2024); however, the IUCN states that at least five of 26 subspecies are of conservation concern (MacDonald et al. 1998). The species *M. pennsylvanicus* is listed as vulnerable (S3) in South Carolina where it is at the edge of its geographic range (NatureServe 2024). An apparent isolated population of meadow voles in the Charleston area may be of particular concern. In Georgia, the species is vulnerable (S3) while in North Carolina it is considered secure (S5) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Meadow voles purportedly range throughout the upper piedmont of South Carolina with an isolated population(s) in Charleston (Sanders 1978) and southern Georgetown County (Figure 1). Meadow vole populations fluctuate, sometimes dramatically from several to several hundred per hectare, within a period of 2 to 5 years (Krebs and Myers 1974).

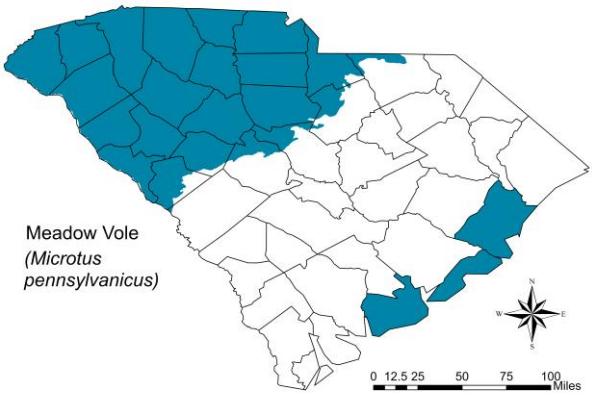

Figure 1. Distribution of the meadow vole in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Meadow voles depend on grassland habitat. Apparently, density and height of grass cover are more important than food quality in determining the suitability of habitats in maintaining high, stable vole populations. In a 25-year study, Getz et al. (2001) found that meadow vole populations exhibited the highest densities and lowest fluctuations in tall grass prairie habitats as compared to bluegrass and alfalfa habitats, which had successively lower cover and increased food quality.

Meadow voles coexist with numerous other small mammal species. In the southern Appalachians, meadow voles generally coexist with star-nosed moles (*Condylura cristata*), southern bog lemmings (*Synaptomys cooperi*), and meadow jumping mice (*Zapus hudsonius*). However, there is some evidence to suggest that meadow voles avoid areas where short-tailed shrews (*Blarina brevicauda*) are present (Fulk 1972), and previous studies indicate that there may be competitive avoidance between meadow voles and other vole species (Klatt 1986 and Blatzi et al. 1999). Evidence of this phenomenon has not been investigated in South Carolina meadow and woodland voles.

CHALLENGES

The major challenge to meadow vole populations is most likely habitat loss. Dense grassland habitats are lost through at least three mechanisms: agricultural development via cultivation or grazing, urban development, and the natural process of community succession whereby fields and meadows revert to pine or hardwood forest in the absence of disturbances such as fire. An additional problem may be displacement of native grasses by those favored for livestock production.

CONSERVATION ACCOMPLISHMENTS

To date, very little work has been done on the status or management of the meadow vole in South Carolina. However, from 2001 to 2003, researchers at Furman University worked closely with SCDNR biologists to assess the effects of vegetation type, fire and mowing on meadow vole populations in an old field on the Bunched Arrowhead Heritage Preserve in Greenville County. The results of these studies indicated that mowing is the preferred means of maintaining early successional habitats as voles moved back into mowed habitats sooner than burned habitats. Further, meadow voles preferred dense stands of planted switchgrass (*Panicum virgatum*) to naturally regenerated stands of broomsedge (*Andropogon virginicus*) and blackberry briar (*Rubus* spp.) or planted stands of deer tongue (*Panicum clandestinum)*.

CONSERVATION RECOMMENDATIONS

- Conduct a multi-year live-trapping survey of suitable habitats throughout the historical range. As meadow vole populations are known to fluctuate dramatically within periods of two to five years, areas will need to be surveyed over successive years to ensure that populations cycling through low density are not overlooked. Use Sherman live traps to survey known populations and suitable habitats annually during mid to late summer when densities should be highest. A standard trapping protocol should be used to enable reliable comparisons across years and sites. A trap density of 50 per 1/20 hectare (0.5 acre) in a grid formation should be sufficient.
- Investigate the apparently disjunct populations in the Charleston area with molecular techniques to determine if this isolate is unique and deserving of more serious independent conservation concern.
- Consider purchase of lands where meadow voles are documented on large areas of pasture or old-field habitat that can be easily maintained in an early succession grassland community.
- To the extent feasible, plant switchgrass (*P. virgatum*) and other tall, dense, native grassland species in open areas on existing SCDNR lands and mow on a two-year cycle to ensure tall dense stands and prevent conversion of grassland areas to brush and woodland.
- Partner with local colleges to complete initial survey work for meadow voles through educational field exercises.

MEASURES OF SUCCESS

Surveys and monitoring will allow the re-evaluation of the status of the species in South Carolina. The molecular study of the coastal versus piedmont animals will allow researchers to discern the appropriate taxonomic designation of the coastal animals.

Southern Red-backed Vole

Contributors (2005): Edward Pivorun (Clemson University) and Mary Bunch (SCDNR)
Reviewed and Edited (2013): Edward Pivorun (Clemson University)
Reviewed and Edited (2024): Ben Cooper (SCDNR) and Jennifer Kindel (SCDNR)

DESCRIPTION

Taxonomy and basic description

The southern red-backed vole was first described by Vigors in 1830 (Gapper 1930) and is a member of the group of rodents termed microtine or arvicoline rodents. This species is readily distinguished from the other voles in South Carolina by the presence of a reddish dorsal pelage, with grayish sides and a silvery white to pale yellow underside pelage. The reddish color is usually present as a broad band running from the forehead to the rump. The tail is bicolored. The ears are relatively prominent and extend above the fur. Females possess eight mammae. Young voles are gray until their post-juvenile molt, which occurs at approximately 30 days of age. There is no sexual dimorphism. Adult length is 116 to 172 mm (4.57 to 6.77 in.) with a tail length of 30 to 50 mm (1.18 to 1.98 in.). Adult weight varies from 14 to 42 g (0.49 to 1.48 oz.). In general, the animals from the Appalachians are larger than their northern counterparts (Whitaker and Hamilton 1998). The skull has a short rostrum, large auditory bullae, and the palate ends posteriorly as a straight, transverse shelf in contrast to the structure of the palate of other microtines.

The subspecies of southern red-backed vole that occurs in South Carolina is the Carolina red-backed vole, *Clethrionomys gapperi carolinensis* (formerly *Myodes gapperi carolinensis*. This subspecies is present in the Appalachian Mountains from northern Georgia north through eastern Tennessee, western North Carolina, the northwest corner of South Carolina, western Virginia and West Virginia. The separation line between *Clethrionomys gapperi carolinensis* and *Clethrionomys gapperi gapperi* is farther to the north in Virginia and West Virginia (Whitaker and Hamilton 1998).

Status

This species is tracked by the South Carolina Department of Natural Resources (SCDNR) Heritage Trust database and is of special concern in South Carolina. The state rank for the southern red-backed vole is imperiled (S2) (NatureServe 2024), which indicates it is rare;

the factor that makes the species vulnerable is the limitation of suitable habitat within South Carolina. This species has a global rank of secure (G5) (NatureServe 2024). The southern red-backed vole is listed as apparently secure (S4) in West Virginia and Tennessee, as secure (S5) in Virginia and North Carolina, and as vulnerable (S3) in Georgia (NatureServe 2024). The species currently has no status rank in Kentucky (NatureServe 2024). Southern red-backed voles are included on the IUCN Red List as a species at lower risk/least concern (Cook and Kirkland, Jr. 1998; Lizney and NatureServe 2008; Cassola 2016), because the species is widespread, common, and no major threats have been noted across most of its range.

POPULATION SIZE AND DISTRIBUTION

The southern red-backed vole is distributed throughout Canada and the northern tier of states in the US. The range of this species extends south in the Appalachian Mountains to northern Georgia (Wharton and White 1967; Merritt 1981).

There are no population estimates available in the southern Appalachian Mountains, which represent the southern end of the southern red-backed vole's range. However, trapping records from collections in Highlands, North Carolina and the Smoky Mountains National Park indicate that this species can attain high densities and maintain viable populations in suitable habitats (Pivorun, pers. obs.). In addition, the population was observed to cycle over 5 to 8 year intervals in the Highlands, North Carolina National Forest lands (Pivorun, pers. obs.); 6 to 10 year cycles (Patric 1962; Grant 1976) and 4.4 year cycles (Elias et al. 2006) have been observed in other localities. There is such a paucity of trapping records from South Carolina that no data are available on population cycles.

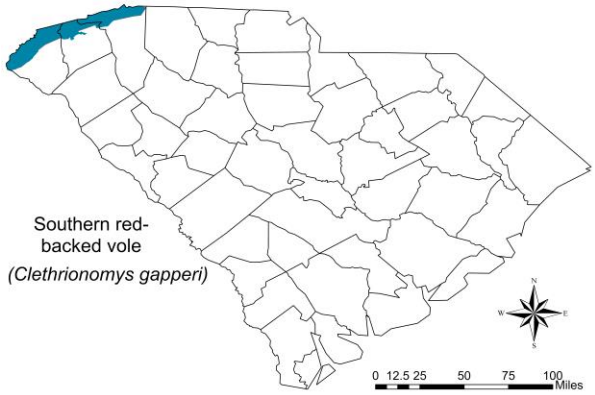

Figure 1. Distribution of the southern red-backed vole in South Carolina.

The southern red-backed vole is restricted to the higher elevation habitats of South Carolina within the Southern Appalachians Ecoregion. Currently, the only published records for this species are from Oconee (Pivorun et al. 1984) and Pickens Counties (Laerm et al. 1995). Suitable habitat for the Carolina red-backed vole is present in Greenville County. This species was one of the most abundant mammals on the summit of Mt. Rogers in western Virginia (Linzey 1998); the higher density populations are usually located at altitudes above 610 to 915 m (2,000 to 3,000 ft.) in the Southern Appalachians. In the eastern states, population size ranged from 24-65 individuals/hectare (or per 2.5 acres) in New York (Fisher 1968) to 0-37 per hectare in Connecticut and Vermont (Miller and Getz 1977a). The majority of suitable habitat in South Carolina is limited and one would expect smaller population numbers in this state. The presence of

voles in South Carolina may also be dependent upon immigration of voles to South Carolina from higher altitudes in the North Carolina mountains when population cycles result in high densities there. Current population studies are not being conducted on the distribution and abundance of this species in South Carolina.

A recent study has shown that since many Southern Appalachian populations of this species are located on "sky islands", or high altitude locations separated by lower altitude valleys or "oceans" of unsuitable habitat, a relatively low genetic variability and a high degree of inbreeding is occurring in these isolated populations (Browne and Ferree 2007). Comparable situations have been noted for the boreal habitat-dependent Southern Appalachian *Desmognathus wrighti*, the dwarf salamander (Crespi et al. 2003) and *Glaucomys sabrinus*, the northern flying squirrel (Arbogast et al. 2005). This results in limited gene flow between various insular populations. The effect of this bottlenecking could result in the loss of local populations due to stochastic fluctuations in climatic conditions or resource availability (Bonnell and Selander 1974; Hartl and Clark 1997).

Predators of southern red-backed voles include snakes, owls, foxes, bobcats, coyote and weasels. Although these voles are prey for several species, survival of the southern red-backed vole population is usually not threatened by these predators.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The southern red-backed vole is found in the Southern Appalachians Ecoregion. Within that ecoregion, the vole can be found in habitat with mesic mixed forests, mesic deciduous hardwood, and high altitude coniferous forests and beech gaps. A mesic environment with an abundance of litter, rotting logs, moss covered rocks, exposed roots and rock crevices would be considered an ideal habitat (Miller and Getz 1977b; Merritt 1981). This species has also been observed on mountain balds and in rhododendron thickets (Pivorun, pers. obs.). Generally, the presence of a bog area or streambed at altitudes above 762 m (2,500 ft.) offers an appropriate habitat (Webster et al. 1985). Neither forest age nor successional stage has been reported as critical factors in determining habitat preference (Merritt 1981). Southern red-backed voles do not colonize post burn communities as readily as other species (Martell and Radvanyi 1977) but will inhabit clear cuts (Kirkland 1990; Schloyer 1977; Martell 1983; Monthey and Soutiere 1985). One study in Wyoming demonstrated that *C. gapperi* clearly preferred forest to harvested stands on all study sites and avoided crossing boundaries between those stands (Keinath and Hayward 2003).

In South Carolina, red-backed voles have only been found in Oconee and Pickens County at altitudes above 915 m (3,000 ft.) in mixed deciduous forests associated with boggy and stream bed habitats that contain rhododendron. In the Southern Appalachians, associated species include the woodland jumping mouse (*Napaeozapus insignis*), star-nosed mole (*Condylura cristata*), the hairy-tailed mole (*Parscalops breweri*), smoky shrew (*Sorex fumeus*) and masked shrew (*Sorex cinereus*) (Watts 1970). Home range varies from 0.25 to 3.5 acres (Merritt and Merritt 1978). Experimentation by Gillis and Nams (1998) suggests that populations separated by an inter-patch distance of 60-70 m (197-230 ft.)

would likely be considered isolated from one another.
The red-backed vole is semifossorial and utilizes the underground tunnels of other species such as shrews and moles for den and nest sites; they also use crevices among exposed roots and rocks for these purposes. These voles forage along the ground and around downed trees. This species is omnivorous and opportunistic, consuming nuts, berries, mosses, lichens, ferns, fungi, arthropods and seeds (Merritt 1981). There is very little known about the use of subterranean fungi by this species in the Southern Appalachians. One study in Virginia demonstrated the consistent presence of spores in fecal pellets suggesting that fungi are an important food item and that *C. gapperi* may be an important disperser of fungal spores. This work supports the notion that *C. gapperi* is a fungal generalist since spores from the genera *Melanogaster, Coprinus, Elaphomyces* and *Glomalean* were present in fecal pellets. In addition, fungi are considered a primary food source for populations inhabiting forests in New York (Fisher 1968). Up to 20-40% of the total food consumed was the fungus *Endogone* and related hypogeous species during the fall and summer; during the winter, some individuals were found to have stomach contents that were 100% fungal. Bark and roots are also an important food source during the winter months.

CHALLENGES

Since this vole is located on a multitude of protected areas across its range in North America and since no widespread declines in populations have been noted, this species is generally not considered of conservation concern (Lizney and NatureServe 2008). However, in South Carolina, it is rare and considered worthy of inclusion in the State Wildlife Action Plan (SWAP). Luckily, a large portion of the habitat in the Blue Ridge Ecoregion that is appropriate for southern red-backed voles is on public land, including National Forests, State Parks, and SCDNR managed properties. Additionally, some lands that contain southern red-backed vole habitat are owned or held in easement by various land trusts. None of these properties were purchased specifically to protect the southern red-backed vole; however, the species benefits from acquisition and protection of its habitat. While these protected areas provide needed habitat, populations on private lands are still impacted by land conversion.

Land development in the Southern Appalachians represents a major challenge to the southern red-backed vole. Land use in this region is rapidly changing from rural/agricultural to urban/retirement or vacation homes. An unpublished study conducted by SCDNR showed a 4-fold increase in development to every one-fold increase in population between 1983 and 1998 (Richard Lacy, pers. comm.). As these conversions occur, habitat for this species is being lost. Even when development proceeds in close proximity to existing southern red-backed vole habitat, the species may be adversely affected as these animals require relatively undisturbed habitats. Additionally, the changes in hydrology that result from urbanization will affect habitat for this species. This species require wet areas like bogs; these areas are expected to diminish as development continues.

The appropriate habitat for this species in South Carolina is limited and a concern that

needs to be addressed is the impact of climate change, elevated temperatures, and drought in the state. In addition, the loss of hemlock forests to the invasive hemlock woolly adelgid (*Adelges tsugae*) may have significant impacts on populations. These factors all adversely impact the montane habitats, thereby contracting the ideal habitat that this species requires.

CONSERVATION ACCOMPLISHMENTS

Terrestrial small mammal surveys that have been conducted in the South Carolina mountains have provided data to better understand habitat requirements and population dynamics of the various rodent and insectivore species. These studies were possible as a result of partnerships between several interested parties including the University of Georgia, the US Forest Service, Clemson University, and SCDNR.

CONSERVATION RECOMMENDATIONS

- Discourage major developments in known southern red-backed vole habitat in the Blue Ridge Ecoregion
- Complete ecoregion-wide surveys for southern red-backed vole distribution and density. Surveys and survey techniques should be standardized throughout the Southeast so that results and data are readily comparable. All capture data should be made available through the statewide Heritage Trust database as well as shared with neighboring states.
- These surveys need to be conducted over a period of at least ten years. The impact of climate change, elevated temperatures, drought in the state, and the loss of hemlock forests need to be addressed.
- Concurrent with surveys, the subspecies designation and distribution needs to be resolved for Carolina red-backed voles (*M. c. carolinensis*) using molecular data and intensive morphometric analysis. This will require cooperation or partnerships with neighboring states. Genetic analyses are needed to determine if a relatively low genetic variability and a high degree of inbreeding is occurring in the isolated populations distributed across the northwestern montane regions of the state. One would expect bottlenecking which could result in the loss of local populations due to fluctuations in climatic conditions or resource availability.
- Provide information on the ecological role and benefits of southern red-backed voles. This species is not considered a nuisance species. This information would allow for better management of private, state, and federal lands in the montane regions of the state; management would be partially based on consideration of the impact on mammalian species that are major prey items for predators such as fox, bobcat, and birds of prey.

MEASURES OF SUCCESS

As research and management needs are identified, projects should be proposed and prioritized by those with the greatest conservation applicability. Surveys and density estimates in the Southern region should provide some population estimations which will

be used to more accurately rank the species and prioritize future management needs.

Weasels Guild

Least Weasel (*Mustela nivalis*)
Long-tailed Weasel (*Neogale frenata*)

Contributors (2024): Stephen Harris (Clemson University) and David Jachowski (Clemson University)

DESCRIPTION

Taxonomy and Basic Description

Two weasel species occur in South Carolina, the diminutive least weasel (*Mustela nivalis*) and the larger long-tailed weasel (*Neogale frenata*). A third weasel species, known as the short-tailed weasel or American ermine (*Mustela richardsonii*), also occurs in the contiguous United States but is not found in South Carolina. Weasels are in the family Mustelidae (badgers, otters, wolverine, etc.) in the order Carnivora. These weasels are well-known for their elongated, cylindrical bodies, narrow heads, short legs, and their movements that appear serpentine at times. They are also known to be formidable predators despite their small size.

Least weasel. © Hennadii Tarasenko (CC BY-NC), cropped from original

The least weasel is the smallest mammalian carnivore in the world (Sheffield and King 1994). Head and body length for the species is 4.75–6.75 in. (12–17 cm) and body mass ranges from 1–2 oz. (31–57 g; Reid 2006). Females are usually smaller in size than males (i.e., sexually dimorphic; King 1989). The tail is relatively short—less than 25% of the head and body length (approximately 0.75-1.375 in. or 2–4 cm) and lacks a black tip unlike the short- and long-tailed weasel (Hall 1951, Reid 2006). Colors and patterns can vary some, but generally the dorsal pelage can range from tan to a chocolate or rusty-brown color (Sheffield and King 1994). The ventral pelage ranges from yellow to white and may have brown. In northern locales, the coat turns completely white in winter.

The long-tailed weasel is considerably larger than the least weasel, with a head and body length of 7–11.5 in. (18–29 cm) and a body mass of 3–10 oz. (85–284 g; Reid 2006). As its name indicates, it has a longer tail than the least or short-tailed weasel, ranging from 3–6.625 in. (7–17 cm) and more than half of the head and body length. Like the least weasel, females are generally

Long-tailed weasel. © Michael Donahue (CC BY-NC)

smaller than males. The tip of the tail is black. In eastern North America, its dorsal pelage in summer is medium to dark brown and its ventral pelage is light yellow to white (Reid 2006). Northern populations turn white in winter, but southern populations remain brown. The long-tailed weasel can be discerned from the American mink (*Neogale vison*), which also occurs in South Carolina, by the mink's larger size and completely dark brown coat excepting a white chin patch.

Status

The least weasel is globally secure (G5), but within North America the species is of current conservation concern in 53% of range states and provinces (Jachowski et al. 2021). Over the past century, Cheeseman et al. (2024) predicted a 54% loss of suitable habitat. It is critically imperiled (S1) in Georgia and New York, critically imperiled/imperiled (S1S2) in Wyoming, imperiled (S2) in North Carolina, South Carolina, and Tennessee, possibly imperiled (S2?) in Indiana, and has an elevated status in other states as well (NatureServe 2024). It is considered Least Concern with a stable global population trend by the International Union for Conservation of Nature (IUCN; McDonald et al. 2019)

The long-tailed weasel is globally secure (G5). The species is ranked as imperiled (S2) in Nebraska, Oklahoma, and South Carolina, imperiled/vulnerable (S2S3) in Kansas, and has an elevated status in other states as well (NatureServe 2024). The long-tailed weasel is ranked as Least Concern with a stable global population trend by the IUCN (Helgen and Reid 2016).

Recent research has provided evidence that weasel observations and harvest levels in North America have declined in the last century and likely reflect a real decline in weasel numbers during that period (Jachowski et al. 2021). In particular, there is a recent lack of records for the long-tailed weasel in non-mountainous portions of its southern range, which includes South Carolina.

In South Carolina, weasels are considered a furbearer and can be trapped from 1 December–1 March with a valid Commercial Fur Harvester's License. A limit of 5 weasels can also be trapped for non-commercial purposes (with a valid hunting license) from Thanksgiving–March 1 (https://www.eregulations.com/southcarolina/hunting/trapping-commercial-fur-harvesting).

POPULATION SIZE AND DISTRIBUTION

The least weasel is a species found in the northern (circumboreal) region of the Northern Hemisphere worldwide, as well as having been introduced outside of its native range in New Zealand and on other islands (Sheffield and King 1994). It reaches the southern limit of its range in North America in the Southern Appalachian/Blue Ridge Mountains, as far south as Georgia. In South Carolina, the species has only been recorded in Cherokee County (Figure 1), but records come from bordering Henderson and Jackson Counties in North Carolina, including one record 16 km from the South Carolina border (Barkalow 1967, Linzey and Hamed 2016). Suitable habitat for the least weasel across North America appears to be declining, driven by habitat fragmentation or loss and climate change (Cheeseman et al. 2024).

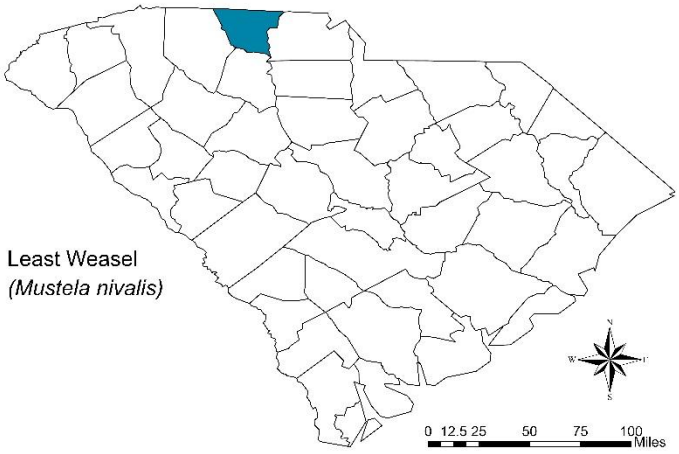

Figure 1. Distribution of the least weasel in South Carolina.

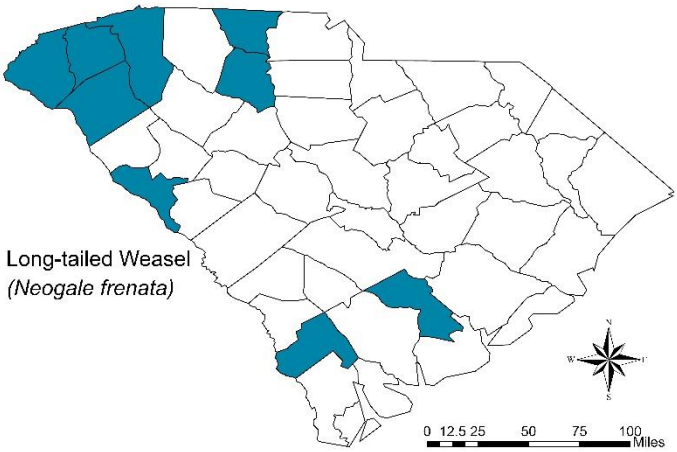

Figure 2. Distribution of the long-tailed weasel in South Carolina.

The long-tailed weasel occurs throughout most of the United States, in southern Canada, throughout most of Mexico and Central America, and into parts of northern and central South America (Sheffield and Thomas 1997). Records in South Carolina come from Anderson, Cherokee, Dorchester, Greenville, Hampton, McCormick, Oconee, Pickens, and Union counties (Figure 2). The species also occurs in the adjacent states of Georgia, Florida, and North Carolina.

Due to the dearth of records for the least and long-tailed weasel in South Carolina, nothing populations in the state. Least weasels are thought to be naturally rare (i.e., occurring in low densities) in North America (Sheffield and King 1994). Long-tailed weasel populations can fluctuate greatly, and local populations can go extinct when prey availability decreases (King 1989).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The least weasel is considered a habitat generalist. It has been documented in a variety of forest types, fields, meadows, prairies, cultivated farmlands, hedgerows, steppe, scrub, semi-deserts,

and coastal dunes (Sheffield and King 1994). Least weasel habitat selection may be influenced on a local scale by the distribution of their rodent prey. The species may be restricted to the mountainous northwestern corner of South Carolina due to incompatibly high minimum temperatures outside of this region (Cheeseman et al. 2024).

Like the least weasel, the long-tailed weasel is a habitat generalist. Throughout its range, it inhabits most habitat types besides desert (Sheffield and Thomas 1997). It can be found in forests, fields, meadows, marshes, and pastures (DeVan 1982, Reid 2006). Long-tailed weasels are often found in and near riparian areas with dense vegetation, and these riparian areas act as corridors for movement and dispersal (Fagerstone 1987, Sheffield and Thomas 1997, Reid 2006).

CHALLENGES

Land use change is a threat to many imperiled species, and weasels in South Carolina are likely negatively impacted as well. As previously noted, habitat loss and fragmentation, paired with climate change, have likely led to declines in suitable habitat for least weasels (Cheeseman et al. 2024). South Carolina's human population rapidly increased 10.7% from 2010 to 2020 (U.S. Census Bureau 2021) and will continue to grow, increasing the risk that weasel habitat will be destroyed by human development.

Establishing solid estimates of weasel population size and status and determining if weasels occur in an area of interest are difficult, as weasels may occur at low densities (Sheffield and King 1994) and are hard to detect (Jachowski et al. 2024).

Epizootic diseases such as canine distemper virus are known to have devastating effects on mustelids, with mortality rates near 100% recorded for some outbreaks (Budd 1981, Davidson 1986, Perpiñán et al. 2008). It is currently unknown how impactful or prevalent diseases are to weasel populations in South Carolina. However, a canine distemper outbreak in nearby DuPont State Recreational Forest, North Carolina (a site where long-tailed weasels are known to occur), killed at least 50% of a study population of eastern spotted skunks (*Spilogale putorius*) at the site (Harris et al. 2021), highlighting the potential effects diseases can have on low-density populations of small carnivores in the region.

Least and long-tailed weasels' primary prey are small mammals, especially rodents (Sheffield and King 1994, Sheffield and Thomas 1997). Therefore, they are at risk from poisoning through secondary exposure (i.e., eating poisoned rodents) to anticoagulant rodenticides (Townsend et al. 1984). Anticoagulant rodenticide exposure, and associated morbidity or mortality, have been documented in many carnivore families and species worldwide, but most frequently in mustelids (Keating et al. 2024).

CONSERVATION ACCOMPLISHMENTS

Locations where long-tailed weasels have been recorded in South Carolina are protected and managed by the U.S. Forest Service (e.g., Andrew Pickens District, Sumter National Forest) and Clemson University (e.g., Clemson Experimental Forest). Recent camera trap surveys in the Piedmont ecoregion and Upstate South Carolina have increased the number of recent records of

the long-tailed weasel in the state (S.N. Harris, 2024, pers. comm.) Clemson University and SCDNR researchers have actively participated in the North American Weasel Working Group, which works collaboratively to improve knowledge of weasel ecology, status, distribution in North America.

CONSERVATION RECOMMENDATIONS

- Partner with private and public landowners to maintain known weasel habitat via whatever means are available, including but not limited to acquisitions, conservation easements, designations of green spaces, and encouragement of stewardship by private landowners.
- Engagement of the public to bolster verifiable records of weasels in the state. Examples include pushes for observation submissions through social media, directing the public to record their observations in a new or established database (e.g., iNaturalist), or sending out surveys and calls for observations to hunters and trappers that frequent weasel habitat.
- Surveys in areas with old historical observations (e.g., >40 years ago) to determine whether weasels still inhabit these areas.
- Systematic surveys throughout the purported ranges of both species' in South Carolina to improve understanding of distribution and allow for population estimates. There are a number of non-invasive methods that have been effectively used to monitor weasels, each with their own advantages and disadvantages. Regardless of the method(s) used, a commitment to sustained monitoring over a long period of time is essential to collect population trend data for weasels (Jachowski et al. 2024).
- Investigate the level of current weasel harvest and what effect it may have on weasel populations in the state.
- Further research into the effects of diseases and rodenticides on weasels will aid in determining if these pose a serious threat to populations in the state.

MEASURES OF SUCCESS

Obtaining new observations of the least weasel and long-tailed weasel would be beneficial in updating our current understanding of both species' distribution in South Carolina. New records may inform researchers as to sites where further, more in-depth studies of weasels could be conducted. Finally, observations obtained from systematic surveys throughout the state would be instrumental in establishing baseline density or population size estimates for these species.

Eastern Woodrat
Neotoma floridana

Contributors (2005): Mary Bunch (SCDNR), Stanlee Miller (Clemson University), and David Webster (UNC-W)
Revised & Edited (2012): Steve Fields (Culture and Heritage Museums) and David Webster (UNC-W)

Photo by D. Webster

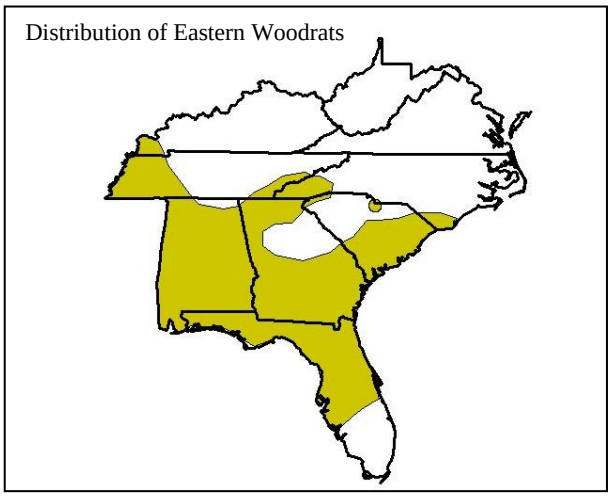
DESCRIPTION

Taxonomy and Basic Description

The Eastern woodrat was first described by Ord in 1818. Woodrats build extensive stick nests in which they larder bright, shiny objects, hence the nickname "packrats." The Eastern woodrat (*Neotoma floridana*), the only woodrat species in South Carolina, has gray-brown or rusty brown fur on the back with darker hairs down the center of the back, a white belly and whitish paws. The white extends to the underside of the jaw. The well-furred tail is nearly as long as the body. It has short hairs and is bi-colored (dark on top and light underneath). Woodrats have long whiskers and large, unfurred ears. They are easily distinguished from black rats (*Rattus rattus*) and Norway rats (*Rattus norvegicus*) because woodrats have relatively large eyes, four white feet, well-furred tails and rather blunt snouts. Both black and Norway rats, introduced invasive species, have scaly tails and pointy snouts (Webster et al. 1985).

Males are slightly larger than females (Wiley 1980). Specimen weights from South Carolina at the Campbell Museum of Natural History range from 119.5 to 306.4 grams (4.1 to 10.7 ounces) for males and 104 to 268.8 g (3.6 to 9.4 oz.) for females. The average weight of woodrats captured at mountain sites in South Carolina during winter were 264 g (9.2 oz.) in males and 207.5 g (7.3 oz.) in females (Bunch and Dye 1999c).

The woodrats in South Carolina were formerly recognized as two distinct subspecies. The mountain or Appalachian population was referred to as the southern Appalachian Eastern woodrat (*Neotoma floridana haematoreia*). Coastal populations were assigned *Neotoma floridana floridana* (Hall and Kelson 1959; Wiley 1980). They are now considered to be the same subspecies, *Neotoma floridana haematoreia,* based on molecular genetic comparisons (Hayes and Harrison 1992; Ray 2000).



Farther to the north and west, ranges of both the Eastern woodrat and the less common Allegheny woodrat (*Neotoma magister*) almost overlap. Allegheny woodrats were once recognized as a subspecies of *Neotoma floridana* but are now recognized as a discrete species (Hayes and Harrison 1992; Hayes and Richmond 1993; Ray 2000; Edwards and Bradley 2001). The differences between the two species are subtle. Woodrats in the mountains tend to have longer whiskers than their coastal counterparts (Ray 2000), and their tails are more distinctly bi-colored and hairier. In this regard, Eastern woodrats from the southern Appalachians more closely resemble Allegheny woodrats; those from the coastal plain of North and South Carolina more closely resemble Eastern woodrats from Florida.

Status

In South Carolina, the species is apparently secure (S3/S4). Currently, coastal and mountain populations are not ranked separately in South Carolina. North Carolina ranks coastal populations of Eastern woodrats as critically imperiled and mountain populations as rare or uncommon. Georgia and Florida rank *N. floridana* as secure (S5), and the global rank is secure (G5) (NatureServe 2004, 2013). Eastern woodrats are on the IUCN Red List in the "lower risk, least concern" category (Yensen and Kirkland, Jr. 1998).

POPULATION SIZE AND DISTRIBUTION

Woodrats range along the coast from Pender County in southeastern North Carolina (Webster et al. 1985), southward along the entire Coastal Plain and into the Sandhills of South Carolina. The distribution broadens westward into Piedmont habitat as it continues southward into Georgia. The mountain populations of Eastern woodrats are restricted to the southwestern mountains of North Carolina and northwestern South Carolina, ranging west and southward in Georgia.

A record of an Eastern woodrat from York County, South Carolina (Dowda et al. 1981) in the Upper Piedmont suggests that the distribution in the Midlands and Upper Piedmont of South and North Carolina is not well understood.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Woodrats use a wide variety of habitats in South Carolina. In the Southern Appalachian Ecoregion, they can be found in dry or mesic deciduous or mixed deciduous forests including coves, bottomlands and swamps. They also occur in pine-heath communities and early successional stands such as old fields and clear cuts. Woodrats will use harvested woodlands prepared mechanically if piles of woody debris are present, but do not use sites that have been treated with herbicides within the previous five years (O'Connell and Miller 1994). They are often found in, but are not limited to, rock outcrops, boulder fields and cliffs.

In the Coastal Plain, woodrats use floodplain and swamp forests, wet scrub thickets, logged areas, dry and mesic deciduous forests, and hardwood-pine forests. At the Naval Weapons Station near Charleston, woodrats were captured in natural pine regeneration areas that were approximately 12 years old; these areas were affected by Hurricane Hugo and contained abundant coarse woody debris. Woodrats were also captured in mature hardwood pine forest habitat and mixed stand edge with an adjoining field at the Naval Weapons Station (Louie et al. 2001). At coastal North Carolina sites, Webster et al. (1987) reported an apparent association of

woodrat prevalence in deciduous forest with dense dwarf palmetto (*Sabal minor)* cover and circum-neutral soils.

Woodrats are opportunistic; they forage on a variety of items including berries, stems, buds, leaves, seeds, fruit, bark, fungi, insects, acorns and other nuts (McMurry et al. 1993; Monty and Feldhamer 2002; Schwartz and Schwartz 1981; Wiley 1980). Hard mast, such as acorns, may be an important food source in winter.

Two obvious items can be found to indicate the presence of woodrats: large, bulky nests and latrines. Nests for woodrats are built inside a large house constructed of sticks, leaves, branches, and scavenged litter such as vinyl flagging, bottle caps, and Mylar balloon remnants. The bulky houses are continually maintained. Several nests can be found in one large house or den structure. Often these structures are in or under rock outcroppings, large cavity trees, large slash piles or in abandoned buildings. Latrines are often found on rock ledge sites where large piles of droppings accumulate.

Photo of woodrat nest by SC DNR

CHALLENGES

Coastal populations of Eastern woodrats in South Carolina are impacted by habitat loss and isolation due to development. Although some habitat for this species is protected on public lands, barriers of intense development isolate many preserved sites, particularly in the coastal plain. Much of the suitable habitat found in the midlands needs additional protection, and many suitable areas found in the Inner and Outer Coastal Plain are not protected at all.

Predation (Monty and Feldhamer 2002), and factors that increase predator density or woodrat detection by predators, also represent challenges to this species. Additionally, placement of recreational trails near suitable bolder or rock outcrop nest sites may adversely affect Eastern woodrats by resulting in increased access to and, therefore, increased predation of nests.

Raccoons and their associated parasite, the raccoon roundworm (*Baylisascaris procyonis*) may also pose a threat to Eastern woodrats (Monty and Feldhamer 2002). Although this parasite is not common outside of the Southern Appalachians, the potential exists for parasite transmission to woodrats. Once transmission occurs, raccoon roundworm larvae migrate to the brain and death can occur. Such mortality has been documented in the rare Allegheny woodrat (*Neotoma magister*). As raccoon populations increase, an observable decrease in the woodrat population has been noted; transference of the roundworm is believed the cause (NatureServe 2004). Recent research indicates that the parasite is experiencing a range expansion and has been documented in isolated regions of Florida and Georgia (SCWDS 2013). Raccoons are a cosmopolitan species that often coexist and benefit from human activity, readily foraging in garbage, gardens, agriculture fields, aquaculture areas, koi ponds, pet food and bird feeders. Anything that causes an increase of raccoons within woodrat habitat can therefore increase the likelihood of raccoon parasite transfers to woodrats.

The exotic gypsy moth (*Lymantria dispar*) may pose a threat to populations of woodrats. Gypsy moth caterpillars prefer oak trees, but will defoliate most hardwoods when present in large numbers. This defoliation reduces mast production; repeated defoliations lead to tree mortality (McManus et al. 1992; Pearson 2002). Gypsy moths were first reported in South Carolina in 1998 (Pete Bischoff personal communication 2005). To date, no significant outbreaks of gypsy moth caterpillars have occurred in this state; however, should such an outbreak occur, it could result in significant impacts to woodrat food sources.

Sudden Oak Death (SOD) results from an introduced fungus (*Phytophthora ramorum*) that recently arrived in South Carolina via nursery stock. The impacts of this fungus on our forests could be devastating as it attacks many species of shrubs and trees (O'Brien et al. 2002). Specific impacts to the many types of oak trees (*Quercus* spp.) in the southeast are not yet known. If the blight is not contained, serious losses of oak trees can be expected. Red, northern pin and black oaks have been shown to be susceptible to the fungus in experimental exposures (Tooley and Kyde 2003). The warm, humid climate in the southeast is conducive to the spread of the fungus. Unfortunately, SOD is believed to be distributed by air borne spores; such distribution makes it very difficult to control this fungus. Infected nursery stock has been shipped to several southeastern states, and was documented in South Carolina for the first time in 2005 by Clemson University (Kent 2005). Woodrats use acorns, as do many other species of wildlife. Losing a significant proportion of our mature oaks could create a forage bottleneck that could decimate woodrat populations.

Currently, very few people are aware of woodrats or packrats in South Carolina, except for the perception that they are a nuisance species. This perception contributes to the assumption that this species is responsible for nuisance rat infestations. However, this species is generally not found living in areas populated by humans. Lack of knowledge of the Eastern woodrat and its relevance in the ecosystem can represent a challenge for protection of this species.

CONSERVATION ACCOMPLISHMENTS

Extensive holdings in various public ownerships and nonprofit conservation organizations or conservation easements have protected over 162,000 acres of land in the mountains of South Carolina. Most, if not all of the tracts, have woodrats (Bunch et al. 1999 a,b,c). Some habitat preservation exists in the midlands and lower coastal plain on sites such as the Congaree National Monument and the Silver Bluff Audubon Sanctuary. Significant tracts, such as the SCDNR's system of Heritage Preserves, the Francis Marion National Forest, the multi-partnered ACE Basin project and the various National Wildlife Refuges also protect some coastal populations.

CONSERVATION RECOMMENDATIONS

- Conserve woodrat habitat linkages between sites that are already under protection through acquisition and/or conservation easement and encourage stewardship by private landowners.

- Encourage landowners and foresters to avoid use of herbicides as a site preparation technique in areas with woodrats.
- Survey the upper piedmont region in York County and surrounding counties to determine the distribution of woodrats in that region.
- Determine if trails by-passing outcrops and boulder fields lead to increased predation of woodrats.
- Acquire Eastern woodrat density estimates for each ecoregion and designate selected sites for long-term monitoring in each of the following geographical area: Southern Appalachians, Inner and Outer Coastal Plains, and Piedmont.
- Educate the public about the relevance of the Eastern woodrat in the ecosystem. Such education could occur at a demonstration site that illustrates important habitat and species in the mountain region of South Carolina.
- Continue to monitor the spread of raccoon roundworm, gypsy moths, and SOD in South Carolina and develop an action plan in the event these threats adversely affect wildlife species within this state.

MEASURES OF SUCCESS

Surveys and density estimates in the southern region should provide some population estimations that will be used to more accurately rank the species and prioritize future management needs.

DESCRIPTION

Taxonomy and Basic Description

Istiophoridae and xiphiidae family species, found within the order Carangiformes (Page et al. 2023), hereafter referred to collectively as billfishes, are highly migratory pelagic marine predatorial fish characterized by their protruding upper jaw pointed bills that appear sword or spear-like (Nakamura 1985). The species of billfishes that inhabit the waters off the South Carolina coast include sailfish, blue marlin, white marlin, longbill spearfish , roundscale spearfish, and swordfish (Collette 2006). These fish species vary in total length, with some species demonstrating sexual dimorphism; females typically grow larger than males. Sailfish, white marlin and spearfish reach a maximum size of approximately 200 cm total length (TL), while swordfish grow to 400 cm TL. The blue marlin is the largest of the group with a maximum length of 500 cm TL for females and 290 cm for males (FishBase). They are considered apex predators, noted for their fast speeds, and feed on a wide variety of fish, crustaceans and cephalopods using their long rough bills when swimming through bait fish, slashing their head/bills back and forth to stun, injure or kill prey.

Status

Billfishes are both ecologically significant and economically valuable pelagic fishes, existing in every ocean (Nakamura 1985). With a high exploitation rate in some areas of the world, for food consumption and revenue, billfish stock status can be difficult to determine and varies from healthy to severely depleted or rebuilding (Pons 2017). Billfishes, excluding swordfish, are often caught as bycatch in other large-scale fisheries for tunas and swordfish. Not surprisingly, many of the populations of these species show signs of overfishing (ICCAT 2021). Additionally, preferred open ocean habitat hinders large scale research activities, resulting in limited information about their movements and life histories further complicating management, especially if only locally applied (Collette 2011).

In the western North Atlantic, swordfish are the only species targeted commercially, with federal restrictions on the harvest and sale of the other billfishes; however, all the billfishes are considered an economically important recreational fishery off the U.S. East coasts (Ditton 2003). Commercial swordfish landings and bycatch of other billfishes are tracked under strict federal quota monitoring efforts, and recreational landings for all these billfishes are relatively low with several species being prohibited. Documentation of these recreational landings are self-reported to NOAA Highly Migratory Species Division (NOAA-HMS). In SC, conservation measures began in the early 1970s. As these concerns about population declines of billfishes ramped up in 1989, the South Carolina Governor's Cup Billfishing Series, a SCDNR-administered program, was initiated (SCDNR Series). The program promotes research, education and conservation of a suit of these species through efforts to encourage catch and release fishing practices.

POPULATION SIZE AND DISTRIBUTION

SCDNR has not conducted any directed fishery independent studies on billfishes. The South Carolina Governor's Cup Billfishing Series does collect fishery dependent data and limited biological data from tournament focused fishing activities. These data have varied over the timeframe of the program and are collected through interviews with participants post fishing activities to determine catch rates and both estimated and measured billfish lengths, sex and weights. Limited otoliths have been collected in more recent years but have not yet been processed. Specialized equipment is needed to read these extremely tiny and delicate structures.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Billfishes prefer tropical and subtropical waters, specifically clear-blue waters of the Gulf Stream near the outer continental shelf and are more concentrated during the spring through fall months; however, smaller sailfish and spearfish will stray into nearshore waters during the summer (SCDNR Sea Science).

CHALLENGES

As a highly migratory species occurring in every ocean, billfishes are subject to a variety of fishing pressures and vastly different regulations regarding harvest, bycatch and reporting requirements. This does limit the ability to conduct a comprehensive stock assessment and collect sufficient data. Understanding the hurtles to management of some billfishes has allowed conservation and management strategy evaluations to be developed.

CONSERVATION ACCOMPLISHMENTS

NOAA-HMS has an Advisory Panel that consists of fishermen from all sectors, non-governmental representatives from scientific and environmental groups and state agency personnel to share perspectives and gain insight of each billfish species to aid in the development and implementation of management strategies for these species.

Additionally, the South Carolina Governor's Cup Billfishing Series encourages catch and release of billfish species, and the program has a 99% release rate averaged between the participating fishing tournaments since 1989. In recent years, the program has assisted with small scale scientific studies, using popoff satellite archival tags to enhance the understanding of basic patterns of the species' daily and seasonal movements, which may aid in fisheries management (Walter 2020).

CONSERVATION RECOMMENDATIONS

- Characterize stock status in Atlantic waters compared to globally
- Determine potential spatial and temporal shifts in distribution
- Further investigate migration patterns
- Expand research and monitoring of fishery-independent surveys and better utilize and expand fishery-dependent data
- Improve data of bycatch or incidental catch and better documentation of fish encounters

MEASURE OF SUCCESS

The highly migratory nature of billfishes and occurrence in all oceans with varied regulations complicates the measure of success. Additionally, not all species have been assessed nor are managed similarly, which further makes ensuring the sustainability of these fish more difficult. The continuation and expansion of regional fisheries management organizations, such as the International Commission for the Conservation of Atlantic Tunas, will increase the success of cohesive internationally approached future management measures.

DESCRIPTION

Taxonomy and Basic Description

Atlantic croaker, members of the order Perciformes and family Scienidae, is the only representative of the genus *Micropogonias* occurring on the US Atlantic coast; the other *Micropogonias* species, *M.* furnieri, occurring in North America occurs along the far southern coast of Mexico (Page et al. 2023). This species gets its name from the deep croaking sounds created by muscular action on the air bladder. It is one of 23 members of the family Sciaenidae found along the Atlantic and Gulf of Mexico coasts (Mercer 1987). The species has a typical fusiform shape, although it is somewhat vertically compressed. The fish is silvery overall with a faint pinkish-bronze cast. The back and upper sides are grayish, with brassy or brown spots forming wavy lines on the side (Manooch 1988). The gill cover has 3 to 5 prominent spines, and there are 3 to 5 small chin barbels. It has a slightly convex caudal fin.

Atlantic croaker south of Cape Hatteras reach maturity after one year at lengths of 140-180 mm (5.5-7″) total length (TL) and have previously been thought to not survive longer than one or two years (Diaz and Onuf 1985). More recent data, however, has expanded the age range with ages as high as 7 in South Carolina (ASMFC 2010). North of Cape Hatteras, they mature a year later at lengths greater than 200 mm (8″) TL. The age range in the mid-Atlantic region for croaker is greater with age-12 fish landed in Virginia and North Carolina in 2001 (Bobko et al. 2003) and 15 to 17-year-old fish landed by the Chesapeake Bay Multispecies Monitoring and Assessment Program (ChesMMAP). The Atlantic Croaker reaches a maximum length of 500 mm (20″) TL (Hildebrand and Schroeder 1927). Catches of large Atlantic croaker appear to be relatively common in Chesapeake Bay, but large individuals are rare in South Carolina.

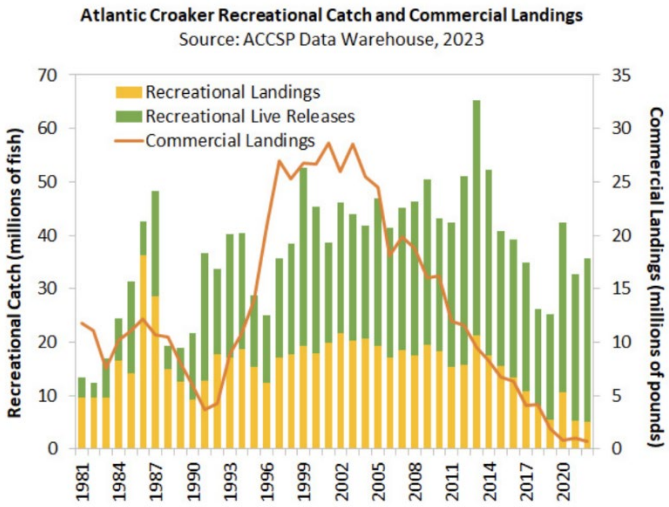

Figure 1: Atlantic croaker recreational and commercial harvest and recreational discards from 1981-2022 (Source: ASMFC 2024).

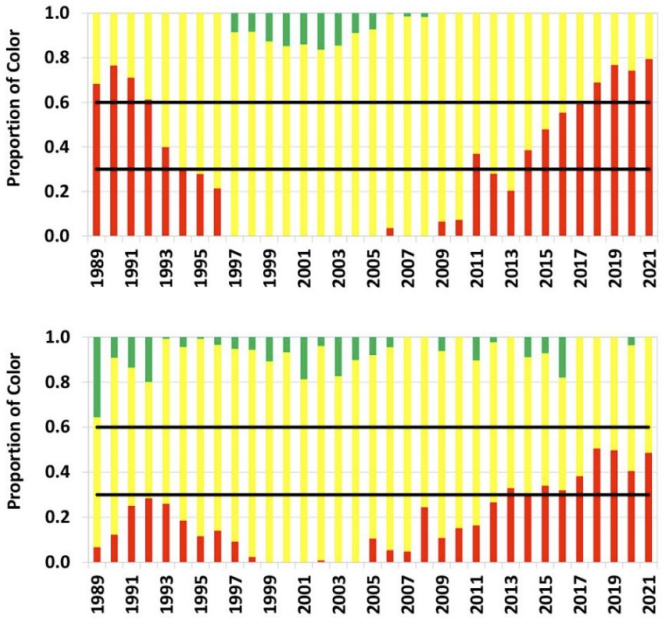
Status



Sought by recreational and commercial fishermen alike, coastwide an estimated 2.8 million pounds of croaker were landed in 2022, 25% and 75% from the commercial and recreational fisheries, respectively (ASMFC 2024). Atlantic croaker have been part of a mixed-stock commercial fishery on the Atlantic coast since the 1800s, contemporarily being caught commercially with a wide variety of gear. The dominant types include gill nets, pound nets, haul seines, and trawls. Coastwide commercial landings, dominated by harvest in North Carolina, exhibit a cyclical pattern with low landings in the 1960s to early01970s and the 198-s to early-1990s and high landings in the mid- to late-1970s and the mid-1990s to 2011 (Figure 1; ASMFC 2024).

Two other, potentially unaccounted for "commercial" fisheries land Atlantic croaker. First, Atlantic croaker are a major component of "scrap fisheries," or fisheries in which fish species that are unmarketable as food, due to size or palatability, are sold unsorted, usually as bait. Second, small Atlantic croaker have also been a major part of the bycatch in the Southeastern Atlantic shrimp trawl fishery (Hoar et al. 1992; Nance 1998), and while the use of turtle excluder devices (TEDs) and by-catch reduction devices (BRDs) has reduced this bycatch, the overall impact of the trawl fishery on the Atlantic Croaker population and the magnitude of the reduction through the use of TED's and BRD's is difficult to quantify. Currently, there are limited to no monitoring efforts for by-catch composition of the shrimp trawl fishery along the Southeastern Atlantic Coast of the US.

Recreationally, coastwide landings from New Jersey through Florida have varied between 5.1 million fish in 2022 to 36.2 million fish in 1986 (Figure 1; ASMFC 2024). Landings generally increased until 2001, and held stable from 2001-2006 before exhibiting a declining trend from 2007 though 2022. However, recreational discards have generally increased throughout the time series, with 85.5% of croaker captured recreationally released in 2022 (Figure 1; ASMFC 2024). The rise in catch-and-release fishing, as with many other coastal species, means a large component of contemporary annual removals is now comprised of dead discards due to post-release mortality.

The Atlantic Croaker is not a federally or state listed species. The Atlantic States Marine Fisheries Commission (ASMFC) oversees the management plan, with limited

management recommendations for the Southeastern US Atlantic. While a 2017 benchmark stock assessment was completed, conflicting trends in abundance and harvest, as well as other uncertainties, led to the assessment not being recommended for management use (ASMFC 2017; ASMFC 2024). The 2010 stock assessment, the last approved for management use, for Atlantic croaker determined that the Atlantic stock (including South Carolina) was not overfished and is not currently undergoing overfishing (ASFMC 2010).

Independent of stock assessments, each year a traffic light analysis (TLA) is performed to analyze trends in the fishery and implement state-specific management actions if necessary (ASMFC 2024). However, recent TLA analyses have also shown conflicting trends in abundance (adult and juvenile) and harvest of Atlantic croaker, with significant decreases in overall harvest but increases in adult abundance and some juvenile abundance (ASMFC 2024). The 2020 TLA showed significant declines in abundance and harvest of Atlantic croaker in the mid-Atlantic which triggered management actions be put in place for the entire region (ASMFC 2024). Overall status could not be determined in the 2022 TLA due to limited data availability from fishery independent surveys and the TLA was not run in 2023 due to an ongoing stock assessment (ASMFC 2024). An updated benchmark stock assessment for Atlantic Croaker will be completed in 2024. Results of the most recent TLA, for fishing year 2021, is found in Figure 2.

Figure 2: Atlantic croaker traffic light analysis harvest metrics for mid-Atlantic (NJ-VA; top) and south Atlantic (NC-FL; bottom) regions. Management response is triggered when the proportion of red exceeds either the 30% (moderate management response) or 60% (higher management response) threshold level for 3 out of 4 of the most recent years in both harvest and abundance metrics. (Source: ASMFC 2022)

POPULATION SIZE AND DISTRIBUTION

Atlantic Croaker are a very common species in the waters of South Carolina. Globally, they occur in coastal waters from Cape Cod, Massachusetts to Campeche Bank, Mexico, and possibly from southern Brazil to Argentina (Mercer 1987). The species has an extended spawning season— depending on the coastal area—that can range from October through April (ASMFC 2010). Adults in spawning condition have been found in depths of 7-131 m (23-430 ft.) north of Cape Hatteras, and from 5-50 km (3-31 mi.) offshore of South Carolina in depths of 40-91 m (131-298 ft.; Bearden 1964).

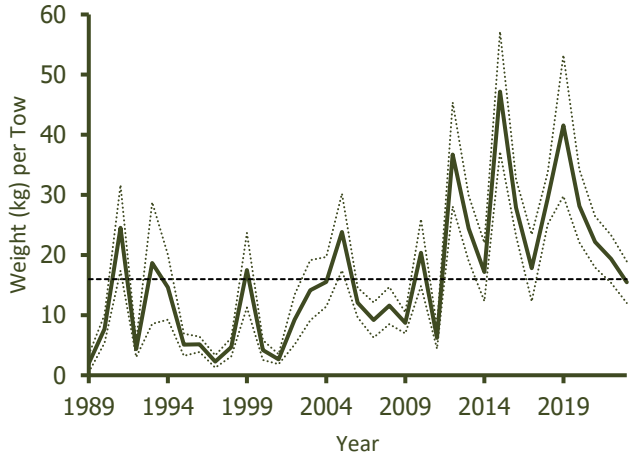


Figure 3: Stratified mean annual CPUE (kg/tow) for Atlantic croaker for fall months across for the SEAMAP-SA coastal trawl survey. The blue line represents the long-term mean and the dashed lines represent the 95% confidence intervals.

Joseph (1972) examined historical landings and catch-per-unit-effort data for Atlantic croaker stocks in the mid-Atlantic states and Chesapeake Bay and concluded fluctuations in abundance over the previous 80 years were largely attributable to the natural environment, namely temperature. He noted unusually cold winters could decimate larval and juvenile fish. More recent evidence indicates year-class strength is decoupled from larval supply and is determined by temperature-linked, overwinter survival of juveniles (Hare and Abel 2007). Hare and Abel (2007) hypothesized the environment drives the large-scale variability in Atlantic Croaker abundance and distribution, but fishing and habitat loss decrease the resiliency of the population to periods of poor environmental conditions and subsequent weak year classes.

Additionally, there is archeological evidence for changes in the population age structure of Atlantic croaker in the south Atlantic region. Hales and Reitz (1992) examined Native American middens and Spanish colonial sites in Florida for Atlantic croaker otoliths and found large fish (12-46 cm (5-18") TL) that were present from 2000 BC to the mid-16th century. They concluded there has been a severe reduction in size and age of Atlantic croaker in the southeast within historic times due to overfishing or habitat degradation. This reduction could be related to mechanized commercial shrimp trawl bycatch since the early 20th century.

Several contemporary South Carolina Department of Natural Resources (SCDNR) long-term fishery independent monitoring programs encounter Atlantic croaker in sufficient numbers for the development of relative abundance indices. First, the Southeast Area Monitoring and Assessment Program – South Atlantic (SEAMAP-SA) coastal trawl survey (CTS) is a shallow water, fishery independent trawl survey that monitors status and trends of numerous coastal species within the coastal zone in Atlantic waters off the southeastern United States between Cape Canaveral, FL to Cape Hatteras, NC. The stratified annual mean catch per unit effort (CPUE) in kilograms per tow for fall months for Atlantic Croaker from the CTS has been highly variable since 1989. The general trend has been increasing abundance since 2007, although the index value has been declining for the last four years of the series (Figure 3).

SCDNR Inshore Fisheries runs three additional long-term fishery independent indices in estuarine waters that encounter Atlantic croaker regularly, namely the trammel net,

electrofishing and estuarine trawl surveys. In the trammel net survey, relative abundance of Atlantic croaker has increased since the early-2000s, particularly since a recent low in 2018 (Figure 4). Of note, evident is the impacts of marine cold spells during the winters of 1993-1994, 2000-2001, and 2017-2018, which affected the abundance of spotted seatrout in coastal waters but also apparently affected the abundance of Atlantic croaker in subsequent years. This supports the finding that Atlantic croaker recruitment is environmentally, and likely temperature linked as suggested by previous research (Hare and Abel 2007; Joseph 1972). The relative abundance trend in the electrofishing survey, in contrast, suggests a stable to declining population through time, with recent years near all-time lows (Figure 4). Finally, the estuarine trawl survey suggests increasing relative abundance through the late-2010s, with potential recent declines (Figure 4). Of note, the estuarine trawl and electrofishing survey encounters similar sized young-of-the-year croaker, while the trammel net survey due to the nature of the gear selects for larger individuals (Figure 5). This suggests local environmental conditions are leading to driving different trends in Atlantic croaker abundance between the electrofishing and estuarine trawl surveys.

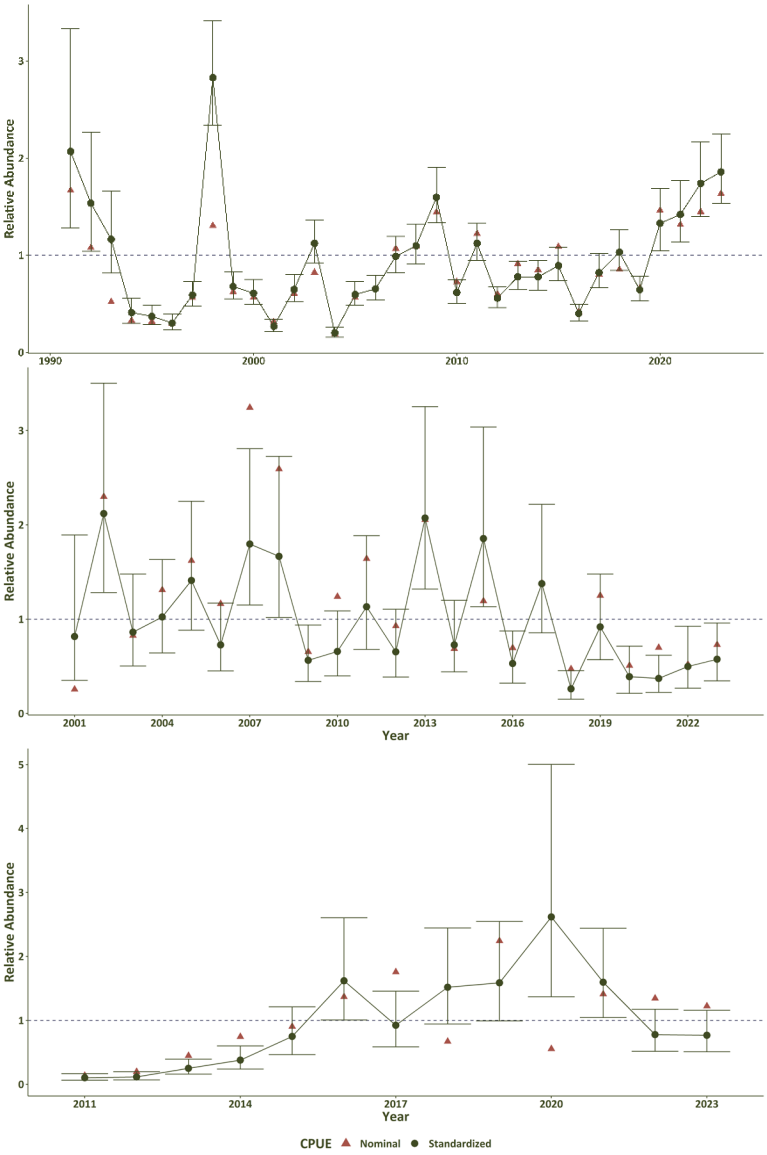

Figure 4: Atlantic croaker standardized catch per unit effort in SCDNR's Inshore Fisheries trammel net (top), electrofishing (middle) and estuarine trawl (bottom) surveys by year. Shown is the standardized index of abundance (green line and circles) with a 95% CI (error bars) as well as nominal catch per unit effort (red triangles). Both the standardized and nominal indices are normalized to average catches from 2010-2023 (trammel net) or time-series average catches (electrofishing and estuarine trawl; dashed lines), such that if annual estimates are greater than 1, catch was above average and vice versa if below.

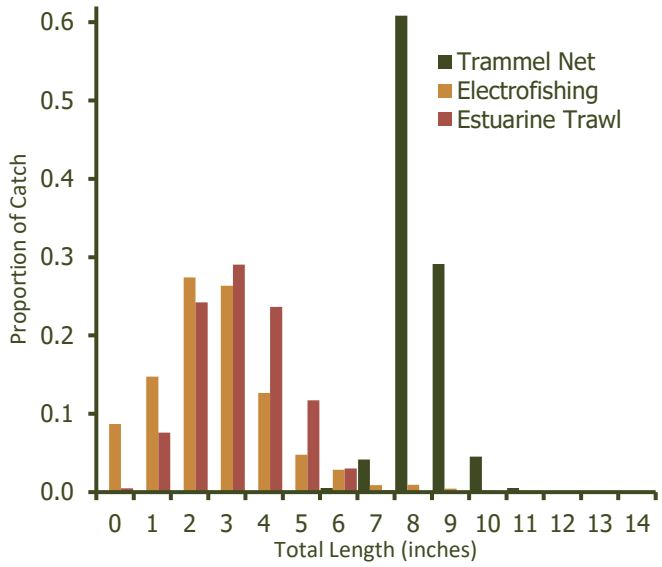

Figure 5: Length frequency of Atlantic croaker captured in the trammel net (green), electrofishing (gold), and estuarine trawl (red) surveys.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Atlantic croaker has a down-turned mouth, making it well-suited for its bottom-feeding life style. Adults spawn offshore, producing larvae that are carried into the coastal inlets by tidal currents. Larvae ride the "salt wedge" which moves along the bottom into estuaries (Bearden 1964). Larvae have a day-night (diel) distribution in the water column that is opposite of that for most planktonic animals (Comyns and Lyczkowksi-Shultz 2004). This "reverse diel vertical migration" means they are more common in deeper water during daylight compared to night. Optimal habitat for post-settlement juveniles are the low salinity zone in the upper portion of the estuary. Peterson et al. (1999) demonstrated in controlled laboratory experiments Atlantic croaker grew considerably faster in salinities of 5 parts per thousand (ppt) than those growing in 20 ppt or a variable salinity (5 to 20 ppt). Young Atlantic croaker first recruit to the upper estuarine areas and gradually move seaward toward higher salinities as they become larger (Bearden 1964). Lower salinity estuaries typically had larger numbers of Atlantic Croaker compared to higher salinity estuaries, indicating survival and growth are enhanced by lower salinities and/or other factors that might be related to salinity (Bearden 1964). Miglarese et al. (1982), also working in South Carolina estuaries, found salinity affects size distribution, and Chao and Musick (1977) found croakers were most abundant in lower salinities in the York River, Virginia. However, others have suggested depth and food preference may be related to size distribution (Miglarese et al. 1982).

Rogers et al. (1984) found seasonal freshets of river flow were important to estuarine-dependent species including Atlantic croaker. They noted it was striking that low salinity and freshwater areas serve as primary zones of recruitment and peak recruitment and utilization periods occur during the period of maximum riverine influence, temporarily creating "a much larger proportion of the preferred habitat." Ross (2003) concluded oligohaline habitats (low salinity: 0.5-5.0 ppt) provided better habitats for spot and Atlantic croaker because mortality rates are lower there. There are several explanations of why mortality rates are lower in the lower salinity areas including: reduced predation, lower respiration rates (compared to high salinity), and higher growth rates.

Parker (1971) noted that the "large concentrations of Croaker were always observed in shallow waters less than 1.2 m (4 ft.) deep and in close proximity to a source of fresh or brackish water." Parker also noted these habitats were generally soft mud bottoms with large quantities of detritus, suggesting these shallow areas provide abundant food and protection from predators. Bearden (1964) also found young Atlantic croaker were most often found in small tidal creeks where bottoms are composed of soft mud and decomposing organic matter. He noted larger Atlantic croaker were found on a great variety of bottom types, but were most abundant on "bottoms composed of mud and sand mixture, particularly near the mouths of tidal sounds and several miles offshore." Miller and Able (2002), working in Delaware Bay, found young Atlantic croaker used the entire range of marsh creek habitats. When found in deeper waters of the bay, croaker were most abundant over the mud bottoms.

In summary, it appears that the lower-salinity upper reaches of estuaries are optimal habitat in South Carolina for young Atlantic croaker. Survival and growth rates appear to be higher in low salinity areas although the reason(s) is unknown. Atlantic croaker move seaward as they become larger, using the deeper channels to migrate. Mud bottom habitats throughout the estuary appear to be important to the species regardless of depth. Atlantic croaker are a significant and ubiquitous component of the near-shore and inshore benthic fish community and as such, this species is a valuable indicator species of the relative health of estuarine benthic finfish and their associated habitat.

CHALLENGES

Atlantic croaker along coastal South Carolina face a number of challenges, including increased fishing pressure, changing and increasingly stressful environmental conditions, loss and degradation of critical habitats, and other anthropogenic stressors such as contaminants and pollutants. Further, major data gaps still exist including the size composition of recreationally released fish, and hence the sizes and ages subject to post release mortality and fishery selectivity. Since colonial times, size- and age-structure of Atlantic croaker populations appears to have changed drastically in ways consistent with heavy fishing pressure (Hales and Reitz 1992).

Emerging challenges facing Atlantic croaker, and many other estuarine species, included the impact of warming estuarine waters and marine heat waves during critical life history stages, phenological changes in weather patterns and food web dynamics, and increased variability in the climate. Further, adequate freshwater flow into the coastal zone appears to be very important to the species with inadequate freshwater flow into estuaries when juveniles are on the nursery grounds negatively impacting the species due to changing estuarine salinity profiles. Loss of shallow saltmarsh habitats through construction of seawalls in the upper reaches of tidal creeks could also be detrimental. Additionally, compromised water quality resulting from nutrients and

chemicals associated with untreated storm water from coastal development could negatively affect the species, particularly the juveniles while in the nursery habitats

The potential impacts of chemical pollutants on Atlantic Croaker and other fishes are just now coming to light. Emerging contaminants of concern, including per- and polyfluoroalkyl substances and microplastics among others, on the productivity of the population still needs investigation, particularly given recruitment appears closely tied to environmental conditions. The impact of other endocrine disrupting chemicals (EDCs) such as organo-chlorines, polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), and alkylphenols are being investigated in fishes. Thomas (1990) found female Atlantic croaker exposed to cadmium had elevated levels of reproductive hormones resulting in precocious ovarian growth; exposure to lead, benzene(a)pyrene, and the PCB Aroclor 1254 each caused a decline in circulating steroid hormone levels and ovarian growth. McCarthy et al. (2003) demonstrated environmentally realistic loadings of a PCB (Aroclor 1254) in eggs of Atlantic Croaker through dietary exposure and maternal transfer can have significant effects on survival and growth rates of larvae. In a separate study, Khan and Thomas (1996) showed that Aroclor 1254 significantly blocks testicular growth in Atlantic Croaker.

CONSERVATION ACCOMPLISHMENTS

Actions taken by the South Atlantic Fishery Management Council in Amendment 2 to Shrimp Management Plan (SAFMC 1996) and by the Atlantic States Marine Fisheries Commission in the Weakfish Management Plan (ASMFC 1994) have resulted in the mandatory use of by-catch reduction devices in shrimp trawl nets. Studies have shown that these devices are useful in reducing by-catch-related fishing mortality of fishes including Atlantic Croaker. Additionally, the South Carolina General Assembly closed most of the area in the State's sounds and bays to shrimp trawling in 1986, thus reducing fishing mortality and providing greater survival of juveniles. Another legislative action by South Carolina eliminated small mesh gill nets in the state's estuaries and significantly reduced the length of recreational gill nets to 30.5 m (100 ft.). Beginning in 2014, Atlantic Croaker are regulated in the recreational fishery by an aggregate bag limit along with other Sciaenids, spot (*Leiostomus xanthurus*) and southern kingfish (*Menticirrhus americanus*), where any combination of the three species can sum to 50 fish per person.

Regionally, Atlantic croaker are managed under Amendment 1 to the Interstate Fishery Management Plan for Atlantic Croaker (ASMFC 2005) and Addenda I, II, and III (ASMFC 2011, ASMFC 2014, ASMFC 2020). The Amendment did not require any specific measures restricting harvest but encouraged states with conservative measures to maintain them while also implementing a set of management triggers to respond to changes in the fishery or resource.

CONSERVATION RECOMMENDATIONS

Regional assessments have identified numerous research recommendations conducive to the effective assessment and management of Atlantic croaker (ASMFC 2010). Added to this list are some state specific priorities. Combined, identified research priorities include:

- Continue fisheries-independent surveys throughout the species range and subsample for individual weights and ages, particularly in the southern range.
- Encourage fishery-dependent biological sampling of Atlantic croaker from the southern region. Collect age samples from the recreational fishery when the length distribution of the recreational fishery is not adequately represented by the fisheries from which the age-length keys are developed.
- Conduct post-release mortality studies for recreational and commercial fisheries, including investigation of sub-lethal effects of landings, particularly as impacted by fishing depth, fish size, fishing season, and the type of terminal tackle used.
- Better characterize the reproductive potential of the population, particularly in the southern region, through investigations of batch fecundity, lengths- and age-at-maturity, sex ratios, spawning seasons, and spawning frequencies. Investigate who these values change with size and/or age.
- Evaluate drivers of recruitment success and other environmental covariates affecting population dynamics.
- Develop a coast-wide tagging program to evaluate migration and movement and continue any coast-wide studies (e.g., genetic, otolith microchemistry) designed to improve understanding of stock definition.
- Quantify the level of Atlantic croaker bycatch from the South Carolina commercial shrimp trawling fishery and associated mortality levels.
- Determine the level of contaminants (organics, pesticides, heavy metals, per- and polyfluoroalkyl substances) found in Atlantic croaker as well as the sediments/waters in the areas in which they are caught. Relate that to the potential effects of bioaccumulation.
- Examine ecological interactions between Atlantic croaker and other species, including red drum.
- Protect water quality in marine ecosystems by encouraging municipalities to use Best Management Practices (BMPs) to reduce runoff from highways, agricultural fields, and housing developments.
- Plan development based on sound terrestrial and estuarine ecology that takes into consideration all factors affecting the long-term health of the estuary ecosystem.
- Partner with other state agencies to improve resource management at the whole estuary or drainage basin level using a more holistic ecological approach. Such

restructuring should provide for greater regulatory authority in implementing migratory fish management plans.

- Work with partner agencies and municipalities to minimize the loss of salt marsh habitat to construction projects in the Coastal Zone.
- Along with OCRM and other partners, work with municipal and county planners to work toward reducing the negative impacts of urban development to sensitive areas in coastal marshes.

MEASURE OF SUCCESS

The fishery-independent programs conducted by the SCDNR annually monitors the relative abundance, population demographics (size- and age-compositions) and reproductive potential of estuarine and nearshore demersal finfish, such as Atlantic croaker. These surveys can detect changes in those parameters, providing critical data for the assessment of stock status and early detection of change (positive or negative) in abundance or population demographics. Although there appears to be much variability in relative abundance year to year, the ultimate measure of success will be to document stable to increasing population trends over long-term periods.

Further, work identifying abiotic and biotic drivers of population fluctuations, in particular concerning recruitment, remain critical for projecting the response of Atlantic croaker to future climate change, climate variability, and emerging contaminants of concern.

Atlantic Menhaden

Brevoortia tyrannus

Contributors:
Joseph C. Ballenger (SCDNR)

Revised 2025:
Joseph C. Ballenger (SCDNR), Keilin Gamboa-Salazar (SCDNR)

DESCRIPTION

Atlantic menhaden, a Clupeoid fish of interest to fisheries, is one of the most common forage fish species encountered in South Carolina estuarine and coastal waters. It is estuarine-dependent with juveniles utilizing estuarine nursery areas (Whitehead 1985).

Taxonomy and Basic Description

Atlantic menhaden, *Brevoortia tyrannus* (Latrobe 1802), belong to the order Clupeiformes and the shad family, Alosidae (Page et al. 2023), and are similar in appearance to the alewife and shad. They belong to the subfamily Alosinae (a.k.a. the shads), which includes 7 genera, 2 of which (*Brevoortia* and *Alosa*) have representatives in the western Atlantic (Whitehead 1985). The genus *Brevoortia* includes 6 species: *B. aurea*, *B. gunteri*, *B. patronus*, *B. pectinata*, *B. smithi*, and *B. tyrannus*. *B. tyrannus* and *B. smithi* (yellowfin menhaden) overlap in distribution off the East coast of the United States, particularly off Florida (Whitehead 1985). In areas of overlap, *B. tyrannus* and *B. smithi* commonly will hybridize (Dahlberg 1970).

Atlantic menhaden have a bluish body above with silvery sides possessing a reddish luster and fins tinged with pale yellow and edged in black (ASMFC 1981). They are distinguished from other Alosidae by a large head, an upper jaw with distinct median notch, no teeth, pectinated scales, the location of the dorsal fin over the interval between the pelvic and anal fins, the pelvic fin with a rounded hind margin, modified pre-dorsal scales, and a compressed body with bony scutes along the belly (ASMFC 1981; Whitehead 1985). Atlantic menhaden posses long gill rakers and a muscular pyloric stomach or gizzard (ASMFC 1981). The lateral line scales above the base of the anal fin and at the base of the tail are much smaller and irregularly spaced (Whitehead 1985). There is a conspicuous black spot behind the gill opening that is usually followed along the flank by a variable number of smaller spots (or blotches) forming up to 6 approximate lines (ASMFC 1981; Whitehead 1985). Atlantic menhaden are readily distinguished from yellowfin menhaden due to the difference in lateral line scale number (40 to 58 (usually 45-52) versus 54 to 80 (usually 60-70) in *B. tyrannus* and *B. smithi*, respectively) and a lack of lines of spots on flank in *B. smithi* (Whitehead 1985). Other *Brevoortia* species do not overlap in range while other alosids lack the modified pre-dorsal scales (Whitehead 1985).

Status

Currently, the Atlantic menhaden population is managed by the Atlantic States Marine Fisheries Commission (ASMFC) as a unit stock along the east coast of the United States. In February 2020, the ASFMC Atlantic Menhaden Board accepted the results of the Atlantic Menhaden Single-Species and Ecological Reference Point (ERP) Assessments and Peer Review Reports (ASMFC 2020; SEDAR 2020) for management use. Of note, the ERP assessment evaluates the health of the stock in an ecosystem context using an ecosystem model focused on four key predator species (striped bass, bluefish, weakfish, and spiny dogfish) and three key prey species (Atlantic menhaden, Atlantic herring, and bay anchovy; ASMFC 2020). The ERP assessment indicated lower fishing mortality (F) reference points for menhaden, relative to the single-species model, to account for menhaden's role as a forage fish were necessary. This lead to the development of ERP reference points directly accounting for the menhaden needed to sustain Atlantic striped bass at their biomass target (or threshold) when striped bass are fished at their target (or threshold; ASMFC 2020). An update of the Atlantic menhaden single-species model was performed in 2022 (ASMFC 2022), with stock status determined relative to the defined ERP reference points accepted following the benchmark assessments (ASMFC 2020).

The recent update assessment determined the stock was not overfished nor experiencing overfishing in the terminal year (ASMFC 2022). The assessment suggested that while overfishing had occurred only briefly throughout the assessment time series (1972-1973 & 1985), F exceeded target levels most years from 1955- 1998 (Figure 1; ASMFC 2022). Since the late-1990s, F has hovered around the target F (ASMFC 2022). The last extended period when the stock was overfished was from 1971-1990, with the stock being approximately at the target fecundity since the early-1990s (Figure 2; ASMFC 2022).

The grey represents the 5th and 95th percentiles across Monte-Carlo Bootstrap (MCB) iterations, while the black line with closed black circles represents the base run. The dashed line represents the median of the MCB analysis.

POPULATON SIZE AND DISTRIBUTION

Atlantic menhaden are distributed from Nova Scotia, Canada, southward to Indian River, Florida. Throughout this range, they are a euryhaline species that occurs in the Atlantic Ocean and inland tidal waters (Hildebrand 1948;

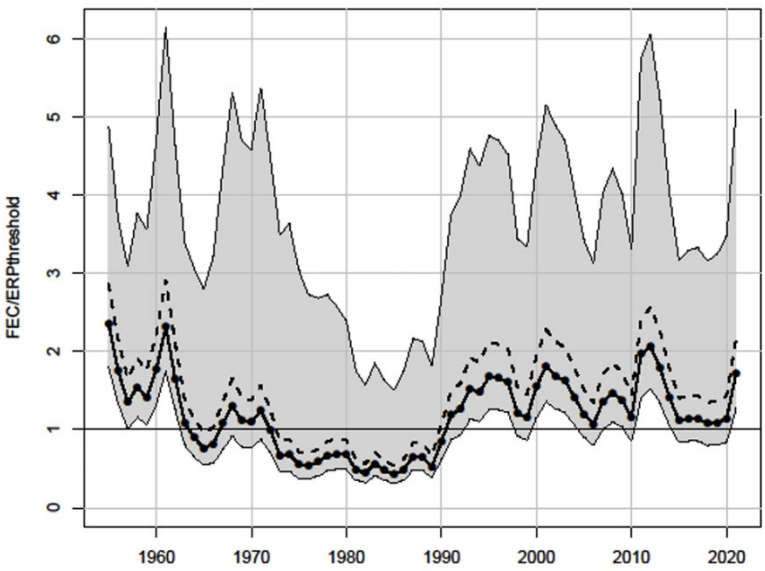

Figure 2: Annual population fecundity relative to threshold fecundity (Source: ASMFC 2022). The grey represents the 5th and 95th percentiles across Monte-Carlo Bootstrap (MCB) iterations, while the black line with closed black circles represents the base run. The dashed line represents the median of the MCB analysis.

Hildebrand 1964; Reintjes 1960; Reintjes 1964). Juveniles and adults occupy bays, sounds, and estuaries to the uppermost limits of brackish water (ASMFC 1981). In coastal ocean waters, they are confined to waters of the Continental Shelf and are never observed far from land (ASMFC 1981). Seaward, the farthest from land an Atlantic menhaden has been captured was approximately 130 km (81 mi.) south of Cape Cod by a Soviet trawler (Gusev 1964). Historically, this distance from shore is about the maximum distance from land schools have been sighted by scouting aircraft, and further offshore than the seaward limit of the purse seine fishery (ASMFC 1981).

Generally, Atlantic menhaden are found inshore during summer months, but at least some move into deeper waters in winter. It is thought this offshore movement during winter months is less pronounced in the southern part of their range (Whitehead 1985). Adults are found in near surface waters (June 1961), most commonly in continental shelf water, in greatest abundance immediately adjacent to major estuaries (Jones et al. 1978). Juveniles are generally found in shallower, potentially lower salinity waters, with the smallest size groups being found farthest upriver (June and Chamberlain 1959).

Menhaden are pelagic, forming large and compact schools (Whitehead 1985). The majority appear to be migratory in nature, with northward migrations occurring during the spring/summer and southward migrations occurring during the fall (Figure 3; ASMFC 1981; Whitehead 1985). More specifically, different size/age menhaden appear to undergo migrations of different degrees, with larger/older individuals migrating

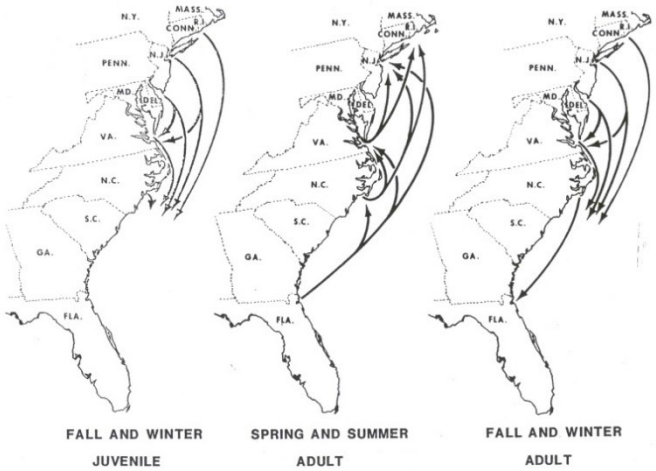

Figure 3: Juvenile and adult migrations of Atlantic menhaden (Source: ASMFC 1981).

further distances (Dryfoos et al. 1973; Nicholson 1978). Menhaden typically school with individuals of a similar size and age in a locality, with schools remaining distinct from those of overlapping sizes and ages in adjacent localities. The net effect is a north-south gradient in size and age becoming established during summer months, with larger and older fish found farther northward (Dryfoos et al. 1973; June and Reintjes 1959; McHugh et al. 1959; Nicholson 1978; Whitehead 1985). In the fall, there is once again a southward withdrawal of fish from the summer grounds, with fish congregating in large schools (sometimes covering a surface area of many square kilometers) for the southward migration (ASMFC 1981). These large, migrating schools are last seen off the North Carolina coast in December and January (June 1961; Roithmayr 1963; Reintjes 1969; Nicholson 1971; Nicholson 1972; Dryfoos et al. 1973; Kroger and Guthrie 1973). Kroger and Guthrie (1973) found juvenile Atlantic menhaden also exhibit a seasonal north-south movement. From tag recoveries, they report juveniles (age-0's) migrate as far south as Florida in fall and winter, then redistribute northward along the coast by size as age-1 fish during the following spring and summer. Due to the redistribution by size, the smaller age-1 fish tend to remain along the south Atlantic coast.

In South Carolina, juvenile and adult Atlantic menhaden are present in estuaries and coastal ocean waters throughout the year. Unfortunately, there is not an estimate available of their absolute population size off South Carolina. However, several SCDNR fishery-independent surveys encounter menhaden in low to moderate numbers, including the SCDNR trammel net, SCDNR electrofishing, SCDNR estuarine trawl, and SCDNR coastal trawl surveys. The three inshore surveys (trammel net, electrofishing, and estuarine trawl) primarily encounter age-0 (electrofishing and estuarine trawl) and age-1 (trammel net) individuals. The 2022 benchmark assessments considered and, in the case of the electrofishing survey, included these indices in the coastwide assessment (ASMFC 2022). The SCDNR coastal trawl survey primarily encounters age-1+ Atlantic menhaden, and this survey was incorporated in the 2022 assessment as an adult abundance index for the southern region (ASMFC 2022). The recruitment indices suggest generally low recruitment interspersed with periodic strong recruitment in coastal South Carolina (e.g., 2001, 2003, 2012, 2023) which is typical for recruitment surveys where recruitment success is environmentally driven (Figure 4). The trammel net survey suggests higher relative abundances were observed in the early-1990s through mid-2000s, before an extended period of low abundance from the late-2000s through 2014, followed by a general increase since with peaks in abundance in 2017 and 2021 (Figure 5). Catches of Atlantic menhaden adults in the SEAMAP-SA coastal trawl survey indicate low relative abundance in general, though with a period of higher abundance in the late 2000s (Figure 5).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Being euryhaline, Atlantic menhaden can tolerate a wide range of salinities. As such, both juveniles and adults can be found in a wide array of nearshore habitats, including bays, sounds, and estuaries to the uppermost limits of brackish water (ASMFC 1981). In general, the smallest size groups are found farthest upriver (June and Chamberlain 1959), as attested by the catch of very small young-of-the-year in the SCDNR electrofishing survey. Regardless of size, Atlantic menhaden are pelagic in nature, feeding by filtering phytoplankton and zooplankton (Whitehead 1985; Scott and Scott 1988). As adults they are obligate filter-feeders, while larvae and pre-juvenile fish (smaller than 4.0 cm or 1.6 in. TL) are particulate feeders (Lazzaro 1987; James 1988). In the ecosystems where menhaden are found in South Carolina, they are a significant forage fish for a host of predators, including striped bass, bluefish, spotted seatrout, red drum, and various sharks and rays.

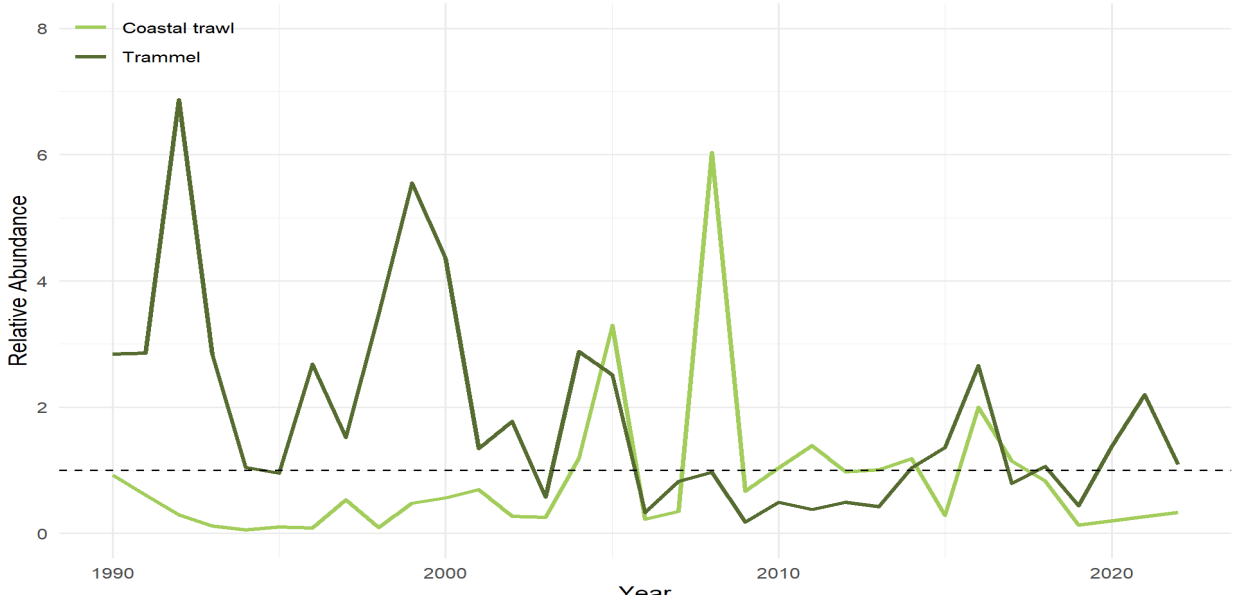

Figure 5: Standardized indices of abundance of Atlantic menhaden as developed from the SCDNR fishery-independent trammel net (dar green line) and coastal trawl (light green line) surveys.

Spawning likely occurs year-round, though there is evidence that the breeding season in specific locales is limited by high water temperatures (Higham and Nicholson 1964; Whitehead 1985). This limits spawning to certain seasons along the entire coast: spawning during the spring (April/May) in New England waters, autumn (October/November) in the mid-Atlantic, and winter (December to March) in the South Atlantic (Whitehead 1985). It is thought the major spawning season occurs off the Carolinas during December-February (ASMFC 2011), with the majority of ovigerous

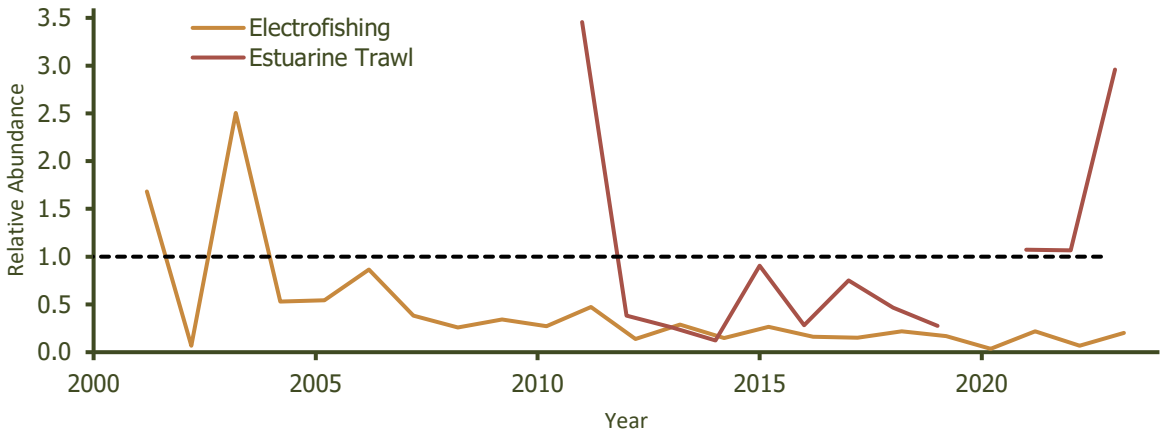

Figure 4: Standardized indices of abundance of Atlantic menhaden as developed from the SCDNR fishery-independent electrofishing (gold line) and estuarine trawl (red line) surveys.

females being observed in the South Atlantic (Nelson et al. 1977). The temperature, depth, and salinity at presumed spawning locations varies widely depending on latitude and distance from shore (Kendall and Reintjes 1975; Bourne and Govoni 1988; Berrien and Sibunka 1999; Checkley et al. 1999). Reported water temperatures are typically in the range of 55-77ºF (13 to 25ºC). Spawning occurs at depths <33-66 ft. (<10-20 m). Salinity at spawning sites has been reported to be 29-36 ppt at offshore mid-Atlantic sites and 35.8-36.6 ppt at South Atlantic sites. Eggs have been found at 18-28 ppt in Long Island Sound (Wheatland and Lewis 1956) and 10-22 ppt in Chesapeake Bay (Dovel 1971). Post hatching, larvae are pelagic (Massman et al. 1962), probably spending approximately a month in waters over the Continental Shelf (McKenney 1969), prior to entering estuarine waters at about 0.39 in. (10 mm) and larger (Reintjes 1969).

In the mid- and south-Atlantic nursery areas, bottom composition is "unconsolidated," consisting of sand-mud, and organic material which may be important to juvenile consumption (Lewis and Peters 1984; Peters and Schaaf 1991). Juvenile menhaden remain in their estuarine nursery areas throughout the summer. In fall, most juveniles emigrate southward, though some overwinter in the Chesapeake Bay and south-Atlantic region estuaries. Immature adult menhaden are most abundant in inshore and estuarine areas from Chesapeake Bay southward (Nicholson 1978). Older, larger adults are typically found in colder, rockier northerly habitats during summer, while they overwinter off North Carolina and further south (Nicholson 1978). Adults appear to prefer temperatures of about 64ºF (18ºC; ASMFC 2011).

CHALLENGES

As menhaden of different life stages use a diverse array of habitats, almost all estuarine and nearshore waters along the Atlantic coast from Florida to Nova Scotia serve as an important habitat for some life stage. As such, pollution and habitat degradation of any estuarine and nearshore habitat could be expected to threaten the coastal menhaden

population. Such habitat degradation concerns are especially acute in estuarine waters due to the residency of larvae and juveniles in these habitats (ASMFC 2011). An indication of the threat habitat degradation poses to menhaden is the concern that the outbreaks of ulcerative mycosis in the 1980s may have been symptomatic of deteriorating water quality in estuarine waters along the East coast (Ahrenholz et al. 1987). As coastal development increases, we expect estuarine water quality to further deteriorate unless steps are taken to ameliorate their effect on the environment (Cross et al. 1985). Estuarine and coastal habitats have been significantly affected by dredging, filling, coastal construction, energy plant development, pollution, waste disposal, and other human-related activities (ASMFC 1999a). Other potential threats in coastal waters include the offshore dumping of sewage. High concentrations of DDT have been reported in menhaden due to their feeding on plankton and detritus (Warlen et al. 1977). Directly applicable to Atlantic menhaden is the concern regarding microplastic pollution, with a study in Charleston Harbor finding the highest concentration of microplastics per gram of fish reported to date in Atlantic menhaden digestive tracts captured from the system, suggesting potential impacts of this emerging contaminant of concern (Parker et al. 2020).

An additional challenge to the Atlantic menhaden population is the large-scale fisheries that operate on the population. At present, two large-scale fisheries target Atlantic menhaden: a commercial reduction fishery and a commercial bait fishery (Figure 6; ASMFC 2022). Combined landings from the fleets peaked during the late-1950s (>600,000 metric tons), and then declined to lower levels during the 1960s. The stock rebuilt some during the 1970s, with landings rising before leveling off in the 1980s through mid-1990s as decreases in commercial reduction landings were offset by increases in commercial bait landings. Since the mid-1980s coastwide bait landings have gradually increased as reduction landings decreased, resulting in a relatively stable harvest of just over 200,000 mt annually since the early-2000s. Though landings off the coast of South Carolina have generally been small, due to the migratory nature of the stock, any overharvest of the stock in other regions can have an adverse effect on the sub-population located off the coast of South Carolina.

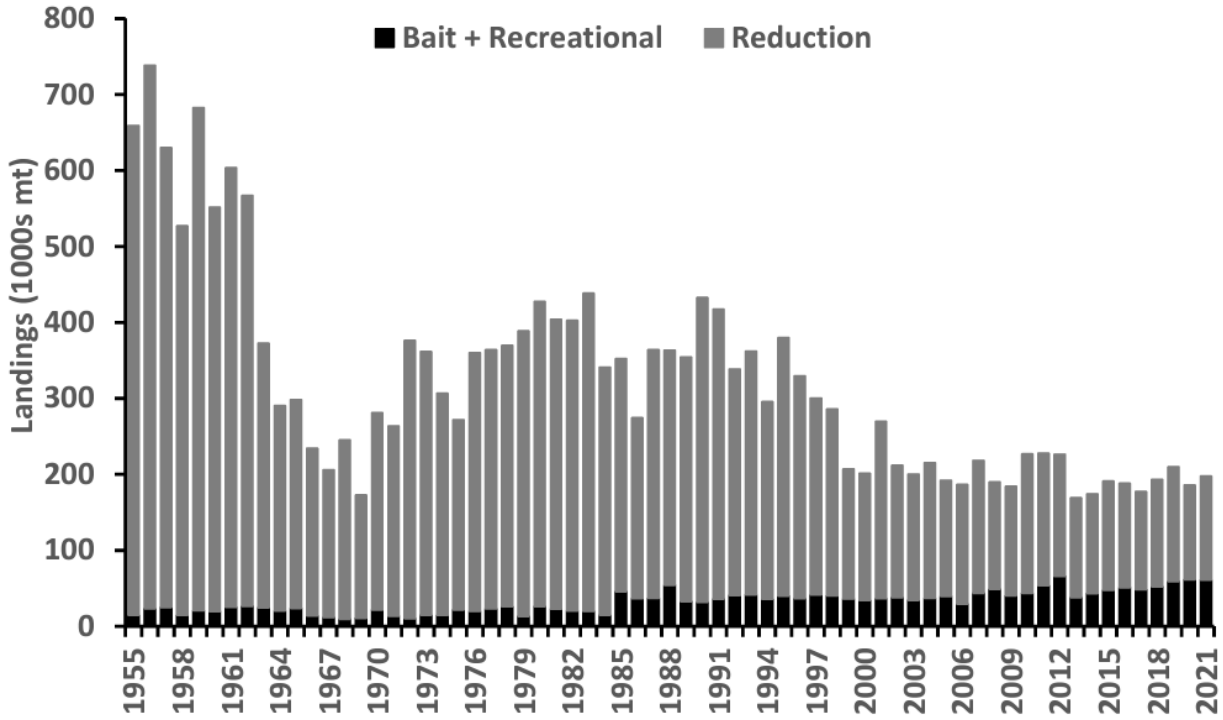

Figure 6: Coastwide Atlantic menhaden landings for the reduction and bait fisheries (1955-2021; Source: ASMFC 2022).

CONSERVATION ACCOMPLISHMENTS

Atlantic menhaden are currently managed under Addendum I to Amendment 3 to the Interstate Fishery Management Plan (FMP) for Atlantic Menhaden established via the Atlantic States Marine Fisheries Commission (ASMFC 2023). This Addendum includes provisions for setting annual total allowable catches (TAC; 2023-2025 = 233,550 mt), allocated percentages of the TAC to individual states, sets aside 1% of the TAC for episodic events, and prohibits purse seines as a permitted small-scale directed gear, thereby prohibiting them from harvesting the incidental catch/small-scale fishery provision. The addendum also continues to prohibit the rollover of unused quota, maintains the 6,000 pounds trip limit for applicable gear types following the closure of a directed fishery, and keeps the current Chesapeake Bay Cap, which was first implemented in 2006 to limit the amount of reduction harvest within the Bay, at 51,000 mt. This recognizes the Chesapeake Bay as nursery grounds for many species by capping reduction landings from the Bay to current harvest levels.

Further, the ASMFC Atlantic Menhaden Board continues to place a high priority on advancing the development of ecosystem-based reference points using a multispecies modeling approach (ASMFC 2020). This is because of the realization that Atlantic menhaden constitute a major component of the diet of coastal water piscivores. Ecosystem reference points are expected to address the forage needs of menhaden's predator species. The current single-species stock assessment is scheduled to complete

another update assessment in 2025, while the next benchmark ecological reference point assessment is also scheduled for completion in 2025.

CONSERVATION RECOMMENDATIONS

At the state level, conservation recommendations include:

- Continue to evaluate the effects of fishing and management plans on the South Carolina sub-population of Atlantic menhaden
- Initiate studies to investigate the within-year age composition variability of Atlantic menhaden in South Carolina coastal waters,
- Explore the trophic assemblages involving menhaden,
- Monitor trends in Atlantic menhaden young-of-the-year and adult relative abundance by continuing to collect data about this species during ongoing fishery-independent monitoring programs,
- Initiate additional work to understand the local and regional movement patterns of menhaden occurring in South Carolina waters,
- Protect water quality in marine ecosystems by encouraging municipalities to use Best Management Practices (BMPs) to reduce runoff from highways, agricultural fields, and housing developments. Improve BMPs in areas already affected by non-point source pollution.
- Plan development based on sound terrestrial and estuarine ecology that takes into consideration all factors that will affect the long-term health of the estuary ecosystem.
- Identify the origin of non-point source pollution and specific point source pollution and develop a plan of action to mitigate any negative impacts to the affected aquatic systems.
- Monitor the impact of contaminants of emerging concern in estuarine environments, such as per- and polyfluoroalkyl substances and microplastics.

The most recent benchmark assessment (single-species and ecological reference points; ASMFC 2020; SEDAR 2020) identified the following research recommendations for the coastwide stock applicable to South Carolina:

- Develop and implement a menhaden-specific, multi-year coastwide fishery-independent index of adult abundance-at-age with ground truthing for biological information (e.g., size- and age-compositions).
- Continue age-specific studies on spatial and temporal dynamics of spawning

- Conduct an ageing validation study, making sure to sample older age classes
- Continue to investigate environmental covariates related to productivity and recruitment on a temporal and spatial scale
- Consider other ageing methods for the future, such as the use of Fourier transform near infrared spectroscopy (FT-NIRS)
- Expand collection of diet and condition data along the Atlantic coast to provide seasonally and regionally stratified annual, year-round monitoring of key predator diets to provide information on prey abundance and predator consumption
- Improve monitoring of population trends and diet data in non-finfish predators (e.g., birds, marine mammals) and data-poor species (e.g., bay anchovy, sand eels, benthic invertebrates, zooplankton, and phytoplankton) to better characterize the importance of Atlantic menhaden and other forage species to the ecosystem dynamics

MEASURE OF SUCCESS

The SCDNR fishery-independent programs that annually monitor the relative abundance and length frequency of inshore fish species are already in place to monitor for changes in size distribution and relative abundance as a result of regional management efforts. The measurement of success will be to see an increasing trend in catch of Atlantic menhaden in these surveys.

Atlantic Tripletail

Lobotes surinamensis

Ashley Bobnar (SCDNR), Jason Broach (SCDNR) & Joseph C. Ballenger (SCDNR)

Illustration by Duane Raver, Jr.

DESCRIPTION

Taxonomy and Basic Description

The Atlantic tripletail, *Lobotes surinamensis*, is a compressed, deep-bodied fish recognizable as an adult by its three rounded fins and a concave head (Gudger 1931). Found in warm coastal waters around the globe, this fish can reach up to 1100 mm (43 in.) in total length (TL) and 19.2 kg in weight (Baughman 1941; IGFA 2001). Atlantic tripletail are relatively short-lived, with an average lifespan of 5-10 years (Merriner and Foster 1974; Armstrong 1996; Strelcheck et al. 2004). As a result, juveniles reach maturity around age 1, growing the most during their first year of life (up to 600 mm TL; Merriner and Foster 1974; Franks et al. 2001; Jefferson et al. 2021). Juveniles are often brown to dark brown or black and yellowish in coloration, while adults may vary from brown to red or greyish mottling (Baughman 1941). Both are known to prefer shaded areas, where they often float on their sides to camouflage as drifting mangrove leaves or debris (Baughman 1941). Tripletail are gonochoristic, meaning males and females remain separate sexes throughout their entire lifespan. This species is one of the two members in the family Lobotidae, found within the order Acanthuriformes, and the only member found in the Atlantic Ocean (Page et al. 2023).

Status

Atlantic tripletail were previously managed by the Gulf of Mexico Fishery Management Council (GMFMC). However, due to variability or a lack of data, the GMFMC decided to remove Atlantic tripletail from inclusion in federal management practices. As a result, this species is managed on a state-by-state basis. In 2020, South Carolina implemented catch (3 per person per day or 9 per boat per day) and size (at least 18 inches TL) limit regulations. There is currently no stock status information available for this species. Based on a 2012 IUCN assessment, the Atlantic tripletail is listed as a species of 'Least Concern'. However, this assessment dates from over a decade ago and is noted as 'needs updating'.

POPULATION SIZE AND DISTRIBUTION

Along the eastern seaboard, Atlantic tripletail are distributed from Massachusetts to Argentina, throughout the Gulf of Mexico, and the Caribbean Sea (Gudger 1931; Hoese and Moore 1998), though the densest populations are found southward of the

Chesapeake Bay (Gudger 1931). This species is commonly found in association with structure (e.g., *Sargassum*, pilings, buoys, platforms, etc.) and shade, both in nearshore and offshore coastal regions (Gudger 1931; Baughman 1941; Caldwell 1955). Atlantic tripletail are migratory fish (Merriner and Foster 1974; Streich 2013), yet these patterns are not very well understood. This species has become more commonly encountered in our fishery-independent trammel net survey since the early-2010s, in which we sample randomly selected sites along salt-marsh edges within five estuaries statewide (Winyah Bay, Cape Romain, Charleston Harbor, ACE Basin, and Port Royal Sound), with 9 of 12 (75%) years since 2102 encountering 10 or more individuals while 10 individuals or more were only encountered during five of 21 years (24%) from 1991-2011. However catch rates are currently not high enough for the development of indices of abundance.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In the summer, Atlantic tripletail occupy inshore and nearshore areas such as bays, basins, and lagoons (Gudger 1931; Baughman 1941; Merriner and Foster 1974). This species prefers structured habitat including wrecks, pilings, buoys, jetties, and patches of *Sargassum* for juveniles (Gudger 1931; Baughman 1941; Caldwell 1955). Adults may be found in open waters or passes such as the mouths of estuarine systems (Baughman 1941). Outside of seasonal occurrences (typically April-October), estuarine habitat-use of the Atlantic tripletail is not very well known (Streich 2013). These fish are opportunistic feeders eating both small finfish and invertebrate species, a few of these prey items including menhaden, blue crabs, and shrimp (Gudger 1931; Baughman 1941).

CHALLENGES

The population status of Atlantic tripletail in South Carolina is difficult to assess due to a lack of data in the region. Little is known about the species' habitat-use and life history, particularly in South Carolina, and therefore fishing pressures and climate change consequences are challenging to gauge. However, as South Carolina is near the northern extent of their current range, warming estuaries may allow larger populations of Atlantic tripletail to develop in South Carolina, which may be what the SCDNR trammel net survey is currently observing.

CONSERVATION ACCOMPLISHMENTS

The Atlantic tripletail fishery in South Carolina is managed by the state, with recent implementation of catch (3 per person per day or 9 per boat) and size (at least 18 in.) limits in 2020. Prior, no size limits existed for this species. South Carolina was the last state within the northern species range to enact regulations due to growing recreational and commercial fisheries over the last decade.

CONSERVATION RECOMMENDATIONS

- Performing a formal stock assessment for Atlantic tripletail in the Southeastern US coastal waters would allow for a better understanding of their stock status, fishing pressure, and best future direction for the sustainable management of this species, however more robust input data for the assessment is needed.
- Continue to monitor Atlantic tripletail populations via fishery-independent sampling programs such as the SCDNR trammel net survey.
- Initiate studies of the life history, juvenile habitat preference, and spawning locations.

MEASURE OF SUCCESS

Measurement of management success is difficult given the lack of population assessments and fishery-dependent and -independent data. However, the SCDNR Inshore Fisheries (IF) group monitors relative abundance, population demographics, and reproductive status of estuarine finfishes through monthly trammel netting, electrofishing, and longline surveys and can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, and size- and/or age-compositions would indicate positive trends in the population.

Tuna

Atlantic Bluefin *Thunnus thynnus*, Yellowfin *Thunnus albacares,* Blackfin *Thunnus atlanticus*

Contributors:
Amy Dukes (SCDNR), Elizabeth Gooding (SCDNR), & Sydney Bates (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

These tunas, all members of the order Scombriformes and family Scombridae (Page et al. 2023) are further subgrouped into the tribe Thunnini. Tunas within this tribe become sexually mature near 20 pounds and can reach weights of 1,500 pounds (SCDNR Sea Science). Size and age differ among species of tunas; smaller species tend to have shorter lifespans, while other species grow larger and have relatively longer lifespans. Size also varies among tuna between male and female. Male tuna will grow larger and faster than females. The largest tuna, Atlantic bluefin tuna, reach lengths over 13 feet and 1,500 pounds. This species has a suggested lifespan of over 35 years, which is substantially longer than the two to 18 year estimated lifespan of the yellowfin tuna (Murua 2017, Andrews 2020). Blackfin tuna are much smaller, weighing 15 pounds at age five. Blackfins average weight nears 42 pounds suggesting this species lifespan is near 10 years (De Sylva 1987). Tunas have a fusiform body shape with a lunate caudal fin that allows them to move at high speeds through the water column via thunniform swimming (Graham 2004). Tunas have two dorsal fins, the first with 11 to 14 spines, separated by an interspace and the second with 12 to 16 rays. Posterior to the second dorsal fin are seven to 10 distinguished finlets. They have relatively small scales and small, sharp teeth.

Tunas mostly remain in oceanic waters, ranging from epipelagic to mid-water ranges. They remain out of polar regions; however, they have a distinctive trait that allows them to swim in colder waters. These fish have a high metabolic rate which allows them to maintain a body temperature that is much higher than the surrounding water. This, in turn, also creates a high growth pattern for these specific fish. Because they retain warmth in the muscles, they have more power allowing strong swimming to enable high gas exchange providing ample oxygen to support their high metabolism (Collete 1983). Because tunas occur in pelagic waters, they feed in open ocean systems and are considered opportunistic predators with other fishes as their primary diet (Ménard 2006). Tuna species swim in schools, which provides various advantages for protection, energy saving, and foraging (Stocker 1999).

Even though their sexual differences are not visible externally, they are a dioecious species. Once tunas reach maturity, about two years for blackfin, they are reproductive (De Sylva 1987). Tunas spawn via releasing buoyant eggs and sperm into the open water. Egg fertilization will occur there, and larvae will begin to develop (Schaefer 2001). Tunas are considered highly migratory species, where spawning migrations differ between species. The Atlantic bluefin tuna migrates a long distance from feeding to spawning grounds, whereas yellowfin tunas spawn year-round without a long migration to spawning grounds (Muhling 2017).

Status

The Atlantic bluefin tuna and the yellowfin tuna are both considered not to be overfished (NOAA 2024). Many other tuna species have reached endangered status from being overfished. Now, population sizes have rebounded, but ineffective regulation of commercial and recreational landings is a challenge that can easily reappear (Miller 2007).

POPULATION SIZE AND DISTRIBUTION

Tunas are found worldwide in high abundances. Atlantic bluefin tuna are found in the Atlantic Ocean, with higher densities in the northern area. Yellowfin tuna populations are found worldwide but are heavily located in equatorial areas staying in tropical and subtropical waters (Erauskin-Extramiana 2019). Blackfin tuna have a more confined geographical distribution remaining within the western Atlantic Ocean (Collete 1983). Because of these large populations and wide distribution of tunas, they are significant in commercial and recreational fisheries. In 2012, the estimated end value of tuna reached $41.6 billion. Because they hold such high value in commercial fishing, they are more susceptible to overfishing. This creates an increased need for fisheries management to help conserve the tuna resources by enforcing sustainable fishing guidelines (Galland 2016).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

As highly migratory species, the duration of tunas' lifespan is spent travelling long distances in the water column in the open ocean. Habitat preference differs between species. Blackfin tuna are only found in the very clear waters in the Western Atlantic. They also vary in water temperature, where bluefin tuna are found in colder water compared to blackfin (De Sylva 1987). They are found closer to the surface, but often make vertical migrations to depths between 500 and 1,000 meters. Tuna species swim in large schools to provide better advantages to the species for protection and foraging (NOAA 2024).

CHALLENGES

Challenges easily arise in research of tuna, because of their highly migratory patterns. Organizations have struggled in efforts to study climate sensitive tuna species. Effective and efficient management of tuna species is also a challenge. Migrations of tuna causes higher fishing pressures in multiple regions and reduces the ability to properly manage the fishery. Some of the regions tunas move through are not in cooperation with fishing agreements putting certain species at higher risk to overfishing (Miller 2007).

CONSERVATION ACCOMPLISHMENTS

A wide range of amendments have been made to protect tuna species under the 2006 Consolidated Atlantic Highly Migratory Species Fishery Management Plan. These amendments help control fishing pressures by implementing gear restrictions, size limits, time/area closures, and permit requirements.

The International Commission for the Conservation of Atlantic Tunas (ICCAT) is an organization that helps manage tuna fisheries on a global scale. New yellowfin tuna management policies were put in place along West Africa to reduce undersized catch in 2011. Further, in 2013, reporting requirements were broadened to improve data collection on fishing efforts around fish aggregating devices.

Within commercial fishing, specific types of gear are approved and required for fishing to prevent damage to habitat and limit bycatch. One example is fishers are required to use circle hooks to prevent injury when hooking a non-target species and increase the chance of a healthy release (NOAA 2024).

CONSERVATION RECOMMENDATIONS

- Characterize stock status in Atlantic waters
- Determine potential shifts in distribution and driving factors
- Investigate migration patterns
- Expand research and monitoring in fishery-independent surveys

- Research early life stages and develop better understanding of complete life history

MEASURE OF SUCCESS

A successful species can be viewed by measuring a strong population size. Difficulties in assessing population size occur due to the highly migratory nature of tuna and their recent distribution movements. Due to climate change, some species of tuna, like the Atlantic bluefin tuna, have shifted in habitat distribution northward (Erauskin-Extramiana 2019). Another way to measure the success of a healthy population is to use independent or dependent data from recreational and commercial fishing effort and catch to determine population sizes. Successful populations can be suggested from successful management (NOAA).

Barrelfish

Hyperoglyphe perciformis

Contributors:
Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Barrelfish, *Hyperoglyphe perciformis*, is a member of the family Centrolophidae in the order Scombriformes (Page et al. 2023). The species has an elongate but deep body. The snout is blunt and the caudal fin is broad, not deeply forked. Small cycloid scales cover the body except for the head. Color is uniform dark green to gray or brownish with indistinct striping (either vertical or horizontal). The eye is often golden (Haedrich 2002). Juveniles commonly associate with floating objects such as barrels giving the species its common name. The species can grow to over 100 cm in length and is commonly encountered up to 80 cm. Barrelfish are long-lived, at up to 85 years of age. Sexual maturity occurs by 70 cm and 6 years of age (Filer and Sedberry 2008). Adults can be found in deep submarine canyons (Haedrich 2002). The species is gonochoristic with fish remaining male or female throughout their lifetime. Peak spawning occurs November through February (Filer and Sedberry 2008).

Status

Barrelfish is unassessed in southeastern U.S. waters and sustains no targeted fishery in the region. Therefore, little is known about their stock status. However, the species is listed under IUCN as a species of least concern as of February 2009.

POPULATION SIZE AND DISTRIBUTION

The species is landed as bycatch in the wreckfish commercial fishery. Juveniles are found in surface waters around the North Atlantic Ocean in loose schools associated with floating debris such as barrels. Adults are found at > 200 m depth associated with large topographic features such as the Charleston Bump in the western North Atlantic (Filer & Sedberry 2008). Commercial fisheries have recorded between 679 and 54,000 pounds landed off the southeast coast since 1991 with large fluctuations in annual harvest (NOAA 2024).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Adult Barrelfish are top predators found in temperate pelagic and deep-water continental slope habitats throughout the North Atlantic Ocean. A study of stomach content found the species feeds primarily on splendid alfonsino (*Beryx splendens*) and other mesopelagic fishes as well as squids (Goldman & Sedberry 2011). As juveniles,

the species congregate around floating debris in the open ocean, often congregating in large groups and is hypothesized to feed on organisms encrusting this debris, such as barnacles (Filer & Sedberry 2008).

CHALLENGES

Slow-growing, long-lived species are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. Barrelfish are also a deepwater species and they can be highly susceptible to post-release mortality (e.g. barotrauma).

Because the species currently has no targeted fishery and there are no effective methods of fishery-independent monitoring available, it is difficult to know the status or needs of sustainable practices.

CONSERVATION ACCOMPLISHMENTS

SCDNR convened a study of the age, growth, reproduction, and food habits of the species prior to the development of a targeted fishery. This action has provided a baseline for understanding the age, growth, and reproductive parameters of an unfished stock if a fishery were to develop for the species.

CONSERVATION RECOMMENDATIONS

- Increase fishery-independent information to develop reliable indices of abundance
- Partner with commercial fishers for updated life history information, genetic analyses, and reproductive parameter assessments
- Complete research studies of pelagic juvenile movements, settlement requirements, and other factors associated with habitat needs

MEASURE OF SUCCESS

Because there is currently no fishery-independent measure of population size or trends, and no targeted fishery, information for the species is very sparse. In recent years landings have fluctuated. If a fishery-independent or hybrid fishery-independent/fishery-dependent survey can be initiated, a stock level will be able to be estimated, with a measure of success being a stable population and size distribution through time.

Black Drum

Pogonias cromis

Contributors:
Chris McDonough (SCDNR) & Jacqueline Leidig (College of Charleston)

Revised 2025:
Zoe Golden (SCDNR/College of Charleston) & Joseph C. Ballenger (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Black drum (*Pogonias cromis*) are the largest members of the family Sciaenidae, who are members of the order Perciformes (Page et al. 2023), weighing up to 66 kg (145 lbs.). It is an estuarine-dependent saltwater fish found in the western Atlantic and Gulf of Mexico from the Bay of Fundy to Argentina (Welsh and Breder 1923; Bleakney 1963; Sutter et al. 1986). Throughout its range, black drum supports both recreational and commercial fisheries, with most commercial landings occurring in the Gulf of Mexico (Sutter et al. 1986; ASMFC 2012).

Black drum typically have 11 dorsal spines with 19-22 dorsal soft rays, 2 anal spines, and 5-7 anal soft rays. Colors range from silvery grey to very dark in juveniles with 4 or 5 black vertical bars on their sides which tend to disappear with growth. Pelvic and anal fins are usually dark. The chin has 5 pores and 10 to 13 pairs of small barbels along the median edges of the lower jaws and subopercles, increasing in length posteriorly (Chao 2003).

Along the US East coast, Jones and Wells (1998) reported a maximum age of 59 years in Virginia waters, while a maximum age of only 43 years has been observed in the northern Gulf of Mexico (Beckman et al. 1990). Long-lived adults exhibit group-synchronous maturation of oocytes and batch spawning (Fitzhugh et al. 1993) that occurs annually from sexual maturation to death (Pearson 1929). Annual fecundity of a mature female in the northern Gulf of Mexico has been estimated at 32-37 million eggs (Fitzhugh et al. 1993; Nieland and Wilson 1993). Early studies reported black drum reaching sexual maturity by the end of their second year in the Gulf of Mexico (Pearson 1929; Simmons and Breuer 1962; Sutter et al. 1986), but more recent investigations have presented evidence for later maturation. In northeast Florida, Murphy and Taylor (1989) found black drum to mature between 4-6 years, agreeing with findings from other studies in the northern Gulf of Mexico (Fitzhugh et al. 1993; Nieland and Wilson 1993; Olsen et al. 2018).

Black drum form large schools and move inshore for spawning during late winter into spring. In the Gulf of Mexico and northeast Florida, spawning occurs from January to May (Pearson 1929; Murphy and Taylor 1989; Nieland and Wilson 1993) but takes place in later months (April to June) at more northern latitudes, like the Chesapeake and Delaware Bays (Richards 1973; Thomas and Smith 1973). Young black drum recruit to shallow, muddy waters, such as tidal creeks, moving to deeper waters as they grow, until they reach sexual maturity and join the spawning stock (Pearson 1929; Richards 1973). Adults move offshore in the late fall and exhibit the potential for long-range migration along the Atlantic coast, especially along the coasts of southeast states (Jones and Wells 1998).

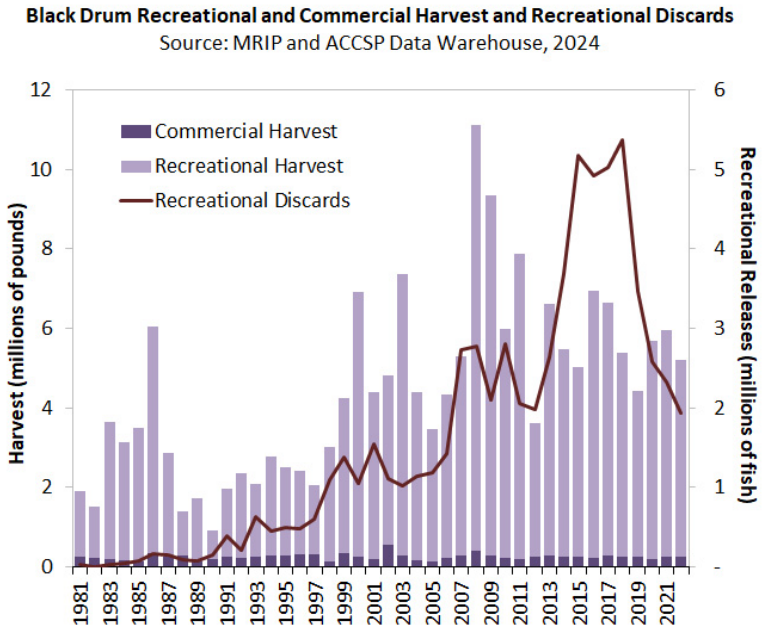

Figure 1: Black drum recreational and commercial harvest and recreational discards from 1980 to 2022 (Source: ASMFC 2023).

Status

Black drum are not listed as either an endangered or protected species in South Carolina or the US. They support a popular recreational fishery along both the Atlantic coast and Gulf of Mexico in the United States. Recreational and commercial landings have remained relatively constant since 2000 besides a considerable peak in 2008 (Figure 1; ASMFC 2023). Compared to commercial landings, recreational landings are typically 20-30 times greater by weight (ASMFC 2023).

In 2022, recreational harvest was 4.9 million pounds, or 849,000 fish, making up about 31% of all black drum caught by the recreational fishery (ASMFC 2023). The other 69%, or 1.9 million, recreationally caught black drum were released alive as a result of the Fishery Management Plan that was put into place in 2013 (ASMFC 2023). However, a portion of fish caught and released in the recreational fishery die to the stress of capture, with the most recent assessment assuming an 8% discard mortality rate (ASMFC 2023). Application of this rate to the 2022 live releases results in an additional 152,000 removals due to the recreational fishery as a result of discard mortality. Florida, followed by North Carolina and Georgia were responsible for the majority of recreational landings (ASMFC 2023). Also in 2022, the commercial fishery landed 244,198 pounds of black drum with North Carolina and Virginia fisheries contributing most to the commercial harvest (ASMFC 2023).

The most recent stock assessment was conducted through 2020 and was accepted in 2023 for black drum management purposes. Based on the most recent stock assessment, black drum are not overfished or experiencing overfishing (Figure 2; ASFMC 2023). Therefore, amendments to the fishery management plan were not deemed necessary. Although management action was not taken, data limitations and assessment uncertainties exist. Several indices of abundance, range, and fishery characteristics will be monitored annually to determine any troubling trends in the stock (ASMFC 2023).

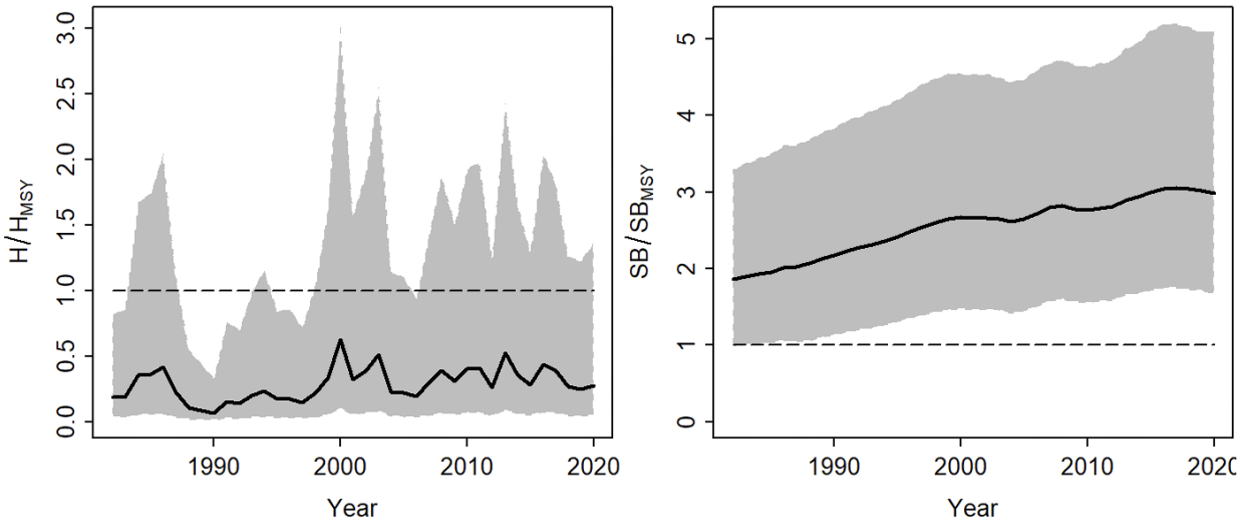

Figure 3:Exploitation (left) and spawning biomass (right) relative to threshold reference points. The solid line is the median and the shaded regions is the 95% credible interval. The dashed line indicates the estimate at its respective threshold. (Source: ASMFC 2023).

POPULATION SIZE AND DISTRIBUTION

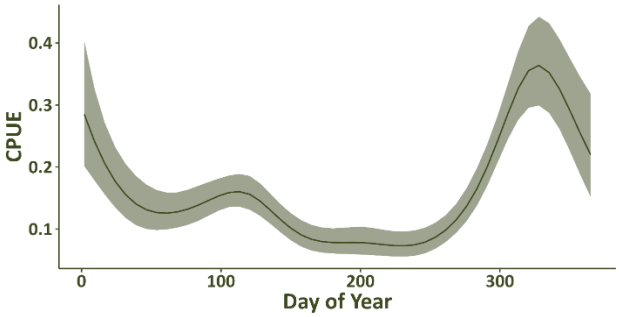

Figure 2: Black drum catch per unit effort in the SCDNR's Inshore Fisheries trammel net survey by day of the year.

Black drum are found throughout South Carolina estuarine marsh and coastal habitats, depending on life stage. While no specific sampling programs conducted by the South Carolina Department of Natural Resources (SCDNR) target black drum, they have been present in multiple estuarine fishery-independent monitoring surveys over the years. Most black drum caught in these surveys are sexually immature juveniles, typically less than 40 cm (16 in.) in total length. Black drum are present in South Carolina estuaries year round but are more abundant during the fall months (Figure 2).

The SCDNR fishery independent trammel net survey (1991-present) has caught black drum at a relatively stable, if cyclical, rate over the last 33 years (Figure 3). Catches were somewhat above 2010-2023 average catches in 1991-1993, 1999-2000 and 2016, indicating strong year classes entering the population. Conversely, catches were below average in 1995-1998, 2004-2005, and 2010-2011, indicative of weak year classes.

Most black drum captured in the trammel net survey are immature fish (ages 0-3). There is much less known above adult black drum in South Carolina, and no long-term fishery-independent indices of abundance exist for adults in South Carolina. As black drum age and become sexually mature, they move to deeper channel habitat within estuaries and eventually move to deep areas with bottom structure both inside and

outside the estuary. This makes them difficult to capture except with recreational hook-and-line gear. Most adult specimens available to SCDNR come from recreational anglers through either

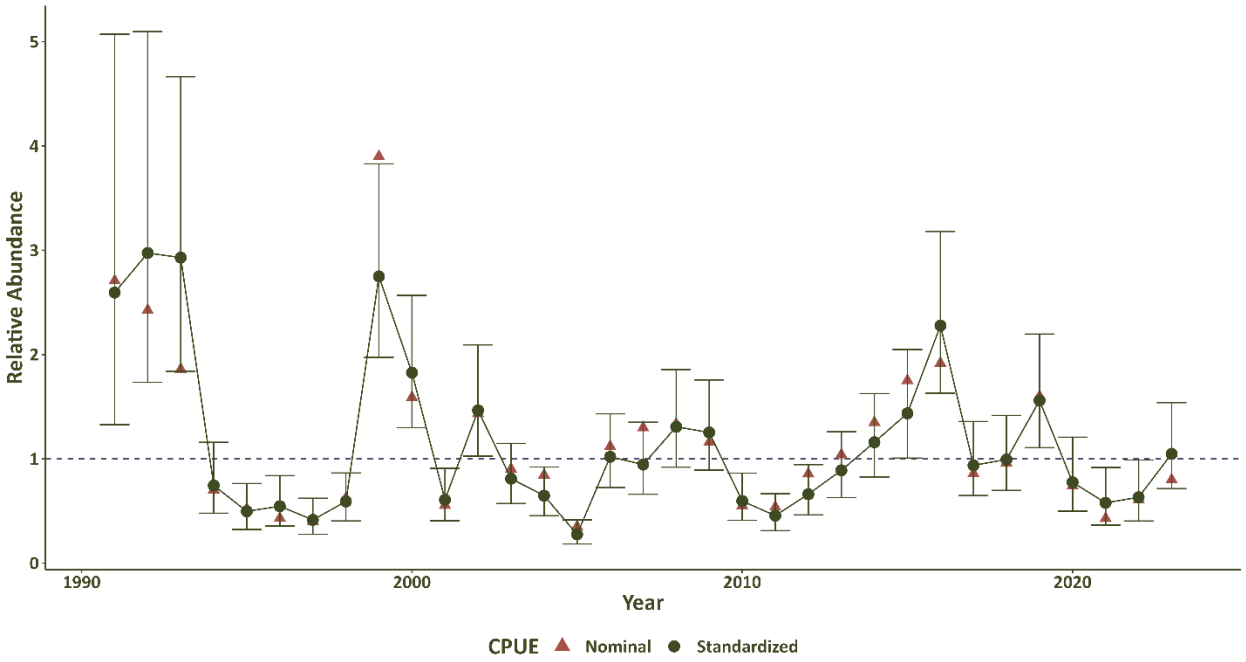

Figure 3: Black drum standardized catch per unit effort in SCDNR's Inshore Fisheries trammel net survey by year from 1991 to 2023. Shown is the standardized index of abundance (green line and circles) with a 95% CI (error bars) as well as nominal catch per trammel net (red triangles). Both the standardized and nominal indices are normalized to average catches from 2010-2023 (dashed line), such that if annual estimates are greater than 1, catch was above the 2010-2023 average and vice versa if below.

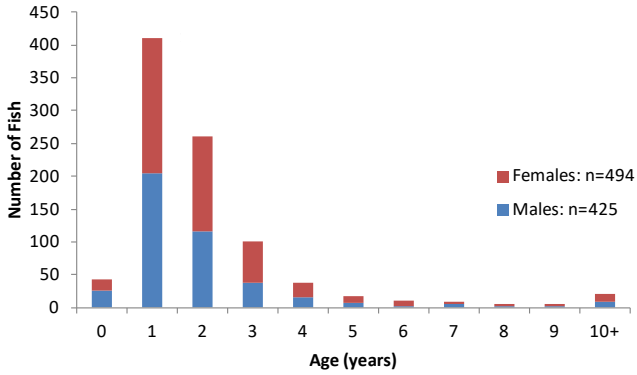

Figure 4: Age frequency distribution by sex for black drum from all SCDNR sampling efforts: 1985-2012.

fishing tournaments or SCDNR's fish wrack recycling program. The age distribution for black drum in South Carolina ranges from 0 - 46 with all fish older than 6 years being mature adults (Figure 4). Overall, however, the age distribution of SCDNR black drum samples are representative of shallow water, estuarine habitats. Figure 4 uses a truncated age distribution for older fish (ages 10+) because this group only represented 2.3% of aged black drum.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Black drum are found in estuaries throughout South Carolina, typically in habitats with vertical complexity such as oyster bars, salt marsh grass, natural rock outcroppings and reefs, and piling structures around docks, piers and bridges. Black drum in South

Carolina are usually found in salinities greater than 18 parts per thousand (ppt), near the mouths of estuaries, although juveniles less than 40 mm (1.5 in.) total length may also occur at lower salinities. As black drum grow during their first few years of life, they move into deeper channels and eventually into deep waters around natural ledges, bridges, and piling structures, both offshore and in higher salinity estuarine habitats.

CHALLENGES

There is currently a lack of information on the population size of black drum in South Carolina, although the coast-wide stock assessment (ASMFC 2023) indicated the regional population is neither overfished nor experiencing overfishing. Black drum feed primarily on fish, mollusks, and crustaceans, and therefore, may be adversely affected by contaminants (organics, pesticides, and heavy metals) that bioaccumulate in these organisms. Further, as with other estuarine species using estuaries for nursery habitats, there is a risk to the population due to habitat loss and degradation as a result of coastal development, coastal hydrography changes, and system eutrophication. Finally, little is known about the role of the environment in successful recruitment, though given the cyclical nature of year classes observed in the trammel net survey there likely is a strong environmental component to successful recruitment. As such, climate change, extreme thermal events (e.g., marine heat waves and marine cold spells) and shifts in phenology of ecological events (e.g., phytoplankton blooms) relative to black drum spawning could impact recruitment success.

CONSERVATION ACCOMPLISHMENTS

Commercial landings in South Carolina reported by the National Marine Fisheries Service (NMFS) are generally low and indicative of reported by-catch rather than a targeted fishery. Section 50-5-360 of the South Carolina Code requires that anyone who buys, receives or handles any live or fresh saltwater fish or any saltwater fishery products taken or landed in the State for sale, must obtain a wholesale dealers license. Prior to 2007, there were no recreational management regulations for black drum in South Carolina. In 2007 the South Carolina legislature amended section 50-5-1705 of the South Carolina Code creating a slot limit of 36-69 cm (14 to 27 in.) total length and a daily bag limit of 5 fish per person for black drum that applies to both commercial and recreational fisheries.

In 2013, the Interstate Fishery Management Plan for black drum was established that requires all states to have a maximum possession limit, a minimum size limit of 14 inches total length, and a continuation of all previous regulations (ASMFC 2023). In 2017, a report was released that included black drum habitat information at each life stage, essential fish habitat, habitat areas of particular concern, habitat threats, and habitat management recommendations (ASMFC 2023). In 2018, there was an addendum to the Interstate Fishery Management Plan that allowed for Maryland to

reopen its black drum commercial fishery in the Chesapeake Bay with a daily limit of 10 fish per vessel and a minimum size of 28 inches (ASMFC 2023).

CONSERVATION RECOMMENDATIONS

- Study basic biological aspects of black drum ecology such as population size, age structure, and reproduction (especially for the adult population).
- Develop length- and/or age-composition estimates for the discarded component of the recreational fishery and better characterize post-release mortality across sizes, age, and environmental conditions.
- Determine the level of contaminants (organics, pesticides, heavy metals, per- and polyfluoroalkyl substances) found in black drum as well as the sediments/wates in the areas in which they are caught. Relate that to the potential effects of bioaccumulation.
- Protect water quality in marine ecosystems by encouraging municipalities to use Best Management Practices (BMPs) to reduce runoff from highways, agricultural fields, and housing developments.
- Plan development based on sound terrestrial and estuarine ecology that takes into consideration all factors affecting the long-term health of the estuary ecosystem.
- Identify the origin of non-point source pollution and specific point source pollution and develop a plan of action to mitigate any negative effects to the affected aquatic systems.
- Improve BMPs in areas already impacted by non-point source pollution.
- Identify important or essential habitat types for different life stages of black drum and partner with other regulatory agencies to reduce impacts of development on these fish habitats.
- Partner with other state agencies to improve resource management at the whole estuary or drainage basin level using a more holistic ecological approach. Such restructuring should provide for greater regulatory authority in implementing migratory fish management plans.
- Evaluate environmental drivers of recruitment success.
- Identify habitat threats and habitat uncertainties for black drum.

MEASURE OF SUCCESS

Currently, the abundance of juvenile black drum appears to be stable, as indicated by the SCDNR trammel net survey. However, very little is known about the size and stability of the adult population. By learning more about this species and protecting the habitat upon which it depends, we can ensure this important recreational game fish remains abundant. In addition, by monitoring black drum populations in response to environmental contaminants, South Carolina will be better able to detect problems and work to correct them more quickly.

Blacknose Shark
Carcharhinus acronotus

Contributor (2025):
Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The blacknose shark, *Carcharhinus acronotus* is a member of the family Carcharhinidae, residing in the genus *Carcharhinus* (32 species). The blacknose shark is a placentally viviparous shark (bears live young with a maternal connection). Blacknose sharks are moderately small sized sharks reaching maximum reported total lengths (TL) of 150 cm (Castro 2011). They have a pale greenish, or yellowish color to their skin with a dusky gray to dark gray blotch at the tip of their nose. They have moderate life histories with males maturing at 4.3 years old (111 cm TL), and females maturing at 4.5 years old at around 119 cm TL (Driggers et al. 2004). The reproductive periodicity of blacknose sharks appears to be based on energetics of females with blacknose sharks presenting both an annual and biennial reproductive cycle (Frazier unpublished). Brood size ranges from one to eight with an average of five pups (Driggers et al. 2004). The maximum observed age for the blacknose shark is 22.8 years old (Frazier et al. 2015).

Status

The blacknose shark is classified as a small coastal shark (SCS) and it is managed separately by the National Marine Fisheries Service (NMFS). The blacknose shark was last assessed in 2011 and the results of that assessment indicated that the US Atlantic stock was overfished and overfishing was occurring (SEDAR 21). This resulted in a separate blacknose shark-specific quota that was linked to the small coastal shark quota, triggering a closure of both fisheries when the blacknose quote was reached (NMFS 2023) The International Union for Conservation of Nature (IUCN) Red List considers blacknose sharks as "Endangered" with a decreasing population trend; however, that is largely based on threats to the populations in Central and South America (Carlson et al. 2021). In South Carolina blacknose sharks are primarily sampled by the SCDNR Coastal Longline; abundances trends vary widely but suggest a moderate increase in blacknose sharks over the time-series (Figure 1).

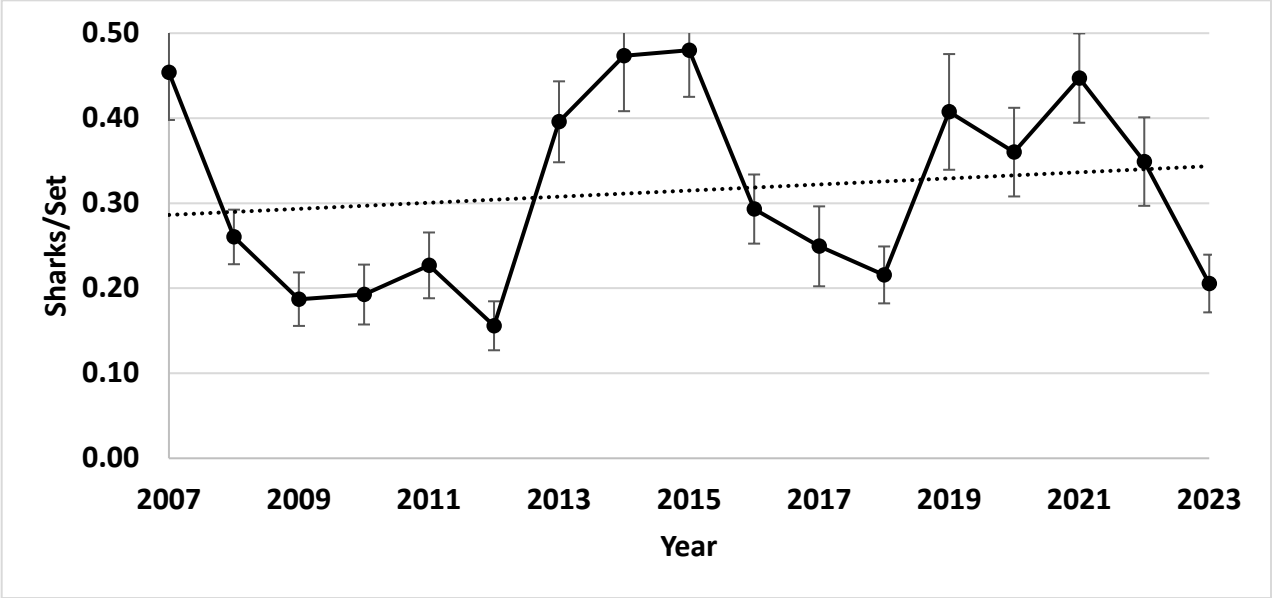

Figure 1. Catch per unit effort (sharks per set) of blacknose sharks from 2007 to 2023 in the South Carolina Coastal Longline Survey. Standard error is denoted by error bars.

POPULATION SIZE AND DISTRIBUTION

Blacknose sharks are restricted to the Western Atlantic Ocean and are distributed from North Carolina south through the Gulf of Mexico and Caribbean to southern Brazil. In the southeastern US they are found are rare north of Cape Hatteras and common off of South Carolina and Georgia. In South Carolina waters, young of the year are rarely encountered although they are thought to reside in nearshore waters, they are primarily captured as juveniles and adults.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In South Carolina, blacknose sharks are commonly found in high salinity waters (>30 ppt) over sandy bottoms in nearshore coastal waters (Ulrich et al. 2007). They appear to have a limited distribution, occurring from front beaches and the mouths of sounds and bays out to nearshore waters with maximum depths of 15 m. While diet hasn't been formally described for this region, they are thought to primarily feed primarily on benthic fishes with a smaller component of their diet being invertebrates.

CHALLENGES

The stock status of blacknose sharks has not been assessed in almost 15 years, while the results suggested overfishing and overfishing occurring species-specific data and life history data were limiting factors. Given the small coastal shark quote is linked to the blacknose shark population it is imperative that the stock status of this species is reevaluated. As there is a limited shark fishery, the primary threat to blacknose sharks is as bycatch in other fisheries, primarily shrimp otter trawls. Blacknose sharks are caught recreationally; however, they do not reach the minimum size limit for harvesting, therefore the primary concern is post-release mortality (Knotek et al. 2021)

CONSERVATION ACCOMPLISHMENTS

There are no conservation accomplishments specific to this species at this time.

CONSERVATION RECOMMENDATIONS

- Continue to monitor the stock status of blacknose sharks within SC waters through fishery-independent methods, primarily the Coastal Longline Survey.
- Increase collection of species-specific data to allow for future species-specific stock assessments.
- Initiate genomic studies of blacknose sharks including using close-kin mark recapture studies to estimate population size.
- Conduct studies using electronic monitoring tags (i.e. PSATs, acoustic tags, and SPOT tags to understand blacknose shark migratory behavior and essential habitat.
- Investigate non-lethal ways of obtaining life history data from blacknose sharks (e.g. epigenetic age estimation)
- Continue to study the reproductive periodicity of blacknose sharks to better understand why both annual and biennial reproductive cycles are observed in this species.
- Improve the public's understanding of the importance of sharks in the ecosystem through outreach activities such as school programs, providing story opportunities for media, and educational brochures.
- Continue to educate the public on the importance of species identification of sharks to ensure undersized and prohibited sharks are not landed.
- The primary action at the state level via law enforcement partnering is to ensure adequate compliance with regulatory actions implemented through the federal management plan and subsequent amendments.

MEASURE OF SUCCESS

One of the most important measures of success will be reassessing the stock status of blacknose sharks in US waters. Regional management efforts to maintain healthy, sustainable populations of blacknose sharks will require active participation from South Carolina due to its importance as habitat for the species. Expanding our knowledge on the life history of blacknose sharks, in particular the occurrence of young of year and reproductive periodicity, is of high importance. Maintaining ongoing monitoring programs to continue indices of abundance and trends over time is critical to the success of future stock assessments.

Black Sea Bass

Centropristis striata

Contributors:
Joseph Evans (SCDNR) & Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Black Sea Bass are a relatively small member of the family Serranidae, found within the order Perciformes (Page et al. 2023). The larger individuals are black, sometimes with a blue wash of color. The smaller individuals can be dusky brown in color. The exposed parts of scales are paler than the margins, giving the fish the appearance of being barred with a series of longitudinal dots. The belly is only slightly lighter in color than the sides. The fins are dark, and the dorsal is marked with a series of white spots and bands. The upper portion of the caudal fin ends as a filament. During spawning, males may have a conspicuous blue nuchal hump (SAFMC).

Black sea bass are protogynous hermaphrodites, changing sex with size. Large individuals are males, and smaller individuals are female. Females reach sexual maturity by approximately their first birthday with the age at 50% transition to male estimated to be 3.83 years (SEDAR 76). The spawning season is February through May in the Southeast U.S. Atlantic Ocean (SEUSA). Black sea bass may live up to 20 years, although fish older than 9 years are rare. The maximum size attained is 24 inches and 6 pounds. (SAFMC).

Status

The most recent stock assessment was completed in 2023 (with 2021 as the last year of data included), and results indicated that the stock off the coast of the Southeastern US was overfished, and that overfishing was occurring (SEDAR 2023). However, IUCN lists Black Sea Bass as a species of least concern worldwide and the species has been documented increasing at the far northern extent of the species range.

POPULATION SIZE AND DISTRIBUTION

Black Sea Bass occur along the US coast from the Gulf of Maine to Cape Canaveral, Florida, and in the Gulf of Mexico, though the Gulf of Mexico individuals are considered a separate subspecies, and thus, managed as its own stock (Bowen and Avise 1990, McBride 2018). Traditionally, US Atlantic coast Black Sea Bass have been managed as two separate stocks – Mid-Atlantic and South Atlantic – with the stocks being split at Cape Hatteras, NC. Genetic and preliminary otolith microchemistry data supports these two separate stocks (Roy et al 2011). Tagging studies suggest minimal movement of

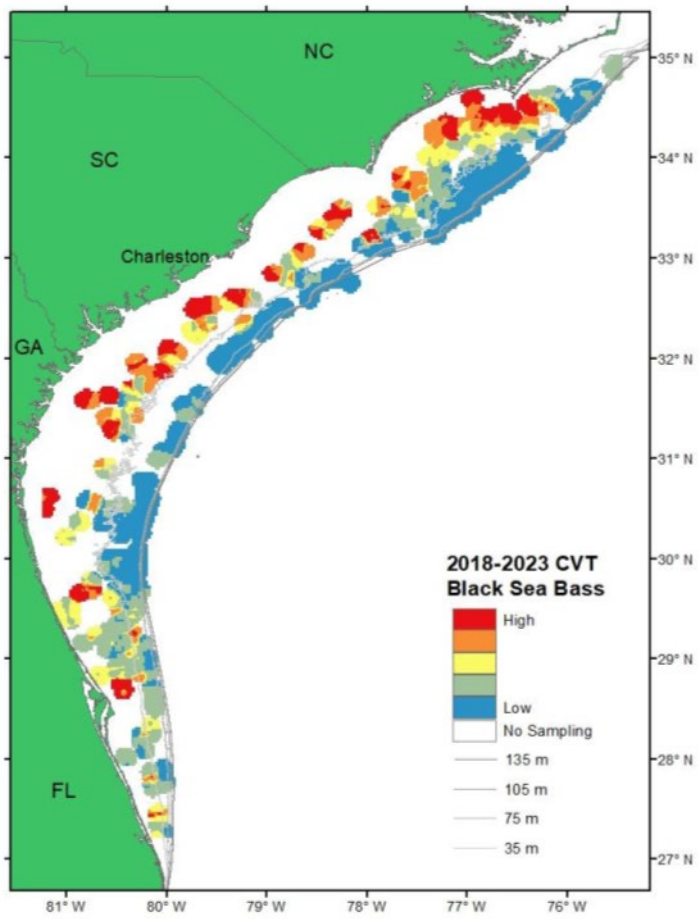

Figure 1: Distribution of Black Sea Bass catches from SERFS Chevron Trap survey in 2018-2023 (excluding 2020).

adult Black Sea Bass in the South Atlantic region (Rudershausen et al. 2010). The species is a major component of the fishery independent chevron trap catches of the Southeast Reef Fish Survey (SERFS) off the coast of Cape Hatteras, NC to St. Lucie Inlet, FL. Highest densities are observed in shallower trap stations at the northern extent of the survey near the SC/NC border and in NC waters (Figure 1).

As represented by SERFS data, the Black Sea Bass population in the Southeast U.S. Atlantic hovered around the long-term average until 2008, when the species went through a period of very high recruitment until 2011. The population has declined steadily since that time reaching a value lower than the long term average in 2014 and remaining below this level for a decade (Figure 2).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Black Sea Bass are a temperate marine species that inhabits irregular hard-bottom areas, such as wrecks or reefs. Larval Black Sea Bass settle in coastal and estuarine waters often near structure (Steimle et al. 1999), subsequently migrating to offshore reefs as they get larger. Once they get to offshore reefs, site fidelity is very high (Rudershausen et al. 2010). Those found in the Southeast U.S. Atlantic usually occur inshore of

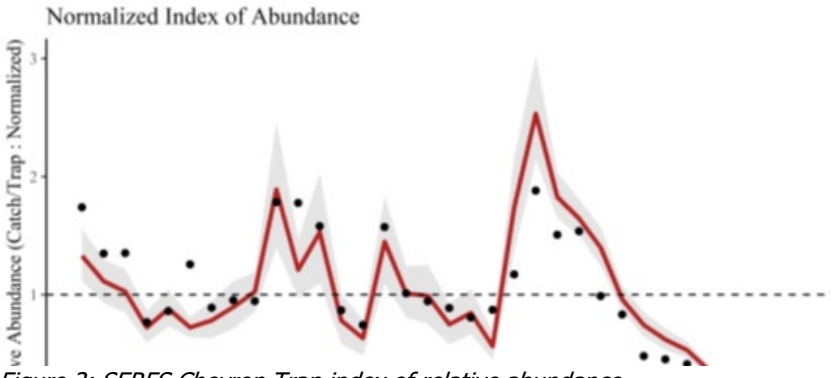

Figure 2: SERFS Chevron Trap index of relative abundance for Black Sea Bass for the Southeast U.S. Atlantic region. Nominal values are black dots. Red line is modeled index value. Gray shading is standard error. Dotted horizontal line is long-term average value.

some other popular reef fish species such as snappers, groupers, porgies and grunts. Black sea bass are opportunistic feeders eating whatever is available, preferring crabs, shrimp, worms, small fish and clams (Schmidtke 2024).

CHALLENGES

The species is currently overfished and undergoing overfishing in the SEUSA. The decreasing biomass trend seems to reflect decreased recruitment since 2014. No mechanism for the recent low recruitment has been identified, but the duration (since 2014) has exceeded a single generation time. Determining the cause of this apparent decline in recruitment will be critical for management decisions. Because Black Sea Bass are sequential hermaphrodites, there is also disproportionate targeting of the larger sex (males) that has the potential to skew population demographics. As with many other reef fish species which have substantial overlap in habitat use, there is potential for mortality even when they are not targeted in this multi-species fishery.

There is currently no effective mechanism for surveying black sea bass in their first year of life. The SERFS chevron trap survey does not effectively capture black sea bass < 50 mm TL, and the coastal trawl survey only infrequently encounters the species. Therefore, it would be beneficial to initiate a survey mechanism that could effectively capture young of year for this species as well as others. The pattern of low recruitment at the end of the time series raises the question of whether there has been a regime shift. More research is needed to determine if this is the case. As of now there is not sufficient evidence to support the regime shift hypothesis (SEADR 76). However, research indicates the most extreme depletion of the stock appears to be in the southern extent of the range (Vecchio et al., *in review*).

CONSERVATION ACCOMPLISHMENTS

The Black Sea Bass fishery off South Carolina is managed in federal waters by the South Atlantic Fishery Management Council (SAFMC 2013). The total annual catch limit (ACL) has been reduced multiple times since 2019 in both the commercial and recreational fishery. The size limits for Black Sea Bass were increased in 2013 (commercial to 11”/recreational to 13”). The recreational retention limit was increased to 7/person/day in 2016. As of July 2020, all recreational fishing boats were required to have a descender device rigged and ready to help mitigate discard mortality.

CONSERVATION RECOMMENDATIONS

- Protogynous life history: 1) investigate possible effects of hermaphroditism on recent low recruitment; 2) investigate the sexual transition for temporal patterns, considering possible mechanistic explanations if any patterns are identified, and 3) investigate methods for incorporating the dynamics of sexual transition in assessment models.

- Initiation of an effective survey for young-of-year in multiple reef fish species, including Black Sea Bass, to produce predictions of population available to the fishery in future years.
- Mark-recapture approaches (conventional, telemetry, close-kin) might make it possible to obtain direct estimates of natural mortality specific to Black Sea Bass in the SEUSA.
- Additional experiments to estimate discard mortality in greater ranges of depths, locations, angler experience related to barotrauma mitigation techniques (venting and descender devices), and times of year to match fishing within the SEUSA.
- More research is needed on the cause(s) of low recruitment in several South Atlantic reef-fish stocks, including Black Sea Bass.
- Direct observation of fishing practices by observers or video are needed to determine reliable estimates of these sources of mortality to fish in the SEUSA.
- Establish a more comprehensive sampling program for ages and lengths of fish captured by the recreational fleet in all regions of the SEUSA.

MEASURE OF SUCCESS

The fishery independent SERFS program annually monitors relative abundance, length frequency, size and age at maturity of reef fishes and can detect changes in those parameters that result from management efforts.

A new survey of juveniles could provide an indicator of recruitment success over time.

Increases in recruitment, abundance, size, size and age at maturity would indicate positive trends in the population.

Bluefish

Pomatomus saltatrix

Contributors:
Joseph C. Ballenger (SCDNR)

Revised 2025:
Keilin Gamboa-Salazar (SCDNR), Tracey Smart (SCDNR), & Joseph C. Ballenger (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Bluefish, *Pomatomus saltatrix* (Linnaeus 1766), are a migratory, coastal, pelagic species encountered in South Carolina estuarine and coastal waters. They are the only member of the family Pomatomidae (bluefishes), within the order Scombriformes (Collette 2002; Nelson 2006; Page et al. 2023).

Bluefish have a sturdy, compressed body and a large head with prominent, sharp, compressed teeth in a single series; the jaw is terminal, with the lower jaw sometimes slightly projecting (Collette 2002). Bluefish possess two dorsal fins, the first being short and composed of 7 to 8 weak spines connected by a membrane and the second long, with one spine and 23-28 soft rays (Collette 2002). The pectoral fins are short, not reaching the origin of the soft dorsal fin (Collette 2002). Bluefish possess small scales that cover the head, body, and bases of vertical fins; the lateral line is almost straight (Collette 2002). Bluefish have a greenish-blue back, silvery sides and belly, dorsal and anal fins that are pale green tinged with yellow, pectoral fins that are bluish at the base, and a caudal fin that is dull greenish tinged with yellow (Collette 2002).

Bluefish are fast-growing, reaching lengths of 115 cm and weights of 12 kg (27 lbs; Shepherd and Packer 2006). They can live up to 12 years (Shepherd and Packer 2006), and they reach sexual maturity at 2 years old and 48 cm total length (Robillard et al. 2008). They are gonochorists (separate sexes) that exhibit indeterminate fecundity and spawn multiple times per season (Robillard et al. 2008), with two main spawning cohorts represented: a spring-spawned cohort south of Cape Hatteras, NC, and a summer-spawned cohort north of Cape Hatteras, NC (Kendall and Walford 1979; Norcross et al. 1974; Fahay 1999). A fall-spawned cohort has also been identified south of Cape Hatteras, NC (Kendall and Walford 1979; McBride et al. 1993).

Status

Currently, the bluefish population off the East Coast of the United States is managed as a single stock (NEFSC 1997; Fahay et al. 1999) under the joint management authority of the Atlantic States Marine Fisheries Commission (ASMFC) and Mid-Atlantic Fisheries

Management Council (MAFMC). A 2019 assessment found the stock to be overfished yet not undergoing overfishing, and a rebuilding plan was established to get the stock to a target Spawning Stock Biomass (SSB) by 2028 (ASMFC 2021). Later, in both the 2022 and 2023 assessments, the stock was found to not be overfished and not experiencing overfishing, yet the rebuilding plan will remain in place until the target SSB is met (Figure 1, NEFSC 2020, NEFSC 2023). These last two assessments showed an increase in SSB above SSB Threshold, with a continuing increasing trend (Figure 1), and it is now estimated to be at 60% of the SSB Target (NEFSC 2023). The IUCN last assessed Bluefish in 2014 and found the worldwide population showed a declining trend, and although there is to be an update by the end of 2024, Bluefish are currently listed as Vulnerable (IUCN 2024).

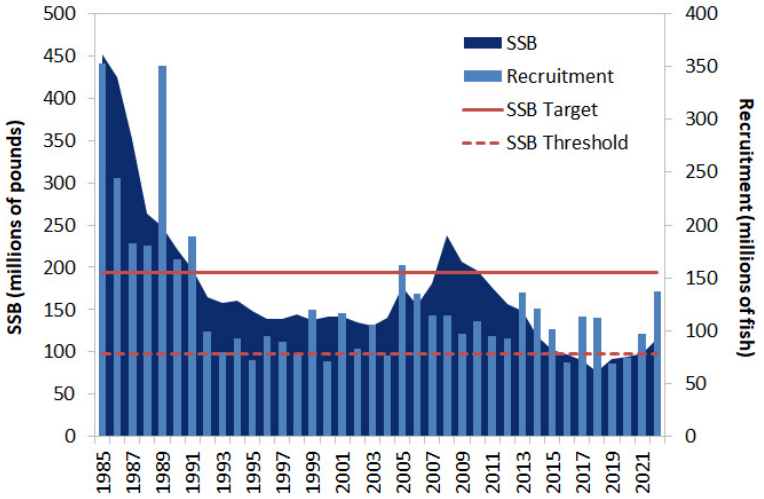

Figure 1. Bluefish Spawning Stock Biomass (SSB) and recruitment in the US Western Atlantic (Source: ASMFC 2024).

POPULATION SIZE AND DISTRIBUTION

Bluefish are found in coastal temperate and subtropical waters around the world, but are absent from the eastern Pacific and the Indo-West Pacific north of the equator (Collette 2002). In the western North Atlantic, they range from Nova Scotia along the East Coast of the Americas (including Bermuda) to Argentina, though they are rare between southern Florida and northern South America (Figure 2; Robins et al. 1986; Collette 2002).

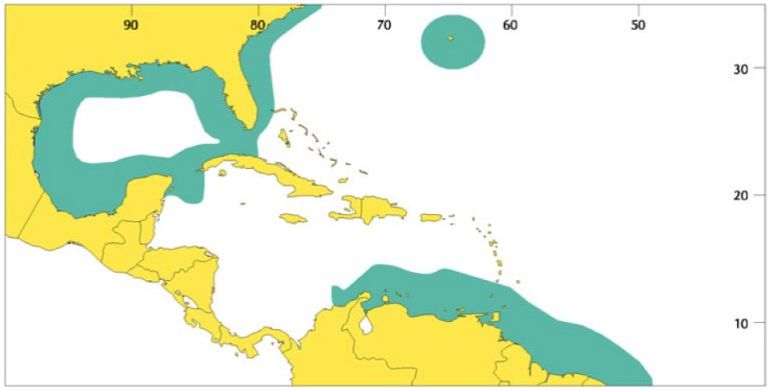

Figure 2. Bluefish native range in the US South Atlantic region through northern South America. (Source: Collette 2002).

Bluefish tend to travel in schools of like-sized individuals while undertaking seasonal migrations following waters between 14 and 16°C (57-61°F): traveling north along the East Coast of the US during spring, and south or farther offshore during fall (Bigelow and Schroeder 1953; Fahay 1999; Shepherd et al. 2006). In South Carolina, juvenile and adult Bluefish are present in estuarine and coastal ocean waters, and they are encountered in some SCDNR fishery-independent surveys. The Coastal Trawl Survey

and the SCDNR Trammel Net Survey encounter bluefish often enough to develop indices of abundance (Figure 3 and Figure 4). The Coastal Trawl Survey primarily indexes juveniles, which have been below the long-term average in recent years (Figure 3). The SCDNR trammel net survey, which also primarily indexes juveniles, shows a

recent uptick in abundance in SC estuaries not reflected in the coastal trawl survey (Figure 4).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The habitat used by bluefish tends to vary by size and cohort. The following is a description of the habitat used by bluefish at various life stages.

Eggs

Bluefish eggs are found in the open ocean at temperatures between 18 and 22°C (64-90°F) and salinities >31.0 ppt (Fahay 1999). Egg distribution varies by month, with eggs being spawned either in the South Atlantic Bight (SAB; in spring) or the Mid Atlantic Bight (MAB; in summer), and rapidly expanding further northward during the summer (Fahay 1999). Most eggs are collected over depths of 30 to 70 m (98-230 ft; Norcross et al. 1974).

Larvae and Pelagic-Juveniles

Larvae occur in open oceanic waters near the edge of the Continental Shelf in the southern MAB and over mid-shelf depths farther north (Norcross et al. 1974; Kendall and Walford 1979). Most larvae occur in temperatures of 18-24°C (64-75°F) and salinities of 30-32 ppt. Bluefish larvae migrate vertically in the water column, occurring near the surface at night but centered at about 4 m (12 ft.) during daylight (Kendall and Naplin 1981). Larvae spawned in the SAB are advected north via the Gulf Stream (Hare and Cowen 1996; Kendall and Walford 1979), although some recruit successfully to local estuaries (Collins and Stender 1987; McBride et al. 1993).

Many pelagic-juveniles are found in the vicinity of Cape Hatteras as early as April (Fahay 1999). In May, several have been collected on the shelf of the SAB (Fahay 1975; Kendall and Walford 1979). By June, pelagic-juveniles occur in the MAB between the shore and the shelf/slope front, actively crossing the shelf (Hare and Cowen 1996). In both the SAB and MAB, there is a strong negative correlation between fish size and depth, indicating an offshore origin and onshore migration with growth (Fahay 1999).

Juveniles

The following description of bluefish juvenile habitats derives from the works of Lund and Maltezos (1970), Olla et al. (1975), Milstein et al. (1977), Nyman and Conover (1988), Rountree and Able (1992), McBride et al. (1995), Able et al. (1996), and Buckel and Conover (1997).

Juveniles occur in estuaries, bays, and the coastal ocean of the MAB and SAB, where they are less common. They are found in many habitats, though they do not use the marsh surface. Juveniles migrate south in October to spend the winter months south of Cape Hatteras. They arrive in estuaries, bays, and coastal ocean waters once water temperature exceeds 20°C (68°F) and subsequently remain in these waters throughout the summer until water temperature declines to 15°C (59°F). Data suggests juveniles cannot survive at temperatures less than 10°C (50°F) or above 34°C (93°F). As they do

occur in estuaries, juveniles can tolerate a wide range of salinities (as low as 3.0 ppt), though they are generally found in salinities of 23.0-33.0 ppt.

Adults

Adults are generally oceanic, distributed nearshore to well offshore over the Continental Shelf, preferring waters warmer than 14-16°C (57-61°F; Bigelow and Schroeder 1953; Olla and Studholme 1971). Bluefish can tolerate water temperatures between 11.8 and 30.4°C (53.2-86.7°F), though there is physiological stress at either extreme (Fahay 1999). Although generally found in waters of oceanic salinity, adults are not uncommon in bays, larger estuaries, and coastal waters (Bigelow and Schroeder 1953; Olla and Studholme 1971) and have been found in most estuarine systems within their range (Fahay 1999).

CHALLENGES

As bluefish of different life stages use a diverse array of habitats, almost all the estuarine and nearshore waters along the Atlantic Coast from Florida to Nova Scotia serve as an important habitat for some life stage. Pollution and habitat degradation of any estuarine and nearshore habitat could be expected to threaten the bluefish population. As coastal development increases, estuarine water quality is expected to further deteriorate unless steps are taken to ameliorate their effect on the environment (Cross et al. 1985). Estuarine and coastal habitats have been significantly affected by dredging, filling, coastal construction, energy plant development, pollution, waste disposal, and other human-related activities. The offshore dumping of sewage is also a threat.

Additional challenges to the bluefish population are the large-scale fisheries that operate on the population, both commercial and recreational. Landings peaked in the 1980s and have since declined (Figure 5). Although there is a catch and release portion of the recreational fishery, dead discards make up 22% of the recreational removals of bluefish (ASMFC 2021). The multi-state nature of the population also creates jurisdictional and management challenges.

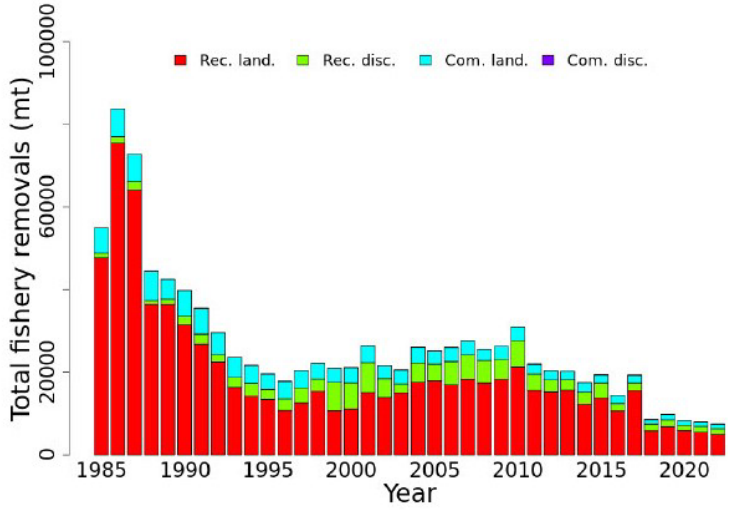

Figure 5. Time series of bluefish total removals (mt; recreational and commercial landings and discards) along the Atlantic coast between 1985 and 2022. (Source: NEFSC 2023).

CONSERVATION ACCOMPLISHMENTS

The current Interstate Fishery Management Plan (FMP) for bluefish, and subsequent amendments, institute the following management practices:

- Allocates fisheries landings between sectors (86% recreational and 14% commercial).
- Establishes that a portion (less than 10% of the Acceptable Biological Catch (ABC)) of each sector can be transferred to the other (ASMFC 2021).
- Establishes a state-by-state commercial quota system based on historic landings, allocating 0.10% of the Annual Catch Limit (ACL) to South Carolina.
- Since 2012, it establishes a coast-wide biological sampling program to improve the quality of information available for use in the age-structured stock assessment models (ASMFC 2012b).
- Since 2021, it puts in motion a 7-year rebuilding plan to get the bluefish population to target SSB. As part of this, it establishes a coastwide recreational limit of 3 fish per person for private fishermen, and a 5-fish bag limit for for-hire fishing.

Finally, the East Coast bluefish population has played a central role in the development of a multi-species stock assessment model developed by the ASMFC to move fisheries management away from individual species assessments to ecosystem-based fishery management. This model explores predator-prey interactions among key ASMFC-managed species, including Atlantic menhaden as the primary forage fish and striped bass, bluefish, and weakfish as predators (Garrison et al. 2010). While this model has yet to be used to manage the bluefish population directly, it has been used to produce annual estimates of natural mortality (M) at age for Atlantic menhaden, which were subsequently included in assessments to help manage that species (ASMFC 2012a). In addition, an Ecological Reference Points (ERP) stock assessment was recently conducted on menhaden, utilizing this multi-species model to provide fisheries managers guidance on how much menhaden biomass is required to meet the forage needs of the primary predators mentioned above (SEDAR 2020). An additional ERP stock assessment is currently being conducted on Atlantic menhaden as well.

CONSERVATION RECOMMENDATIONS

The following are research recommendations taken from the bluefish 2022 research track stock assessment, in addition to other conservation recommendations.

- Improve collection of recreational efforts, landings, and release and determine recreational demand.
- Establish monitoring programs to better characterize dynamics of larger, older bluefish.

- Continue the coastwide collection of biological samples from fishery-independent and -dependent sources to monitor trends in bluefish young-of-the-year and adult relative abundance.
- Develop and refine ecosystem-based modeling approaches that include bluefish (and collect needed trophic data to support).
- Evaluate the effects of fishing and management plans on the South Carolina sub-population of bluefish.
- Understand the local and regional movement patterns of bluefish occurring in South Carolina waters.
- Identify the source of bluefish recruits.
- Protect estuarine habitats through responsible development and minimization of pollution and disturbance.

MEASURE OF SUCCESS

The SCDNR fishery-independent programs that annually monitor bluefish, the coastal trawl survey and the inshore trammel net survey, are already in place to track changes in size distribution, age, maturity, and relative abundance as a result of regional management efforts. The measurement of success will be to see an increasing trend in catch of bluefish in these surveys. Furthermore, as mentioned above, in the past 5 years the bluefish stock has seen an increase in SSB and recruitment (Figure 1), along with a decrease in fishing mortality that is likely due to implementation of regulations as part of the rebuilding plan established in 2021 (NEFSC 2023). These changes in mortality and abundance, and their current trends towards a more balanced population, exemplify a measure of success in management.

Blueline Tilefish

Caulolatilus microps

Contributors:
Kevin Spanik (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Blueline Tilefish, *Caulolatilus microps*, is a member of the family Malacanthidae (tilefishes), themselves a member of the order Perciformes (Page et al. 2023). They are a medium-sized fish that are dull olive-gray overall and white below. The lack of fleshy protuberance behind the head distinguishes it from the Golden Tilefish, *Lopholatilus chamaeleonticeps*. Blueline Tilefish have elongate, continuous dorsal and anal fins more than half the length of the body, long snout, narrow gold stripe underlined in blue from snout to the tip of the eye and a strong, flat spine on the gill cover.

Blueline tilefish live to a maximum age of 43 years and reach a maximum size of 626 mm total length (TL). Maturity of 50% of fish is reached by age 3, at a length of 326-350 mm TL (Harris et al., 2004). Blueline Tilefish exhibit sexually dimorphic growth, with males attaining larger size-at-age than females. Blueline Tilefish are gonochorists and have an extended spawning season from February to October, peaking between March and September.

Status

Blueline Tilefish support commercial and recreational fisheries in South Carolina. The most recent stock assessment determined that Blueline Tilefish are not overfished, and no overfishing occurring (SEDAR 50 2017a).

POPULATION SIZE AND DISTRIBUTION

Blueline Tilefish are patchily distributed along the outer continental shelf of North America from Cape Lookout, NC, to Campeche Bank, Mexico (Dooley 1978). Adults appear to move little, inhabiting areas along the outer continental shelf, shelf break, and upper slope on irregular bottom (Harris et al. 2004). The distribution of early juveniles is not well known. Atlantic Blueline Tilefish are considered a single genetic stock (O'Donnell and Darden 2016).

Blueline Tilefish are encountered by the Southeast Reef Fish Survey chevron trap survey, however not in sufficient numbers or consistency to develop indices of abundance. Blueline Tilefish were more commonly encountered using Short Bottom longline (SBLL) gear by the Marine Resources Monitoring and Prediction Program (MARMAP) to sample snapper-grouper species in habiting hard-bottom areas with

considerable vertical relief in depths greater than 75 m, from 1996 to 2022. However, SBLL sampling was not conducted consistently enough to develop reliable indices of abundance.

In 2020 a coastwide longline survey, the South Atlantic Deepwater Longline Survey (SADL), was developed which aims to consistently sample deepwater species including Blueline Tilefish. However, at least 5 years of survey data should be available before an index of relative abundance should be considered for use in a stock assessment. The distribution of catches confirmed the patchy distribution throughout the region, including SC, but showed areas of increased abundance in NC and VA and to a lesser extent the Florida Keys (Figure 1).

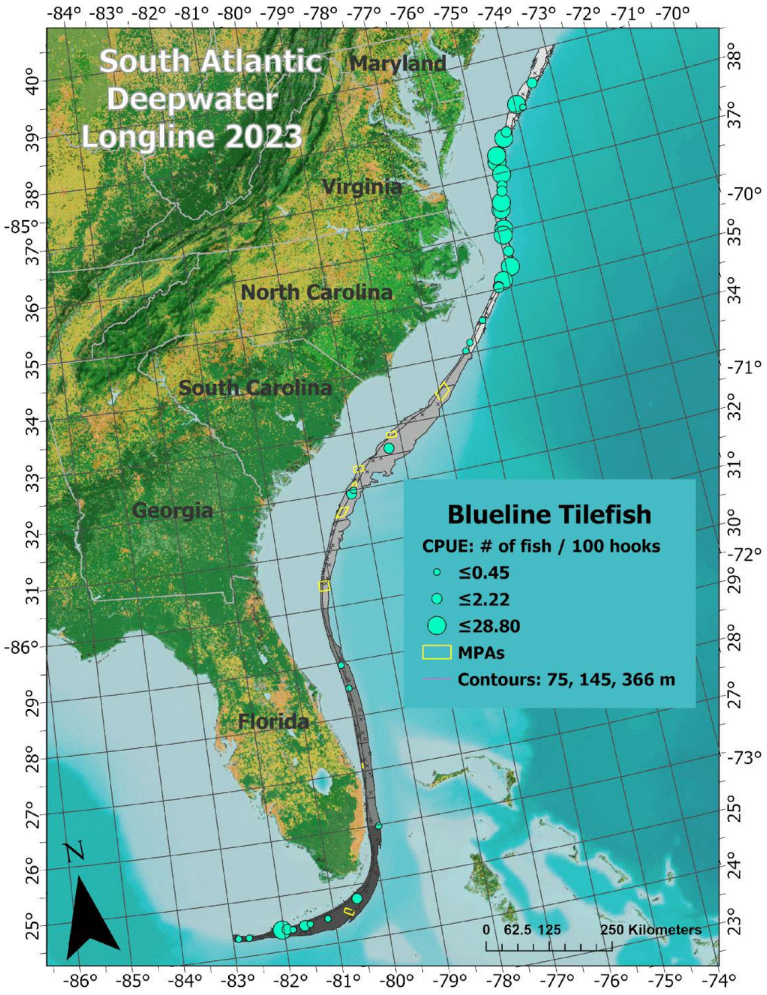

Figure 1. Distribution and magnitude of Blueline Tilefish catches from the South Atlantic Deepwater Longline Survey in 2023.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Usual adult habitats include ledges or crevices and around boulders or rubble piles at depths of 48-236 m, where temperatures are 15-23°C (Struhsaker 1969; Ross 1978; Ross and Huntsman 1982). Individuals have been observed hovering near or entering burrows under rocks (Parker and Ross 1986), a characteristic associated with many malacanthids (Able et al. 1982; Able et al. 1987; Baird and Baird 1992). Blueline Tilefish prey on a variety of fishes and macroinvertebrates closely associated with the substrate, primarily decapod crustaceans (Ross 1982).

CHALLENGES

Blueline Tilefish and other deepwater fisheries have become increasingly important because of their economic value and because they provide an alternate resource when

shallow-water stocks are depleted or access is restricted by management (Large et al. 2013). Deepwater stocks are difficult to monitor, as the depths and distance from shore at which these species occur are often cost-prohibitive for traditional surveys to adequately collect samples for life history analyses, estimation of population demographics, and development of relative abundance trends. As a result, stock assessments for Blueline Tilefish have historically been data-limited. SADL was developed to more effectively sample deepwater species throughout their range and will be a critical data source for stock assessment in the future. Because deepwater species, including Blueline Tilefish, tend to be slower growing and long-lived species they are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. As with many other reef fish species which have substantial overlap in habitat use, there is potential for mortality even when they are not targeted in this multi-species fishery. Because they are a deepwater species (≥30 m), they can be highly susceptible to post-release mortality (e.g. barotrauma) during these encounters.

CONSERVATION ACCOMPLISHMENTS

The Blueline Tilefish fishery off South Carolina is managed in federal waters by the South Atlantic Fishery Management Council. Several management measures to reduce fishing mortality and dead discards have been implemented including the requirement of descending devices, dehooking tools, and non-stainless steel circle hooks.

CONSERVATION RECOMMENDATIONS

- Increased sampling of young fish to improve maturity ogive
- Movement and migration of juvenile and adults
- Identification of larvae as well as location, duration, and dispersal mechanisms of egg and larval stages
- Document the distribution of early life stages
- Determine thermal tolerance and likelihood of climate change induced range expansion
- Characterize and quantify relationships between catch and habitat

MEASURE OF SUCCESS

Management success for Blueline Tilefish is difficult to measure since fishery-independent sampling has not been consistent historically and offshore species recreational catch is more difficult to monitor. SADL was developed to more effectively sample deepwater species throughout their range and will be a critical data source for stock assessments in the future.

Cobia
Rachycentron canadum

Contributors:
Donald L. Hammond

Revised 2015:
Karl Brenkert, Justin Yost, and Matt Perkinson (SCDNR)

Revised 2025:
James Kilfoil (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Cobia, *Rachycentron canadum* (Linnaeus, 1766) are the sole representative of the family Rachycentridae. Adults are characterized by having a depressed head with an elongate body and a lunate caudal fin. The mouth is terminal with a protruding lower jaw. The first dorsal fin is comprised of 7 to 9 short, stout isolated spines with the second dorsal fin long with anterior rays forming a raised lobe in adults. The anal fin is similar to the second dorsal and both are covered in thick skin. Adults are typically chocolate brown on their back and sides with a white to cream-colored belly with small, embedded scales. Juvenile fish have a more rounded caudal fin with lateral white stripes that run the length of their body, fading as the fish grows older.

The South Carolina State Record Marine Gamefish Program, operated by the Marine Resources Division, recognizes a 42.0 kg (92.6 lbs.) Cobia caught offshore of Port Royal Sound in June 2009 as the largest Cobia caught in the state. Franks et al. (1999) reported a female Cobia taken from the Gulf of Mexico that measured 165 cm (63 in.) in fork length and weighed 62.2 kg (137 lbs.). The IGFA recognizes a 61.5 kg (135.6 lbs.) specimen caught off Australia as its all tackle record. Maximum recorded ages are 16 years in the Atlantic and 11 years in the Gulf of Mexico.

Sexual maturity for male Cobia in the South Atlantic appears to occur at a very small size. Because of the paucity of samples of Cobia smaller than 200 mm (7.9 in.) FL, it is not possible to determine the smallest size at which male Cobia reach sexual maturity, but this appears to occur well before they reach age one. Female Cobia appear to reach sexual maturity later than males. Results by SCDNR (unpublished) and Smith (1995) suggest that females typically reach sexual maturity between 2 and 3 years old, with 100% maturity for 3 year-old fish.

Status

In 2017, cooperative management of Atlantic cobia began between the South Atlantic and Gulf of Mexico Fishery Management Councils following approval of the Interstate Fishery Management Plan (FMP) for Atlantic Migratory Group Cobia by the Commission. Subsequently, in 2019, Amendment 1 to the FMP was approved, marking a shift from joint management with the Councils to exclusive management under the Commission's jurisdiction. This Amendment outlined a framework for the Commission to establish harvest quotas, allocate quotas among sectors, define criteria for stock status, and propose management actions for adoption by NOAA Fisheries in federal waters. Additionally, Amendment 1 transferred responsibility for monitoring and potential closure of commercial harvests to the Commission. It also introduced a de minimis status for states with minimal commercial cobia harvests, exempting them from certain in-season monitoring requirements. States were mandated to implement the provisions of Amendment 1 by July 1, 2020.

There are two distinct populations of cobia along the U.S. Atlantic coast: Atlantic cobia and Gulf of Mexico Migratory Group, known as Gulf cobia. Gulf cobia are distributed throughout the Gulf of Mexico and extend to the east coast of Florida, whereas Atlantic cobia are found from Georgia northward. These boundaries were established during a Stock Identification Workshop in 2018. Ongoing tagging and genetic studies are further exploring the structure of these stocks to identify potential subgroups within each population.

According to the 2020 Atlantic Cobia Benchmark Stock Assessment, the Atlantic cobia stock is currently not considered overfished nor subject to overfishing (SEDAR, 2020). This determination was based on comparing spawning stock biomass (SSB) and fishing mortality rate (F) against reference points derived from F40%, which is the fishing mortality rate resulting in 40% of the stock’s maximum reproductive potential in the absence of fishing (SEDAR, 2020).

The biomass of Atlantic cobia has exhibited a trend of significant increase during years of strong recruitment, followed by periods of decline. Despite these fluctuations since the 1980s, the stock has remained above the overfished threshold due to robust year classes, including notable occurrences in 2010 as identified in the assessment.

The next assessment of the Atlantic cobia stock is scheduled for 2025.

POPULATION SIZE AND DISTRIBUTION

Cobia have a world-wide distribution, occurring in all tropical and subtropical seas except for the eastern Pacific (Shaffer and Nakamura 1989). The Marine Recreational Fisheries Statistical Survey (MRFSS), conducted by the National Marine Fisheries Service (NMFS), has recorded recreational Cobia landings from Texas to New York.

There is some evidence of at least 2 migratory groups in the Gulf of Mexico: a north/south migratory group that overwinters in southern Florida and moves west and north throughout the Gulf during the spring and summer; and an inshore/offshore migratory group that overwinters in deeper waters and moves into shallower coastal waters during spring and summer (Franks et al. 1991; Burns and Neidig 1992). Tagging studies in the Atlantic have shown a similar pattern as well with a seasonal northward movement of fish from Cape Canaveral to North Carolina and Virginia. Cobia may also be present in deep (>31 m or 100 ft.) live bottom areas in the winter off the East Coast, suggesting some east-west migration as well. In South Carolina, the vast majority (90%) of recaptures from fish tagged during annual spring aggregations in Port Royal and St. Helena sounds have occurred in those same estuaries in subsequent years, suggesting a high degree of site fidelity. Recent population genetics work indicates that inshore Cobia aggregations in South Carolina and the Chesapeake Bay represent distinct population segments that are genetically different from those found offshore of those locations along the East Coast (Darden et al. 2014). In general, Gulf cobia are found across the Gulf of Mexico and along Florida's eastern coast, whereas Atlantic cobia inhabit waters from Georgia northward. These delineations were verified during a Stock Identification Workshop in 2018. Ongoing research involving tagging and genetic studies aims to delve deeper into the stock structure, seeking to uncover potential subgroups within each population.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Cobia normally occur singularly or in small pods. They commonly associate with any structure in the water (buoys, trash, shipwrecks, and artificial reefs) or large animals (sharks, turtles and stingrays) (Hammond et al. 1977; Shaffer and Nakamura 1989). They are opportunistic feeders, conducting most of their feeding near the bottom where they target crabs, shrimp, squid, and benthic fish (Smith 1995).

Cobia are asynchronous batch spawners with spawning reported for the Gulf stock from April to September (Burns et al. 1998) and peak spawning occurring in the Atlantic from May to July (Brown-Peterson et al. 2001; SCDNR, unpublished data). Spawning frequency for Atlantic Cobia has been estimated at 4-6 days by Hunter and Macewicz (2005), and the application of their histological techniques to data reported in Lefebvre and Denson (2012) produced an estimate of spawning frequency of 6.1 days in South Carolina. Spawning has been shown to occur in the mouth of bays and sounds (Joseph et al. 1964; Richards 1967; Smith 1995). In South Carolina, the presence of eggs and larvae and the collection of gravid females from within Port Royal and St. Helena Sounds suggest that spawning is occurring during these inshore aggregations (Lefebvre and Denson 2012). Based on gonadosomatic indices, peak spawning occurs in May, June, and July in South Carolina, North Carolina, and Virginia, respectively. Migration into these inshore spawning grounds appears to be closely related to temperature, with seasonal appearances of Cobia aggregations beginning as water temperatures approach 20°C (68°F).

CHALLENGES

Their large size, strong fighting ability, and excellent culinary qualities make Cobia a very popular recreational species. In South Carolina, fishing pressure on inshore aggregations in the southern portion of the State has increased steadily in recent years. Uncertainty about population size and pressure on spawning grounds of a genetically distinct population segment during the spawning season are two challenges to maintaining a sustainable fishery for Cobia in South Carolina. Additionally, life history work conducted by SCDNR suggests that recruitment success varies strongly from year to year, and intermittent strong year classes may make up a large proportion of the population structure.

CONSERVATION ACCOMPLISHMENTS

The coastal migratory pelagics FMP, a joint effort by the South Atlantic and Gulf of Mexico Fishery Management Councils, established an 84 cm (33 in.) FL minimum size for Cobia in 1985 and added a 2 fish/person/day bag limit in 1990. In South Carolina, extensive life history and genetic sampling has led to a greater understanding of Cobia population genetics, age structure, and critical spawning habitat of concern. This research has identified critical spawning grounds and contributes important data to the SEDAR stock assessment process.

Additionally, the implementation of a cooperative angler fin clipping program and development of microsatellite markers for Cobia allows catch and release by recreational anglers to contribute non-lethal genetic samples to program biologists and become stakeholders in the research process.

CONSERVATION RECOMMENDATIONS

- Develop fishery-independent sampling program to better understand overall abundance and relative changes in population(s) through time.
- Coordination and expansion of tagging efforts, to improve estimates of mortality rates and growth parameters.
- Determine tag retention and reporting rates.
- Hold workshops to aid in consistent tagging methods across states.
- Expand creel sampling in Beaufort County during April, May, and June to better capture catch and effort data on the inshore Cobia fishery.
- Expand the genetic sampling program throughout the Cobia's range to increase understanding of its population structure, stock boundaries, and to identify additional genetically distinct population segments along the Atlantic Coast.
- Promote sustainable fishing practices by recreational anglers targeting seasonal Cobia aggregations in South Carolina, including catch and release and proper handling of undersized fish.
- Collect fecundity data on fish collected during tournaments and through carcass

collection programs targeted at recreational anglers.

MEASURE OF SUCCESS

Measures of success will include an increased understanding of Cobia life history and genetic structure as well as stable or increasing population trends as determined by further sampling efforts. Furthermore, increases in tagging efforts across states (number of tags released and recaptured), will lead to better estimates of mortality, growth parameter, and understanding of long-term movement patterns.

Common Snook
Centropomus undecimalis

Contributors 2025: Michelle Taliercio and Jimmy Kilfoil (SCDNR)

Photo courtesy of Floridasportsman.com

DESCRIPTION

Taxonomy and Basic Description

Snook have long, concave snouts with a large mouth, and jutting underjaws. The lateral line is pigmented and distinct, extending well into the tail. Pelvic fins are typically yellow in color. Coloration ranges from dark brown on the back to silvery on the sides and white below depending on the habitat. The two dorsal fins are well separated. Common snook are moderately long-lived and fast-growing fish. Females live about 21 years and can grow to lengths of 48 inches. Males live about 15 years and can reach 39 inches. Females attain legal minimum length (current snook regulations in Florida) in about four years, whereas males require five to six years to reach that length. Fifty percent of male snook reach maturity at about 18 inches total length (TL) and about two years of age, whereas 50 percent of females are mature at about 30 inches TL and five years of age. Snook are protandric hermaphrodites: meaning the males reverse sex and change into females. This reversal occurs during the fall after the spawning season, sometimes in a short span of ninety days.

Status

There was no legal commercial fishery of common snook in Florida after the Florida Legislature declared snook a gamefish in 1957 and prohibited the sale of snook. Currently, there are no regulations in place for commercial or recreational regulations in South Carolina. For historical perspective, commercial landings of snook during 1918–1957 can be found in Muller et al. (2015). The recreational fishery on the gulf coast in Southwest Florida (Pasco through Lee counties, and Collier county north of Gordon's Pass) has been restricted to catch and release fishing only since August 30, 2018 due to red tides. However, that has changed with updated catch data. New regulations for snook in state and adjacent federal waters have gone into effect beginning Jan. 1, 2024. These regulation changes will establish nine snook management regions in Florida, and will establish closed seasons as well as bag and slot limits for each management region throughout Florida.

In Texas, from the late 1800s to the early 1940s, commercial snook landings were quite large and even reached 230,000 lbs landed in Port Isabel in 1928. Since the early 1940s, commercial landings dropped to token levels with no landings reported after 1961. In 1987, regulations were passed that limited the catch of snook to rod and reel only. This bag limit remains to be one snook per person per day, adopted in 1995.

The most recent assessment by the International Union for Conservation of Nature (IUCN) conducted in 2019 found the common snook to be of "Least Concern" status across their global range, with a population status of "unknown" (Mendonca et al 2019).

POPULATION SIZE AND DISTRIBUTION

Common snook are found in estuaries, adjacent rivers, and in nearshore waters of the tropical and subtropical western Atlantic (Gilmore et al. 1983; Rivas 1986). Fishes in the genus Centropomus occur in coastal waters bounded by the August 24°C water isotherm in the North Atlantic and the February 24°C water isotherm in the South Atlantic (Rivas 1986). Common snook are the most widely distributed species within the genus. Common Snook have been reported from as far north as New York along the Atlantic seaboard (Schaefer 1972), and throughout the Gulf of Mexico. Common snook are most abundant on the Atlantic coast of Florida from Cape Canaveral south through the Florida Keys and on the Gulf coast from Cedar Key south to the Dry Tortugas. Common snook occur infrequently along the rest of the gulf coast until Galveston, Texas where they again become abundant through Rio de Janeiro, Brazil (Gilmore et al. 1983; Rivas 1986).

Rather than a resident species, common snook are considered seasonal migrants in South Carolina, with infrequent encounters in estuarine waters of the state by recreational anglers and SCDNR sampling projects such as trammel netting and electrofishing. The vast majority of snook encountered are believed to be young of year juveniles that will be very unlikely to survive the next winter unless individuals find thermal refugia such as golf course ponds or impoundments.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Snook are euryhaline, meaning they spend time in both fresh and saltwater. They live in a wide variety of habitats, including river mouths, nearshore reefs, salt marshes, seagrass meadows, and along Gulf beaches, but they have a preference for mangrove-fringed estuaries. Snook are tropical fish. They cannot tolerate cold water, not even for a couple days. The lower lethal limit for adults is 6 to 12°C, though they become lethargic once temperatures fall to 18°C and can begin to die at 15.5°C. Unsurprisingly, temperature is a large factor in distribution. The common snook is by far the most abundant and wide-ranging of all snook species. Adults inhabit coastal waters, estuaries and lagoons, penetrating into freshwater; usually at depths less than 20 m. They feed on fishes (Gobiidae, Gerreidae, Engraulidae) and crustaceans (shrimps and crabs) (Keith et al. 2000). Mature individuals congregate at mouths of passes and rivers during the spawning season, from May through September. Seasonal movements into freshwater occur but are poorly understood. Marketed fresh, it is also a valued game fish and an excellent food fish.

CHALLENGES

Several reasons have been suggested for the decline of snook in Texas and Florida that involve range limitations due to cold temperature, high pesticide levels, disease, overfishing, and reduced freshwater inflows to bays and estuaries; however, the actual reason for the demise remains unknown. (Munyandorero et al.2020)
The population status of common snook in South Carolina is difficult to assess due to a lack of data in the region. Little is known about the species' habitat use and life history in South Carolina, and therefore fishing pressures and climate change consequences are challenging to gauge. However, as South Carolina is near the northern extent of their current range, warming estuaries may allow larger populations of common snook to develop in South Carolina, which may be what the SCDNR trammel net survey is currently observing.

CONSERVATION ACCOMPLISHMENTS

The management history of common snook was described extensively in the 2015 stock assessment (Muller et al. 2015). Snook are managed under Chapter 68B-21 of the Florida Administrative Code. There are variations in open and closed fishing seasons that have been historically established in the recreational fishery of common snook on the Atlantic and gulf coasts during 1957–2019. Recent data provided an account of the evolution of common snook regulations about the size limits, allowance of fish specifically above 34 inches TL, and the daily bag limits. (Munyandorero et al 2020)

Future research on common snook in South Carolina will be aided by the library of genetic fin clip samples and associated capture locations and fish lengths that the Inshore Fisheries section has been collecting from every specimen encountered since 2020.

CONSERVATION RECOMMENDATIONS

- To collect ages and lengths for young fish, especially the young-of-the year and age-1 individuals.
- To continue the collections of the reproductive data on the spawning periodicity, fecundity, sex-ratio, maturation, male-to-female transition, and skipped spawning, etc.
- To monitor and directly estimate the mortality rates or the extent of fish kills subsequent to episodic environmental events.

MEASURE OF SUCCESS

Measurement of management success is difficult given the lack of population assessments and impact fishing pressure on the common snook. However, the SCDNR Inshore Fisheries group monitors relative abundance, length frequency, size and age at maturity of estuarine finfishes through monthly trammel netting, electrofishing, and trawl surveys and can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, size, size and age at maturity would indicate positive trends in the population.

Dolphinfish

Coryphaena hippurus

Contributors:
Amy Dukes (SCDNR), Elizabeth Gooding (SCDNR), & Sydney Bates (SCDNR)

Source: SAFMC

DESCRIPTION

Taxonomy and Basic Description

Dolphinfish (*Coryphaena hippurus*, Linneaus 1758) are a highly migratory pelagic species in the family Coryphaenidae within the order Carangiformes (Page et al. 2023). Dolphinfish are identified by bright green-blue coloration dorsally and silvery-yellow ventrally. Darker spots are usually visible along their sides. Dolphinfish are characterized by a long dorsal fin and deeply forked tail. Males are distinguished by their more straight-edged head compared to a more rounded head on females. Males also grow larger in size than females. Compared to the closely related Pompano dolphinfish (*Coryphaena equiselis*, Linneaus 1758), the anal fins of dolphinfish are pointed and notched anteriorly, while the Pompano dolphinfish have a convex anal fin. Additionally, dolphinfish have slightly more dorsal fin rays (58-66) than Pompano dolphinfish (52-59).

Dolphinfish are fast-growing and highly prolific, reaching sexual maturity around four to five months and spawning hundreds of thousands to several million eggs per female, with larger females producing more eggs, in the open ocean as water temperatures begin to rise (SAFMC 2022). They are relatively short-lived for a highly migratory species, living to a maximum age of three or four years (Schwenke & Buckel 2008). The average fork lengths of dolphinfish range from 34 to 55 inches (SAFMC 2022). The current South Carolina (SC) state record dolphinfish, which was caught offshore of Seabrook Island, SC in 2008, was 77.5 pounds (SCDNR 2024).

Status

Dolphinfish are economically important as a primary target species for both recreational and commercial fishers worldwide. In the United States exclusive economic zone for the Atlantic and Gulf of Mexico, recreational and commercial landings have consistently been in the tens of millions of pounds since 1990, with the recreational sector representing the majority of the landings (NOAA Fisheries 2024). A recent study analyzing data from five southeastern U.S. tournaments in the western North Atlantic found declines in dolphinfish sizes over the past 15-30 years (Rudershausen *et al.* 2023).

NOAA Fisheries is currently in the process of developing a management strategy evaluation to examine possible management plans to determine how effective they might be under varying circumstances. The overarching goals for the evaluation include guaranteeing access to the fishery and opportunities to fish, avoiding closures, promoting an overall increase in size of fish caught, keeping regulations consistent, and balancing different stakeholder needs (NOAA Fisheries 2024).

POPULATION SIZE AND DISTRIBUTION

SCDNR has not conducted any directed fishery independent studies on dolphinfish; however, several surveys intercept the fish and relevant data are recorded.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Dolphinfish are distributed throughout tropical and subtropical waters around the world and are primarily influenced by temperature with an optimal range of 21-30°C (Gibbs and Collette 1959, Maguire 2006). They typically reside and feed in surface waters and can be found in waters up to 200 meters (Maguire 2006). They are generalist consumers with a diet consisting primarily of small fish, swimming crabs and other pelagic crustaceans, cephalopods, and conspecifics (Rudershausen 2010, Teffer 2015) Dolphinfish are pelagic but often associated with *Sargassum* sp., a genus of large, orange-brown algae, and prey on smaller species using the algae as habitat (Rudershausen 2010).

CHALLENGES

Typically, shorter-lived, fecund species can tolerate more fishing pressure; however, dolphinfish distribution and reproduction are highly dependent on environmental factors, specifically temperature. Additionally, due to their migration patterns, dolphinfish are harvested internationally, which can include areas with more lenient regulations and fewer or no reporting requirements thus limiting the ability to conduct a comprehensive stock assessment (NOAA Fisheries 2024).

Additionally, pollution poses a threat to dolphinfish, specifically man-made floating garbage. Dolphinfish live and feed around *Sargassum* sp. floating in the open ocean, making it easy for fish to misidentify and consume trash. Researchers have found plastic wrappers, light bulbs, rope, and string in the stomachs of dolphinfish (SAFMC 2022).

The South Atlantic Fishery Management Council has received concerns from the public about regional declines in the dolphinfish stock and availability of fish in certain areas, which are being considered for the management strategy evaluation.

CONSERVATION ACCOMPLISHMENTS

In January 2021, NOAA Fisheries implemented the Southeast For-Hire Integrated Electronic Reporting Program (SEFHIER). The SEFHIER program required that all charter vessel operators federally permitted through the NOAA Fisheries Southeast Regional Office (SERO) must report trip-level information electronically, and a SERO permit is required to target or retain dolphinfish in federal waters. In May 2022, the SAFMC lowered the recreational vessel limit of dolphinfish from 60 to 54 fish, excluding headboats (Amendment 10).

CONSERVATION RECOMMENDATIONS

- Characterize stock status in Atlantic waters
- Determine potential shifts in distribution and driving factors
- Investigate migration patterns
- Expand research and monitoring in fishery-independent surveys
- Research early life stages and develop better understanding of complete life history

MEASURE OF SUCCESS

The highly migratory nature, short lifespan, distribution changes, and variability in environmental condition complicates the measure of success; however, completing a baseline stock assessment in the Atlantic waters is critical for monitoring the population.

Finetooth Shark

Carcharhinus isodon

Contributors:
Liz Vinyard (SCDNR) & Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Finetooth sharks, members of the order Carchariniformes and family Carcharinidae (Page et al. 2023), are a slender, medium-sized shark which lacks an interdorsal ridge. Body color is a distinctive light blueish gray with a metallic sheen which transitions to a white underside. The color may change to a brownish gray during the winter months or after death. The snout is shorter than the mouth width, the gills are proportionally large and delicate, the fins lack any distinctive markings, and the first dorsal fin originates over the free rear tips of the pectoral fins. The species gets its common name from the fine, smooth-edged teeth which are similar in size and shape in both jaws (Castro, 2011). Finetooth sharks are sometimes mistaken with juvenile Spinner or Blacktip sharks but are easily distinguished by the unique coloration, lack of fin markings, large gill slits, and fine, smooth teeth.

Most sharks encountered are under 160 cm total length (TL) although prior studies suggested they may reach up to 200 cm TL (Compagno, 1984). Observed maximum ages determined by vertebral counts ranged from 8.2 to 21.9 years for males and 8.1 to 22.3 years for females in the Gulf of Mexico and Northwest Atlantic Ocean, respectively (Carlson et al., 2007; Vinyard et al., 2019). Age and growth studies suggest intermediate life history parameters with moderate growth rates which may differ between regions (Vinyard et al., 2019).

Females are thought to mature between 4.2 to 6.8 years which varies based on geographic location and size at maturity likely falls between 990-1043 mm FL (Carlson et al., 2007; Vinyard et al., 2019). Males are thought to reach maturity around 3.5 to 6.6 years and slightly smaller lengths between 935-1010 mm FL (Carlson et al., 2007; Vinyard et al., 2019).

Like many Carcharhinids, they are placental viviparous, giving birth to live young. Reproductive periodicity also differs between regions with annual reproduction reported in the Gulf of Mexico while biennial reproduction has been observed in the Northwest Atlantic (Driggers and Hoffmayer, 2009; Brown et al., 2020). Litters average 4 pups and

typically range from 2 to 6 pups (Castro, 1993). Size at birth has been reported in each region based on umbilical scaring and varies from 374-414 mm fork length (FL) in the Gulf of Mexico to 389-482 mm FL in the Atlantic (Carlson et al., 2003; Vinyard et al., 2019).

In addition to observed differences in life history parameters and reproductive periodicity, a genetic assessment concluded distinct regional populations exist in the Gulf of Mexico and Northwest Atlantic Ocean (Portnoy et al., 2016).

Status

Finetooth sharks have an IUCN Red List status of near threatened. Where they are well-managed in the Northwest Atlantic Ocean, the relative abundance time series suggest an increasing population rate of approximately 3.5% annually. Conversely, intense, unregulated fishing in the Southwest Atlantic has driven population declines in excess of 80%, and in 2012, they were considered regionally extinct by the Brazilian government (Carlson et al., 2021).

The most recent stock assessment was a Benchmark assessment in 2007, and it concluded finetooth were not overfished and not experiencing overfishing (Carlson et al., 2007).

POPULATION SIZE AND DISTRIBUTION

Finetooth sharks inhabit coastal waters in the Northwestern Atlantic from North Carolina to Florida and throughout the Gulf of Mexico. In the Southwestern Atlantic, they are found down to Brazil. Other reported occurrences outside of this range are likely misidentifications (Castro, 2011). Genetic, reproduction, and life history studies suggest two distinct stocks split between the Gulf of Mexico and Western North Atlantic.

In 2023, Finetooth were the most common species captured in the SCDNR Cooperative Atlantic States Shark Pupping and Nursery Habitat (COASTSPAN) survey. This survey acts as a recruitment index as well as an index of abundance. Long-term trends show populations of finetooth sharks have continued to recover from overfishing (Figure 1). Finetooth sharks are the third most common species captured in the SCDNR adult red drum and shark longline. This survey primarily tracks abundance of

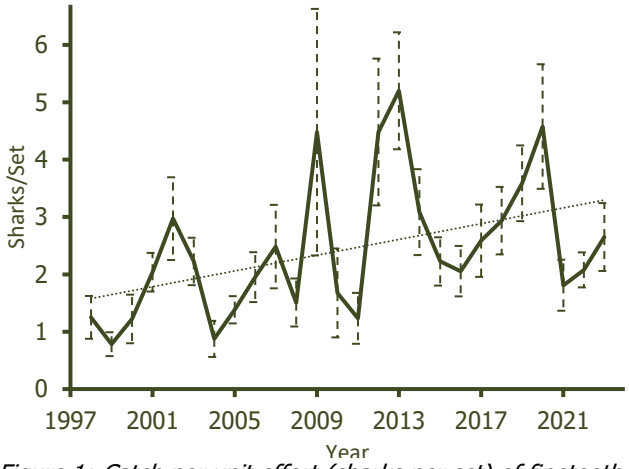

Figure 1: Catch per unit effort (sharks per set) of finetooth sharks from 1998 to 2023 in the South Carolina COASTSPAN Survey. Standard error is denoted by error bars. This survey primarily monitors recruitment of young of year finetooth sharks.

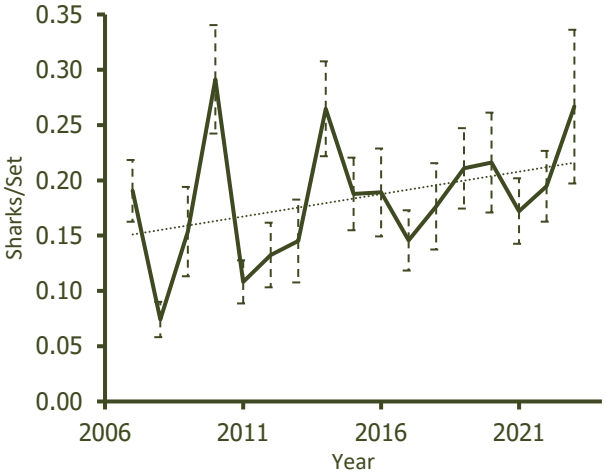

Figure 2: Catch per unit effort (sharks per set) of finetooth sharks from 2007 to 2023 in the adult red drum and shark longline survey. Standard error is denoted by error bars.

large juvenile and adult finetooth sharks. The trends in this survey mirror those of the COASTSPAN survey showing increases in population abundance over the duration of the survey (Figure 2).

Tag recapture reports of finetooth have increased over the past decade with several known time at liberty to 5.8 years (E. Vinyard, pers. comm.).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Finetooth sharks are migratory, utilizing high salinity estuaries and nearshore waters from North Carolina to Florida. They are most often found in shallow coastal waters less than 20 m deep.

South Carolina, Bull's Bay in particular, is a well-known nursery habitat for finetooth and many other coastal shark species. Juveniles typically begin to arrive in late April, just ahead of the adults, who will mate and pup off South Carolina from May to early June. Young of Year (YOY) and juvenile sharks spend more time in the estuaries and rivers, while adults tend to inhabit nearshore waters. As water temperatures drop below 20^{o}C, finetooth migrate south and overwinter off the east coast of Florida.

Diet studies suggest they are specialists, focusing primarily on oil-rich menhaden, however they are known to consume other estuarine teleosts as well as shrimp, squid and other small sharks (Bethea et al., 2004; E. Vinyard, pers. comm.).

CHALLENGES

Population growth along the coast as well as restrictions in other species has increased recreational angler pressure on coastal sharks, including for finetooth sharks. Little is known about post-release mortality rates in this species.

Finetooth are targeted for meat by commercial fishing vessels, and their fins have been identified overseas in the fin trade (Fields et al., 2018; Cardenosa et al., 2020). They are also taken as bycatch in gillnet, longline and trawl fisheries and are thought to be extirpated from the southern extent of their range off Brazil. Several life stages of finetooth sharks are highly dependent on menhaden so proper management and conservation of prey species is vital to their overall success. Further, given their reproductive strategy, as is the case with many shark species, rebuilding populations

from overexploitation that led to declines in biomass and numbers is slow given the low productivity of the species relative to most bonyfish.

CONSERVATION ACCOMPLISHMENTS

There are no conservation accomplishments specific to this species at this time.

Finetooth sharks are managed under NOAA's Atlantic Highly Migratory Species (HMS) Fisheries Management Plan. In recreational fisheries, there is currently a minimum size of 54" FL and a bag limit of 1 per vessel per trip. For commercial fisheries, the Atlantic Shark Directed fishery has no size limit but a retention limit of 55 sharks per vessel per trip while the Atlantic Incidental Permit lists a maximum of 16 combined small coastal and pelagic sharks per vessel per trip. The HMS Commercial Caribbean Small Boat Permit reduces the retention limit to 3 combined sharks per vessel per trip which includes specific large and small coastal sharks (including Finetooth).

CONSERVATION RECOMMENDATIONS

- Continue to monitor the stock status of finetooth sharks within SC waters through fishery-independent methods, including COSTSPAN and the adult red drum and shark longline surveys.
- Initiate genomic studies of finetooth sharks including using close-kin mark recapture studies to estimate population size.
- Conduct studies using electronic monitoring tags (i.e. PSATs, acoustic tags, and SPOT tags) to understand finetooth shark migratory behavior and essential habitat.
- Investigate non-lethal ways of obtaining life history data from finetooth sharks (e.g. epigenetic age estimation)
- Obtain post-release mortality estimates of finetooth sharks in recreational fisheries.
- Continue to educate the public on the importance of species identification of sharks to ensure undersized and prohibited sharks are not landed.
- The primary action at the state level via law enforcement partnering is to ensure adequate compliance with regulatory actions implemented through the federal management plan and subsequent amendments.

MEASURE OF SUCCESS

Continued increases in abundance of finetooth sharks. Continue to increase our understanding including knowledge of finetooth shark's life history and movement ecology.

Large-Tooth Flounders Guild

Summer Flounder *(Paralichthys dentatus)*
Gulf Flounder *(Paralichthys albigutta)*

Contributors:
Brock Renkas (SCDNR), Luke Troha (SCDNR), & Hayden Bessette (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Summer flounder (*Paralichthys dentatus*) and gulf flounder (*P. albigutta*) are members of the order Carangiformes and family Paralichthyidae, or left-eyed flounders (Page et al. 2023). Members of this family possess both eyes on the left side of a dorsoventrally flattened body. When larvae develop into the juvenile form, the right eye migrates to the left side of the fish. There are no spines in the pectoral and pelvic fins, and the dorsal fin originates at the anterior portion of the eye. The dorsal and anal fins are not joined to the caudal fin (Carpenter 2002). They possess small, cycloid scales. These species are often confused with the southern flounder (*P. lethostigma*) and each other, from which they can be differentiated by comparing counts of vertebrae, fin elements, gill rakers, and body pigmentation (Wenner and Archambault, 2005).

Summer Flounder (NC Sea Grant)

The left side of summer flounder possesses five prominent ocellated spots on the posterior portion of their body forming a double triangular pattern. The dorsal fin contains 80-96 rays, and the anal fin contains 61-73 rays. The pectoral fins are on both sides of the body with 10-12 branched rays. The ocular side varies from brown to gray, depending on the substrate color and texture (Smithsonian 2023a), while the blind side is white. The Summer Flounder have been reported to have a maximum size of 94 cm total length but is more commonly found at an average size of 14.7 cm in South Carolina coastal waters (SCDNR 2020, Carpenter 2002). Males typically live to a maximum age of 7 years, while females live 12-20 years (SCDNR 2020). Summer flounder are demersal fish occurring to depths of 185 m, but are generally found at depths of 40 m or less. Spawning occurs on the continental shelf from September-January, with salt marsh and tidal flat habitats in the lower estuary serving as nursery grounds. Summer flounders typically mature at 2-3 years of age and near 10 inches in total length (ASMFC 2024). As juveniles, they forage on invertebrates;

as adults, they forage primarily on fish, squid, crabs, shrimp, and mollusks (Carpenter 2002).

Gulf Flounder (USGS)

The left side of gulf flounder possesses three prominent ocellated dark spots forming a triangle. The dorsal fin contains 71-86 rays, and the anal fin contains 53-63. The pectoral fins are on both sides of the body with 10-12 branched rays. The ocular side is brown but varies in tone depending on the substrate, and the blind side is white. The gulf flounder have been reported to have a maximum size of 71 cm but are most common up to 35 cm in South Carolina waters. Males have a reported longevity of 8-11 years but have commonly been cited in collections as 2 years maximum age. Females have a reported longevity of 7 years but have commonly been cited in collections as 2 years maximum age (Fitzhugh et al. 2008). These demersal fish inhabit hard, sandy substrate at depths of 19-130 m. They spawn in late autumn and winter offshore with the highest spawning frequency observed during late-October to mid-December (Carpenter 2002). Gulf Flounder are carnivores, feeding on bony fish and mobile benthic crustaceans (Smithsonian 2023b).

Status

Summer flounder are managed by the Atlantic States Marine Fisheries Commission (ASMFC), and are one of the most targeted commercial and recreational species along the Atlantic Coast, with total landings estimated at 21.2 million pounds in 2022 (ASMFC 2024). Recreational harvest limits for summer flounder were first implemented in 1993. According to a 2023 stock assessment, they are not overfished but are experiencing overfishing. Though total fishery removals have generally decreased over recent decades, recruitment has also shown gradual declines (ASMFC 2023).

Gulf flounder are not managed by the ASMFC nor the Gulf States Marine Fisheries Commission (GSMFC) but are instead managed by individual states. As such, little information exists on the population status of this species. The majority of flounder research in the southeastern United States (US) focuses on the southern flounder and summer flounder.

POPULATION SIZE AND DISTRIBUTION

Despite being estuarine-dependent fishes, neither summer nor gulf flounder are encountered frequently in the South Carolina Department of Natural Resources (SCDNR) fishery-independent inshore monitoring program surveys. Although catches are low in the estuarine trawl survey, the catch-per-unit-effort (CPUE) of summer flounder has remained relatively stable (Figure 1). Gulf flounder are not encountered in significant numbers in any of the SCDNR inshore monitoring program surveys. The rarity of capture of any life stage of summer or gulf flounder in inshore surveys such as

Commented [AZ1]: Include a sentence about the general range of the species (see southern flounder for example).

the trammel net survey or the electrofishing survey indicate that there is likely not a significant population of either of these species in the South Carolina inshore environment. If there were significant populations of these species, they would likely be caught more frequently as SCDNR samples habitats that would serve as vital nursery grounds for juveniles, as we see with the southern flounder.

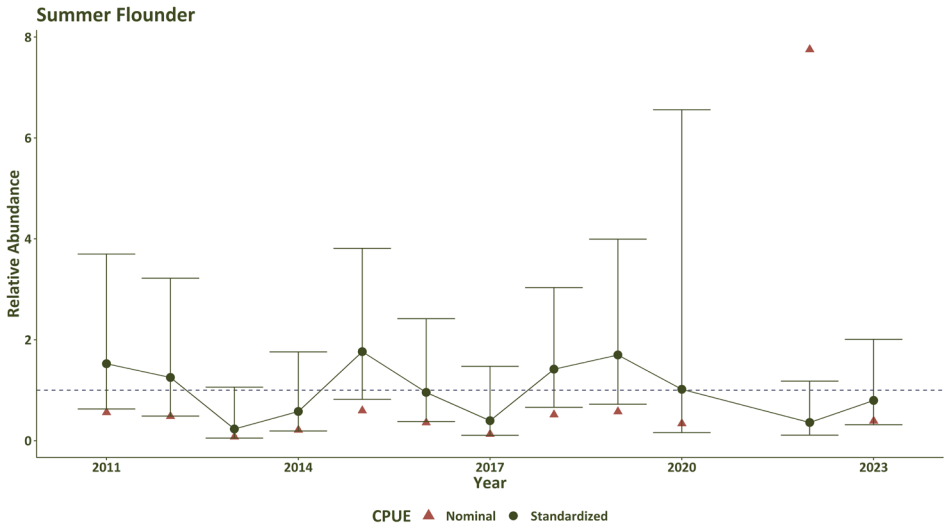

Figure 1: Summer flounder standardized catch per unit effort in SCDNR's estuarine trawl survey by year from 2011 to 2023. Shown is the standardized index of abundance (green line and circles) with a 95% CI (error bars) as well as nominal catch per trammel net (red triangles). Both the standardized and nominal indices are normalized to average catches from 2011-2023 (dashed line), such that if annual estimates are greater than 1, catch was above the 2011-2023 average and vice versa if below.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Both summer and gulf flounder are estuarine-dependent species, as they spawn offshore during their emigration out of the estuary to their wintering grounds (Able et al. 1990, Packer et al. 1999, Fitzhugh et al. 2008, ASMFC 2024). The timing of emigration may be related to several environmental variables such as water temperature, dissolved oxygen levels, and storm intensity (Sackett et al. 2007). After the adults spawn offshore, the larvae immigrate to the shallow inshore waters from October to May to continue development in a more sheltered environment. They spend their life in the estuary until maturation, when they join the adult offshore migration, though some juveniles partake in this emigration as well (ASMFC 2024).

CHALLENGES

As flounder are demersal fishes, both the summer and gulf flounder may be affected by any habitat modification of the seafloor, such as dredging and trawling (Santos et al. 2016), both of which are frequent occurrences in South Carolina waters. It may be difficult to parse out removals of summer and gulf flounder from the recreational fishing data due to the aggregate regulations where southern flounder are also included. Additionally, neither summer nor gulf flounder are common in South Carolina waters according to SCDNR fishery-independent surveys, and there is limited data available for the local populations of these species. Unlike summer flounder, gulf flounder are not formally assessed by any organization, so its overall population status is largely unknown and they are the lesser-studied species of the flounder guild in the southeastern US.

CONSERVATION ACCOMPLISHMENTS

In 2022, the fisheries management program for summer flounder was changed to adjust how recreational limits are set based on harvest estimates (ASMFC 2024).

In South Carolina, southern, summer, and gulf flounder are treated collectively as "flounder," where a fisher may keep five fish per day at a minimum of 16 inches total length. These same aggregate limits for flounder species are applied throughout the states of the southeastern US with variable length limits. South Carolina anglers primarily catch the southern flounder, and individual summer and gulf flounder in excess of 16 inches are relatively uncommon in South Carolina, especially in the inshore environment.

CONSERVATION RECOMMENDATIONS

- Examine long-term trends in summer and gulf flounder population size, abundance and relative distribution; relate these dynamics to fishing pressure, climate variation, pollution affects, and parasite load and disease.
- Monitor the effects of recreational fishing on summer and gulf flounder reproduction, growth, and longevity.
- Develop a management plan for gulf flounder in the southeastern US.
- Characterize the gulf and summer flounder population dynamics in South Carolina, including exploring environmental drivers of recruitment success, particularly in the context of projected climate changes impacts along coastal South Carolina.
- Decrease fishing mortality of summer flounder with well-executed fishery management plans and reduce overfishing levels.
- Test for benthic contaminants. Acquiring this knowledge could benefit a great number of species that associate closely with the estuarine bottoms in addition to summer and gulf flounders.

MEASURE OF SUCCESS

Assess the population status of summer and gulf flounders in South Carolina waters. Neither species has been formally assessed in South Carolina, and in order to detect changes in populations, we first must investigate the local population size and dynamics.

Gag

Mycteroperca microlepis

Contributors:
George R. Sedberry (SCDNR) & Marcel Reichert (SCDNR)

Revised 2015:
Marcel Reichert (SCDNR)

Revised 2025:
Margaret W. Finch (SCDNR) & Tracey Smart (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Gag, *Mycteroperca microlepis*, is a common, medium-sized grouper occurring in commercial and recreational fishery landings in South Carolina. The Gag is a member of the family Epinephelidae (groupers), a family found within the order Perciformes (Page et al. 2023).

Gag are a slender grouper with body depth distinctly less than head length. The body is elongate and the head is pointed. The mouth is large with 2 canine teeth present anteriorly in each jaw. The scales are very small and number from 128 to 146 in the lateral line series. The dorsal fin is continuous with 16 to 18 soft rays and 11 slender spines (rarely 10 or 12) without fleshy tips. The pelvic fin inserts perpendicular to the pectoral fin which has 16 to 18 fin rays. The anal fin has 3 spines and 10 to 12 soft rays. The dorsal and anal fins are rounded, and the caudal fin is emarginated without extended rays (Murdy and Musick 2013, Heemstra et al. 2002). The maximum adult total length (TL) for Gag is at least 1.2 m (4 ft.) and the maximum weight is around 39 kg (86 lbs.; Murdy and Musick 2013, Heemstra et al. 2002).

Gag are protogynous hermaphrodites, which means they are born as females and change sex from female to male at a certain size and age. Females reach sexual maturity at around 75 cm TL or 4.6 years old. Sexual transition from female to male occurs when the fish are around 104 cm, and roughly 10.7 years of age (Gamboa-Salazar et al. 2020; SEDAR 2021). Off South Carolina's coast, Gag spawning occurs on reefs along the continental shelf and shelf edge from January through May, peaking in March and April (McGovern et al. 1998; Gamboa-Salazar et a. 2020).

Gag color is variable with the predominant color pattern for adults being an olive-brown with darker leopard spot-like markings on the side. Adult Gag may also be seen with dark brown and white bars below the dorsal fin or as a black-belly morph with the

ventral part of the body black above the anal fin (Heemstra et al. 2002; Murdy and Musick 2013).

Status

The stock of Gag off the southeast Atlantic coast was listed in 2023 as undergoing overfishing and overfished based on a stock assessment completed in 2021 (with 2019 as the last year of data included; SEDAR 2021). Gag are listed as Vulnerable by the IUCN.

POPULATION SIZE AND DISTRIBUTION

Gag are found in the western Atlantic, primarily from North Carolina to the Yucatan Peninsula, Mexico with juveniles reported as far north as Massachusetts and spotty reports as far south as Brazil. Juveniles are estuarine-dependent, using oyster and sea grass beds, while adults are found offshore (Heemstra and Randall 1993; McGovern et al. 1998; Heemstra et al. 2002). On the continental shelf, including off South Carolina, Gag have been collected at depths from 17 to 95 m (56 to 312 ft.) by the fishery-independent Southeast Reef Fish Survey (SERFS, Figure 1).

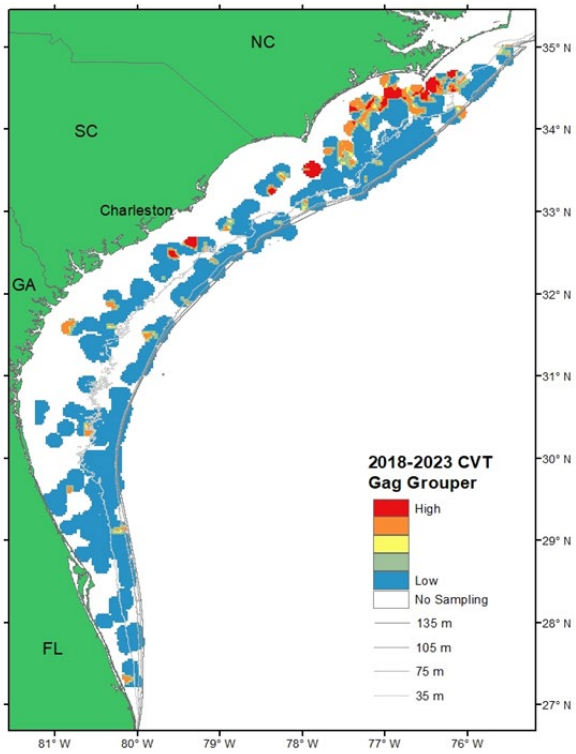

Figure 1: Distribution map of Gag catches from SERFS Chevron Traps from 2018-2023 (excluding 2020; Vecchio et al. 2024).

Two data sources independently support the decline in the Gag population off the U.S. southeast Atlantic coast and were used in the most recent assessment. Fishery-independent data collected by SCDNR during the Marine Resources Monitoring, Assessment and Prediction Program (MARMAP; 1990-2009) and the Southeast Reef Fish Survey (SERFS: 2010-present and includes MARMAP) indicates an overall decline in relative abundance since 1990 (Vecchio et al. 2024; Figure 2). South Carolina commercial fishery landings have averaged 221,170 lbs per year from 1980 to 2022 with an overall declining trend (NOAA Fisheries 2024b; Figure 3), while recreational landings in South Carolina averaged 22,217 lbs per year from 1984 to 2022 with no trend (NOAA Fisheries 2024b; Figure 3). An estimate of absolute Gag population size in South Carolina is not available.

HABITAT AND NATURL COMMUNITY REQUIREMENTS

Juvenile Gag occupy high-salinity estuaries and are found in habitats with natural or artificial structure such as seagrass beds, salt marsh edges, oyster reefs, wrecks, pilings, and dredged canals (Keener et al. 1988; Adamski et al. 2011). Oyster reefs are a favored habitat for juveniles in South Carolina. Post-larvae recruit to inlets, harbors, and saltmarsh creeks in March through June (peak in April) and remain in the estuary until waters cool in October and then they move offshore (Keener et al. 1988; Adamski et al. 2011). In offshore waters, Gag occupy natural and artificial reefs, including wrecks, hard bottom, live bottom, shelf-edge scarps, ledges, sponge/coral habitat, and other habitats that provide vertical relief above the bottom. Small juveniles feed on crustaceans while adults are piscivorous (Mullaney 1994; Spanik 2018).

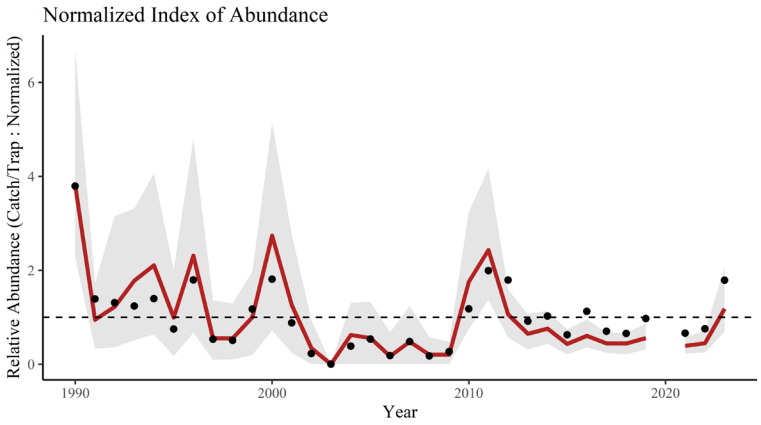

Figure 2: SERFS Chevron Trap index of relative abundance for Gag for the Southeast U.S. Atlantic region. Nominal values are black dots. Red line is modeled index value. Gray shading is standard error. Dotted horizontal line is long-term average value.

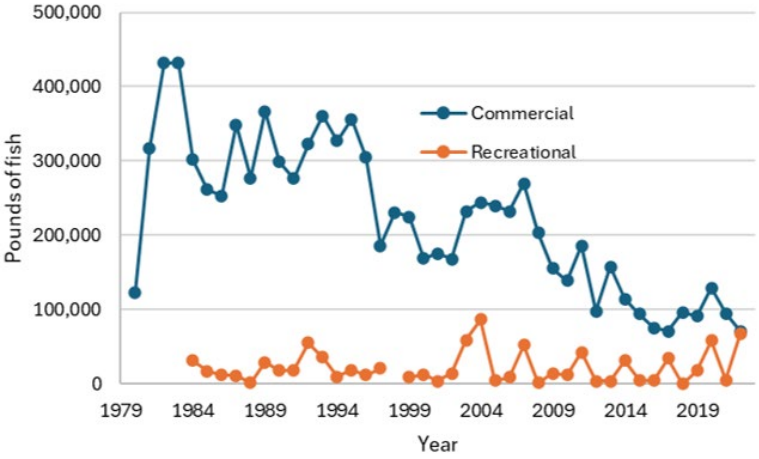

Figure 3: Commercial and recreational landings (in lbs) of Gag in South Carolina.

CHALLENGES

Coastal development adversely affects salt marsh availability and increased harvesting can impact oyster reef availability, both of which are essential habitats for juvenile Gag. Because Gag are long-lived, slow growing and late maturing, overfishing is a primary concern as such activity is likely to reduce the number of fish, skew age compositions, and impact reproductive output (McGovern et al. 1998; Coleman et al. 2000; Harris and Collins 2000; Musick et al. 2000). Additionally, Gag undergo sex transition, which further results in skewed sex ratios under heavy fishing pressure; the largest fish are males and are selectively removed by the fishery (Huntsman et al. 1999; McGovern et al. 1998; Coleman 2000). Gag can be found in deep water (50 to 100 m or 164 to 328

ft; McGovern et al. 1998) where post-release mortality is high due to pressure changes and barotrauma impacts. In addition, Gag are larger in deep water and tend to be more sedentary with increasing depth, further increasing the vulnerability of males to fishing pressure (McGovern et al. 2005). Gag have a minimum size limit and a spawning season closure in place to reduce fishing mortality. However, Gag are also part of a multi-species fishery (snappers, other groupers, etc.), and so they are caught when not being targeted which increases the likelihood of regulatory discards and post-release mortality.

CONSERVATION ACCOMPLISHMENTS

The Gag fishery off of South Carolina is managed in federal waters by the South Atlantic Fishery Management Council, which enacted several management measures to reduce fishing mortality. In the commercial fishery, a limited access snapper-grouper permit is required and there is a 300 lb gutted weight trip limit. There is a commercial and recreational 61 cm (24 in) total length minimum size limit. Between January 1 and May 1, there is a prohibition on recreational and commercial harvest and possession of Gag and other shallow water groupers during their peak spawning period. Outside of the spawning season closure, longline use in areas shallower than 50 fathoms is prohibited and traps and trawls are banned for commercial use for Gag. The recreational fisherman is limited to 3 groupers (mixed species) per person, although no more than one may be a Gag or a Black Grouper. Vessels fishing for snapper-grouper species must have a descending device on board to reduce post-release mortality. Gag must be landed with the heads and fins intact to facilitate enforcement of regulations. In addition, the SAFMC established Marine Protected Areas (MPA) in the region in 2009 that are closed to bottom fishing year-round to product grouper spawning areas (SAFMC 2024).

CONSERVATION RECOMMENDATIONS

- Evaluate the effects of fishing and management plans, such as closures and MPAs, on Gag stocks.
- Investigate the potential for male limitation in the Gag population and its impact on reproductive output and recruitment.
- Investigate drivers of recent low recruitment for Gag.
- Establish a pre-recruit index of abundance by monitoring the abundance of juvenile Gag in South Carolina estuaries. Such an index could be used to evaluate recruitment success and predict trends in adult population size.
- Determine key saltmarsh and oyster reef habitat utilized by juvenile Gag to protect those areas from degradation, either permanently or seasonally.

MEASURES OF SUCCESS

Measurement of management success is difficult in the absence of long-term historical data that precede expansion of the fishery in the 1970s; however, the SCDNR MARMAP and SERFS programs have monitored relative abundance, size structure, age structure, and reproduction of reef fish, including Gag, since 1990. These data have shown an increase in average size of Gag following implementation of size regulations, suggesting small fish have been preserved from fishing mortality. This survey can serve as an early warning sign of population recovery based on abundance and size structure well before a full assessment can be conducted.

Tilefish (Golden Tilefish)

Lopholatilus chamaeleonticeps

Contributors:
Kevin Spanik (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Golden Tilefish, *Lopholatilus chamaeleonticeps*, are members of the family Malacanthidae (tilefishes) found within the order Perciformes (Page et al. 2023). They are a medium-sized fish easily distinguishable from other members of the family Malacanthidae by their large adipose flap, or crest, on the head. The species is blue-green and iridescent on the back, with numerous spots of bright yellow and gold. The belly is white and the head is rosy, with blue under the eyes. The pectoral fins are sepia-colored, and the margin of the anal fin is purplish-blue.

Golden Tilefish live to a maximum age of 40 years and reach a maximum size of 855 mm. Maturity of 50% of fish is reached by age 3. Golden Tilefish are gonochorists and have an extended spawning season from March to November, peaking between April and June (SEDAR 2021).

Status

Golden Tilefish support commercial and recreational fisheries in South Carolina. The most recent stock assessment determined that Golden Tilefish are not overfished, and no overfishing is occurring (SEDAR 2021).

POPULATION SIZE AND DISTRIBUTION

Golden Tilefish are distributed along the outer continental shelf of North America from Nova Scotia to Key West, FL; in the Gulf of Mexico from the northern shoreline to Campeche Bank, Mexico, and off South America from Venezuela to Surinam (Able et al. 1982; Dooley 1978; Grimes et al. 1988; Hightower and Grossman 1988; Turner et al. 1983). Adults move little in depths of 100-400 m and water temperatures of about 9-14°C (Erickson et al. 1985; Grimes et al. 1986; Grimes et al. 1982; Grimes et al. 1988; Hightower and Grossman 1988; Low and Ulrich 1983).

Golden Tilefish were encountered occasionally using Short Bottom longline (SBLL) gear by the Marine Resources Monitoring and Prediction Program (MARMAP) to sample snapper-grouper species in habiting hard-bottom areas with considerable vertical relief in depths greater than 75 m, from 1996 to 2022. However, SBLL sampling was not conducted consistently enough to develop reliable indices of abundance.

In 2020 a coastwide longline survey, South Atlantic Deepwater Longline Survey (SADL) was developed which aims to consistently sample deepwater species including Golden Tilefish. However, at least 5 years of survey data should be available before an index of relative abundance should be considered for use in a stock assessment. The distribution of catches confirmed the patchy distribution throughout the region, including SC, but showed areas of increased abundance in FL (Figure 1).

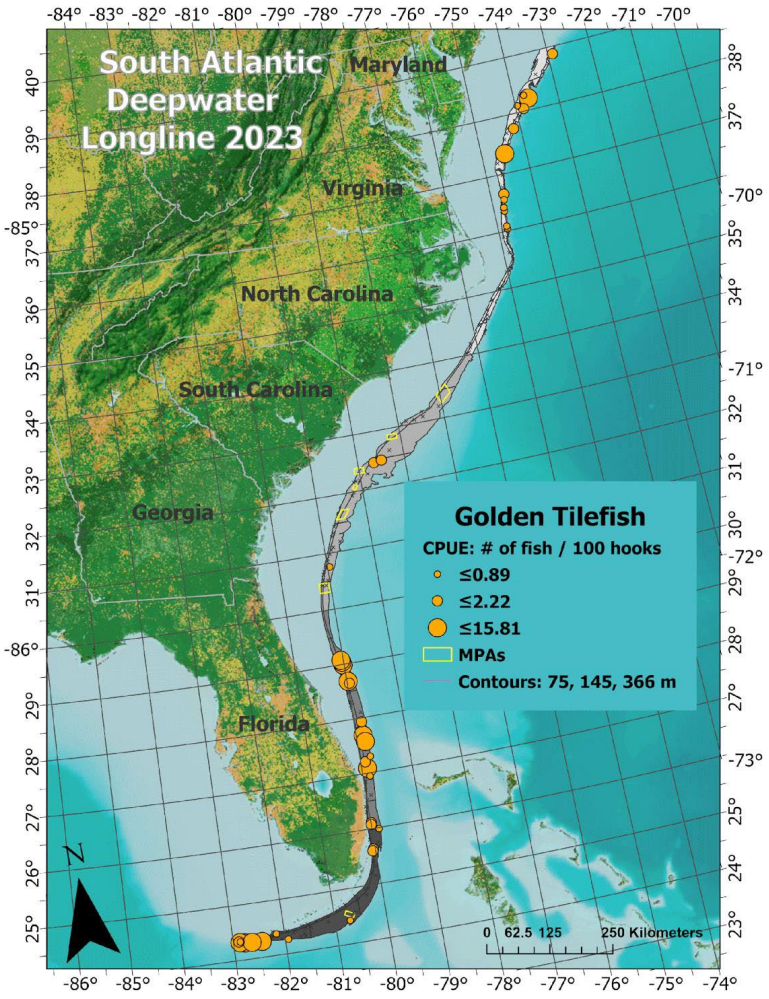

Figure 1: Distribution and magnitude of Golden Tilefish catches from the South Atlantic Deepwater Longline Survey in 2023.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Golden Tilefish occupy burrows within clay bottoms or scour depressions around boulders or rubble piles in depths of 100-400 m and water temperatures of 9-14°C (Erickson et al. 1985; Grimes et al. 1986; Grimes et al. 1982; Grimes et al. 1988; Hightower and Grossman 1988; Low and Ulrich 1983). Golden Tilefish are opportunistic feeders that prey on benthic-associated crustaceans, annelids, mollusks, echinoderms, and fishes (Freeman and Turner 1977).

CHALLENGES

Golden Tilefish and other deepwater fisheries have become increasingly important because of their economic value and because they provide an alternate resource when shallow-water stocks are depleted or access is restricted by management (Large et al. 2013). Deepwater stocks are difficult to monitor, as the depths and distance from shore at which these species occur are often cost-prohibitive for traditional surveys to adequately collect samples for life history analyses, estimation of population demographics, and development of relative abundance trends. As a result, stock assessments for Golden Tilefish have historically been data-limited. SADL was

developed to more effectively sample deepwater species throughout their range and will be a critical data source for stock assessments in the future. Because deepwater species, including Golden Tilefish, tend to be slower growing and long-lived, they are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. As with many other reef fish species which have substantial overlap in habitat use, there is potential for mortality even when they are not targeted in this multi-species fishery. Because they are a deepwater species (≥30 m), they can be highly susceptible to post-release mortality (e.g. barotrauma) during these encounters.

CONSERVATION ACCOMPLISHMENTS

The Golden Tilefish fishery off South Carolina is managed in federal waters by the South Atlantic Fishery Management Council. Several management measures to reduce fishing mortality and dead discards have been implemented including the requirement of descending devices, dehooking tools, and non-stainless steel circle hooks.

CONSERVATION RECOMMENDATIONS

- Reconsider evidence of stock structure
- Investigate effects of weather/oceanographic patterns on catchability
- Characterize and quantify relationships between catch and habitat

MEASURE OF SUCCESS

Management success for Golden Tilefish is difficult to measure since fishery-independent sampling has not been consistent historically and offshore species recreational catch is more difficult to monitor. SADL was developed to more effectively sample deepwater species throughout their range and will be a critical data source for stock assessment in the future.

Gray Snapper

Lutjanus griseus

Contributors:
Amy Zimney (SCDNR), Julie Vecchio (SCDNR) & Joseph C. Ballenger (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The gray snapper also known as the "mangrove snapper" is a member of the Lutjanidae (Snapper) family and order Perciformes (Page et al. 2023) with a maximum reported age of 32 years (SEDAR 2018) and a world record total weight of ~8.45 kg (IGFA 2024). The gray snapper has a relatively slender body with a pointed snout. Starck and Schroeder (1971) described the gray snapper as generally gray dorsally with white countershading but with variable shades and color patterns based on the size of the fish and their environment, ranging from pale gray to dark reddish brown. In most cases, there is a dark stripe running obliquely from the snout through the eye, ending ahead of the first dorsal spine. The gray snapper reaches sexual maturity around ages 2 to 3 (175 to 198 mm standard length) with a general male to female sex ratio of 50:50 (Starck and Schroeder 1971; Domeier et al. 1996). From May to September, adult gray snapper form spawning aggregations offshore; spawning is thought to occur during new or full moons (Starck and Schroeder 1971; Domeier et al. 1996).

Status

Results of the SEDAR 51 assessment (2018) suggest the Gulf of Mexico stock is experiencing overfishing and has been for decades but is not currently overfished. The stock status for the gray snapper population along the southeastern United States (SEUS) Atlantic coast has not been formally analyzed since the early 1990s (Bacheler et al. 2020). The gray snapper is listed as Least Concern by the IUCN (Lindeman et al. 2016).

POPULATION SIZE AND DISTRIBUTION

The gray snapper is found in tropical, subtropical, and warm temperate waters along the United States Atlantic coast to Brazil, Bermuda, and throughout the Gulf of Mexico and the Caribbean (Starck and Schroeder 1971; Denit and Sponaugle 2004; Lindeman et al. 2016; Andrade and Santos 2019; Bacheler et al. 2020). The Southeast Reef Fish Survey (SERFS) uses traps and video cameras to monitor species composition and abundance from Cape Hatteras, NC, to St. Lucie Inlet, FL, with video counts of particular use for gray snapper (Figure 1). The gray snapper is common along the

eastern Florida coast but generally decreases in abundance northward (Starck and Schroeder 1971; Chester et al. 1984; Bacheler et al. 2020). However, there has been evidence of recruitment in South Carolina estuaries since the early-2000s, with individuals captured annually every year since 2001 in the SCDNR Inshore Fisheries fishery-independent electrofishing survey and several years in the trammel net survey; particular pulses occurred from 2002-2006 and 2015-2018 (Joseph C. Ballenger, pers. comm.).

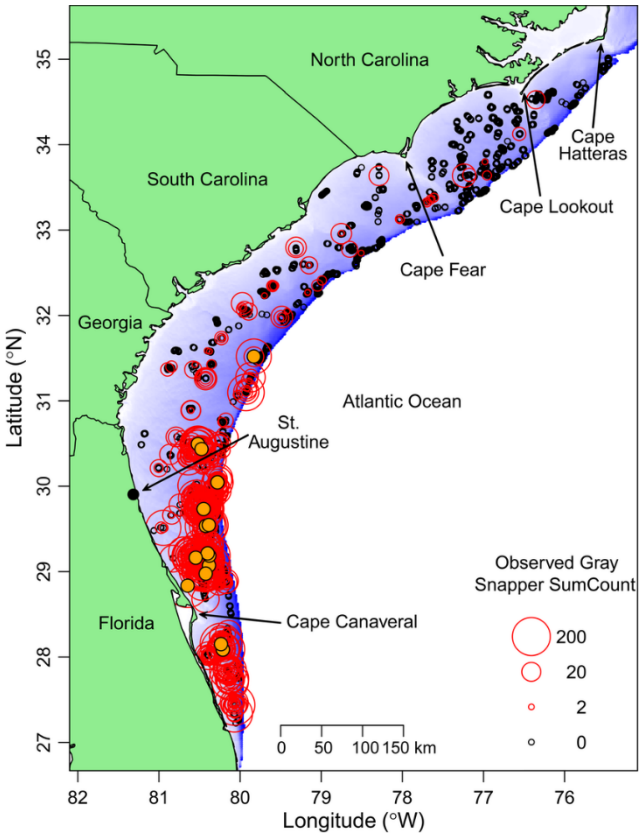

Figure 1: Figure from Bacheler et al. (2020) displaying Southeast Reef Fish Survey (SERFS) distribution of gray snapper from video counts from 2011-2017. The scaled red bubbles indicate the number of observed gray snapper. The orange circles indicate gray snapper aggregations (i.e., >20 individuals). Note that bubbles often overlap. The depth range is from 5 m (light blue) to 100 m (dark blue).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The habitats occupied by gray snapper vary widely and generally with life stage. Juveniles inhabit estuarine seagrass beds, mangroves, and oyster reefs (Starck and Schroeder 1971; Flaherty et al. 2014; Bacheler et al. 2020), subadults move into channels, and adults tend to occupy deeper channels or offshore waters associated with coral reef, rocky reef, or hard-bottom habitats (Starck and Schroeder 1971; Bacheler et al. 2020). Along the southeast US continental shelf, Bacheler et al. (2020) found adult gray snapper were more common in warmer waters (>22 °C) at depths less than 50 m (Fig 1) and in high-relief hardbottom habitats. Schools of adult gray snapper form during the day before dispersing at night to forage, feeding largely on shrimp, crab, and fish (Starck and Shroeder 1971).

CHALLENGES

The gray snapper is susceptible to fishing pressure as an easily accessed coastal species. Latitudinal demographic differences (e.g., size and age) have been noted in gray snapper in Florida waters, with a lack of older and larger fish in south Florida where there is greater fishing pressure (Burton 2001; Allman and Goetz 2009; SEDAR 2018). Although the South Atlantic Fishery Management Council (SAFMC) manages gray snapper, there are limited data available for the southeast US Atlantic population because the species is minimally susceptible to common survey gears due to location

and ecology. The long-term population trend is unknown, and information is limited on adult gray snapper temporal and spatial movements, with no spawning aggregation sites identified in the southeast US (Bacheler et al. 2020). The general lack of information on the gray snapper population in this region creates challenges for fisheries managers, especially considering gray snapper are part of a multi-species fishery, and as coastal development can adversely affect nursery habitats.

CONSERVATION ACCOMPLISHMENTS

The SAFMC manages the gray snapper fishery in federal waters off South Carolina. Commercial fishery regulations include a minimum total length of 12 in. Recreational fishery regulations include a minimum total length of 12 in, a 10 fish bag limit, and a 10 fish aggregate bag limit (10 snapper combined). Recreational fishing vessels are required to have a descending device on board when fishing for species in the snapper-grouper complex.

CONSERVATION RECOMMENDATIONS

- Continue to monitor gray snapper abundance via fishery-dependent and fishery-independent surveys, particularly watching for range expansions in to South Carolina waters.
- Increase biological sampling efforts.
- Conduct discard mortality studies for gray snapper.
- Initiate tagging studies to identify spatial and temporal movement patterns.
- Identify spawning aggregation locations.

MEASURE OF SUCCESS

Data collected by the SERFS, particularly counts of individuals via the video survey, can be used to observe long-term trends in total abundance. Stability or increases in total abundance can indicate a healthy population, suggesting successful management measures. Further, if abundances of juveniles in estuarine waters increases, the SCDNR fishery-independent electrofishing and trammel net surveys may continue to encounter Gray Snapper, offering another avenue to monitor their status in South Carolina.

Gray Triggerfish

Balistes capriscus

Contributors:
Kevin Kolmos (SCDNR) & Tracey Smart (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Gray triggerfish, *Balistes capriscus*, is a marine species in the family Balistidae found within the order Tetraodontiformes (Robins and Ray 1986; Bernardes 2002; Page et al. 2023). Their name accurately describes their coloration (gray with blue or purple spots or shading) and can easily distinguish them from their cousins, the queen triggerfish, which are brightly colored. Gray triggerfish have a laterally compressed body with large incisor teeth and a large dorsal spine that remains erect, for protection, until a smaller second spine is deflexed, triggering the first.

Gray triggerfish are gonochoristic (separate sexes) and demonstrate sexual dimorphic growth where males obtain larger sizes than females. Males build demersal nests and perform courtship behaviors to attract multiple females into a harem-like group (Simmons and Szedlmayer 2012). Both parents will then protect the demersal eggs in the nest until they hatch. Females in the southeastern US can be reproductively mature within the first year but are fully mature by age 4, have a max age of 15 years, and max size of 453 mm (~18 inches) total length (TL; SEDAR 82). Additionally, they spawn from April-September (Kelly-Stormer et al. 2017).

Status

Gray triggerfish in the Atlantic off the U.S. southeast coast (SEUSA) are managed as a single stock based on genetics (Antoni et al 2011). The only completed assessment for this stock characterized Atlantic gray triggerfish as not overfished and overfishing not occurring (SEDAR 2024). IUCN characterizes gray triggerfish as Vulnerable.

POPULATION SIZE AND DISTRIBUTION

Gray triggerfish occur in coastal waters of the western Atlantic from Nova Scotia (Canada) to Argentina, including the Gulf of Mexico and Bermuda (Robins and Ray 1986; Bernardes 2002). Throughout this distribution, they are found at depths to 100 m (Harmelin-Vivien and Quéro 1990). In the SEUSA, the species is regularly encountered by the fishery-independent Southeast Reef Fish Survey (SERFS) chevron trap survey. The species is most abundant on hard-bottom habitats off the coasts of North and South Carolina (Figure 1). Despite their not overfished status, SEDAR 82 used fishery-independent and dependent data, which showed a decreasing trend in biomass in the

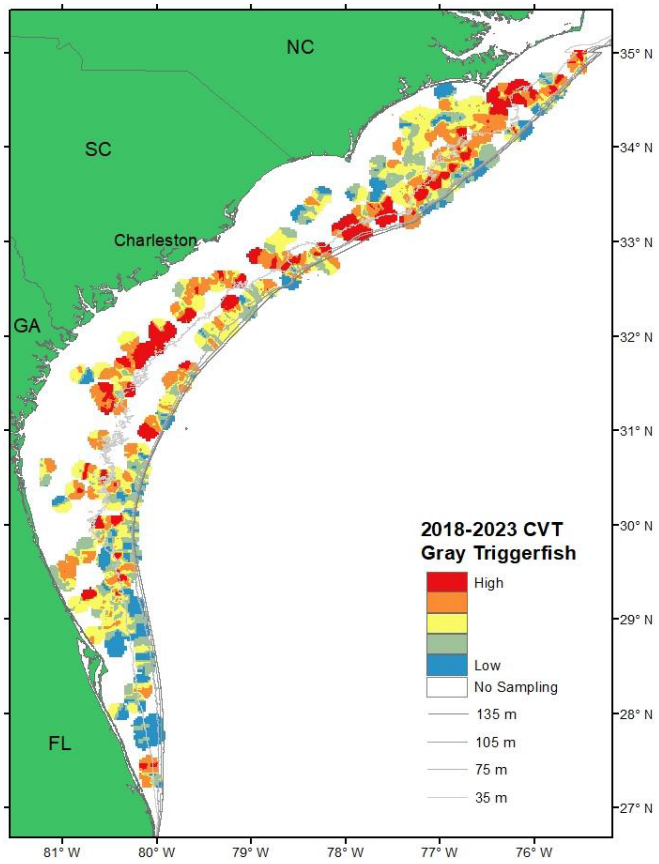

Figure 2: Distribution map of Gray Triggerfish from Southeast Reef Fish Survey chevron traps.

region. Data from the fishery-independent Southeast Reef Fish Survey showed a decline in relative abundance recently compared to the 1990s (Vecchio et al. 2024; Figure 2).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Gray triggerfish have a unique life history strategy where juveniles associate with *Sargassum* spp. in the water column (Ingram 2001; Wells and Rooker 2004; Casazza and Ross 2008) and eventually settle into the benthos and are most associated with natural and artificial reefs, rocky outcroppings/hard bottom, and wrecks as adults. Adults feed diurnally on invertebrate prey, such as mollusks, crustaceans, and echinoderms (Frazer et al. 1991; Vose and Nelson 1994; Blitch 2000). Off the coast of South Carolina, they are found from the mid-shelf out to about 100 m in depth.

CHALLENGES

Gray triggerfish are part of a multi-species reef fish fishery off the U.S. southeast Atlantic coast managed by the South Atlantic Fisheries Management Council (SAFMC). In 2024, gray triggerfish were managed through minimum size limits, bag and trip limits, and annual catch limits. When the fishery is closed for gray triggerfish, they may co-occur with other open species and are therefore subject to bycatch and potentially post-release mortality when released due to

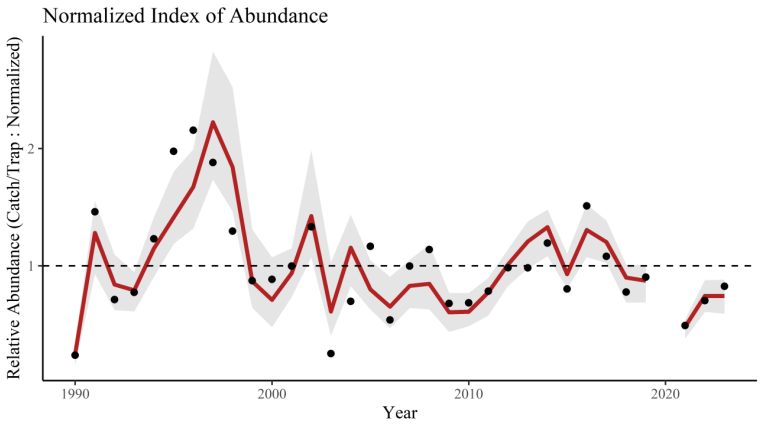

Figure 1: Estimated index of abundance for gray triggerfish off the SEUSA coast as captured by the SERFS chevron trap survey from 1990 to 2023.

regulations. Additionally, they occur in deeper waters (>30 m), which makes them prone to barotrauma during capture, which can also increase rates of post-release mortality.

Gray triggerfish life history also proves challenging for understanding their populations. Capturing juvenile specimens is difficult due to their early association with the sargassum habitat, meaning we lack information about recruitment and early growth and reproduction. Further, age determination in gray triggerfish is notoriously difficult. Because females lay demersal eggs and their eggs may not fully hydrate like other pelagic egg layers, estimating fecundity (reproductive output) is difficult. They also guard nests and may not forage during the short time they are guarding the nest, making it difficult to capture individuals in spawning condition to develop needed parameters for assessments.

CONSERVATION ACCOMPLISHMENTS

SAFMC regulations for gray triggerfish since the first bag limit in 1999 (Amendment #9) have proven to be sufficient to maintain them in acceptable stock status.

CONSERVATION RECOMMENDATIONS

- Age-structure validation
- Research movement and migration in Atlantic waters
- Evaluate their reproductive strategy, including investigations of spawning location, spawning season, effects of nesting behavior on reproductive output, and fecundity type
- Determine early life history parameters, specifically on 4-7 month pelagic stage
- Determine recruitment patterns, including availability of Sargassum as essential juvenile habitat
- Determine the impact of climate change on reproduction, recruitment, and mortality

MEASURES OF SUCCESS

The SERFS program annually monitors relative abundance, population demographics and reproductive status of reef fishes can detect changes in the Atlantic gray triggerfish population that result from management efforts or require management efforts. Further, tracking changes in relative abundance and population demographics from the SERFS survey is faster and more responsive than traditional stock assessments, though only stock assessments can integrate all available data to determine stock status.

Hammerhead Sharks Guild

Bonnethead *Sphyrna tiburo*
Carolina Hammerhead *Sphyrna gilberti*
Great Hammerhead *Sphyrna mokarran*
Scalloped Hammerhead *Sphyrna lewini*
Smooth Hammerhead *Sphyrna zygaena*

Contributors:
Bryan Frazier (SCDNR) & Liz Vinyard (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The bonnethead, great, Carolina, scalloped, and smooth hammerheads are members of the family Sphyrnidae and reside in the genus *Sphyrna* (9 species). They have a distinct head, known as a cephalofoil, which is laterally expanded and dorso-ventrally flattened.

Bonnethead Shark

The bonnethead is a relatively small shark reaching a maximum reported total length (TL) of 140 cm (Castro 2011). Its head is semicircular in outline. Among sharks in general, they are considered rapidly maturing with females reaching maturity around 6 years of age (106 cm TL) and males reaching maturity around 4 years of age (80 cm TL) (Frazier 2014). Bonnetheads are placentally viviparous and have a 4.5 month gestation period with parturition occurring in September. The short gestation period and month of parturition are both unique among sharks inhabiting coastal waters of the US. Mature bonnetheads reproduce annually with an average litter size of 8-9 pups (Gonzales de Acevado et al. 2020). The maximum observed age for bonnetheads is 18 years old (Frazier 2014)

Scalloped/Carolina Hammerhead Shark

The scalloped hammerhead is a large hammerhead reaching a maximum reported size of 430 cm TL, although total lengths of 360 are more common. The head has a median notch at its center and a slight arch that is more prominent

in young of the year and juveniles. They are relatively slow to mature with males maturing at around 12.4 years of age (158 cm FL) and females maturing around 16.2 years old (188 cm FL) (Piercy et al. 2007; Moncrief-Cox et al. 2021). Scalloped hammerheads are placentally viviparous with a 9-to-12-month gestation period and parturition occurring in late spring. Reported litter sizes range from 12-41 pups with an annual reproductive cycle. The maximum reported age for scalloped hammerheads is 39.5 years old (Frazier et al. 2021).

The Carolina hammerhead has only recently been described (Quattro et al. 2013). It is morphologically similar to the scalloped hammerhead, with x-ray counts of pre-caudal vertebrae being the only conclusive characteristic. Carolina hammerheads have less than 92 pre-caudal vertebrae (range of 83-91) while scalloped hammerheads have greater than 91 pre-caudal vertebrae (range of 92-99). Although some external morphological features differ on average between the two species, their ranges overlap, so there is currently no definitive field method of distinguishing one species from the other. Instead, either genetic analysis or x-ray pre-caudal vertebrae counts are required. The Carolina hammerhead was described based on neonate and juvenile stages, and limited data are available regarding life history and ecology. Life history characteristics are thought to be similar to the scalloped hammerhead, but it is likely that existing knowledge of scalloped hammerhead life history included mixed information from both species. The current maximum estimated age of Carolina hammerheads is 22 years; however, only a couple adults have been aged to date.

The great hammerhead is the largest hammerhead species in the family with a maximum reported length of 466 cm TL. They have a head with nearly straight anterior margins, a prominent high first dorsal fin and pelvic fins with curved rear margins. Maturity data are lacking due to relatively low sample availability of juveniles, however the available data suggest they mature at a younger age, but greater length than scalloped hammerheads with males maturing at around 7.8 years of age (201 cm FL) and females maturing around 8.1 years old (207 cm FL) (Moncrief-Cox et al. 2021). Great hammerheads are placentally viviparous with a 11 to 12 month gestation period and parturition occurring in early summer. Reported litter sizes range from 13-56 pups with an annual reproductive cycle. The maximum reported age for scalloped hammerheads is 44 years old (Piercy et al. 2010).

The smooth hammerhead obtains similar lengths to the scalloped hammerhead and has a rounded anterior margin to the cephalofoil similar to Carolina and scalloped hammerheads, but it can be readily distinguished by the lack of a central indentation. Smooth hammerheads are generally found in more northerly latitudes compared to other hammerhead species, and regional abundance is also lower. Given the low abundance, regional life history data are lacking with no studies on age and growth or reproduction in this region. From studies of other populations, it appears that the life history of smooth hammerheads (length, reproduction and maximum age) is most similar to that of the scalloped hammerhead.

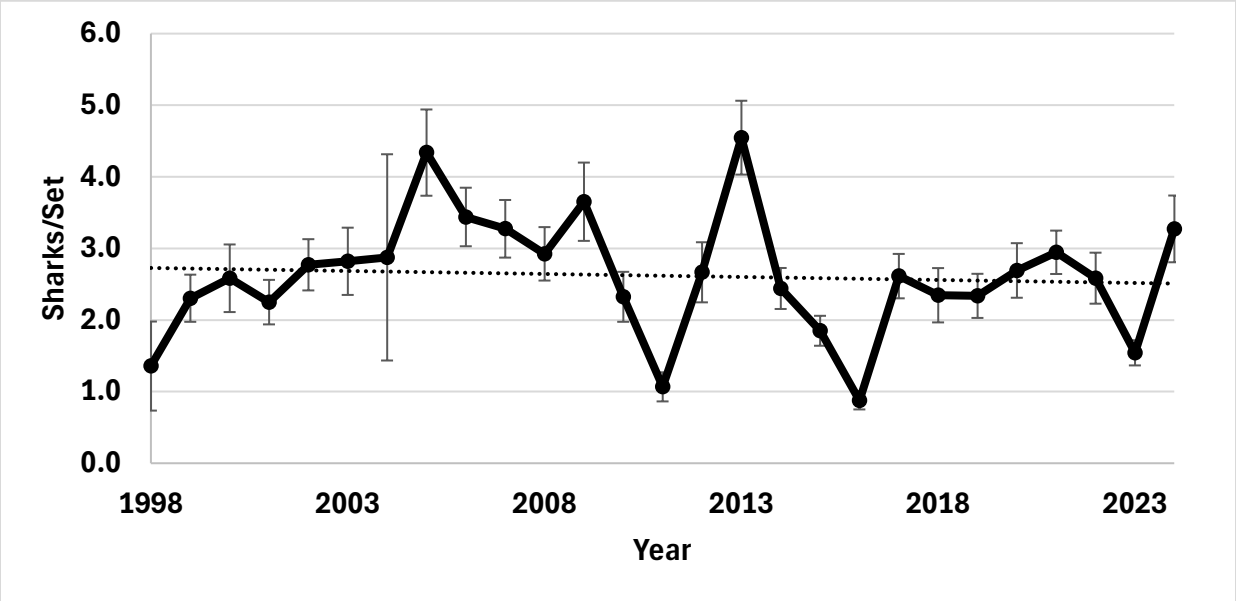

Figure 1. Catch per unit effort of bonnetheads (sharks per set) from 1998 to 2023 in the South Carolina Cooperative Atlantic States Shark Pupping and Nursery Habitat gillnet survey. Standard error is denoted by error bars.

Status

The status of the bonnethead in the US Atlantic Ocean is currently considered unknown. The species was last assessed in 2013; however, the Gulf of Mexico (GOM) and US Atlantic (Atlantic) populations were assessed as a single stock, despite substantial evidence showing multiple stocks (tagging, genetic and life history data) the combination of the stocks confound the assessment results leading external reviewers to reject the assessment for management purposes. The International Union for Conservation of Nature (IUCN) Red List currently considers the bonnethead as an "Endangered" species, although this assessment is largely based on status in countries outside of the US where bonnethead populations are in decline. Data from the South

Carolina Department of Natural Resources (SCDNR) gillnet survey suggest a general decrease in bonnethead abundance since the survey began (Figure 1).

Given the limited availability of Carolina hammerhead specific fishery independent data, commercial and recreational data, as well as life history data, they were most recently assessed as a combined species assessment with scalloped hammerheads. Ultimately the stock assessment determined there was no overfishing occurring, and the combined stocks were not overfished in US waters (SEDAR 77). That said, the stock assessment noted the difficult nature in dealing with the cryptic Carolina hammerhead. A 2012 petition to list the scalloped hammerhead as an endangered species was found to not have merit in the Northwestern Atlantic Ocean and Gulf of Mexico. However, the National Marine Fisheries Service did find populations in the eastern Atlantic Ocean and eastern Pacific Ocean were at high risk of extinction, and the population in the Central and Southwest Atlantic were listed as threatened (NMFS 2013). The IUCN Red List currently considers the scalloped hammerhead to be critically endangered, the Carolina hammerhead is considered data deficient. Data from the SCDNR shark gillnet survey suggest an increase in abundance of young of year scalloped and Carolina hammerhead sharks in SC waters (Figure 2), indicating increasing recruitment.

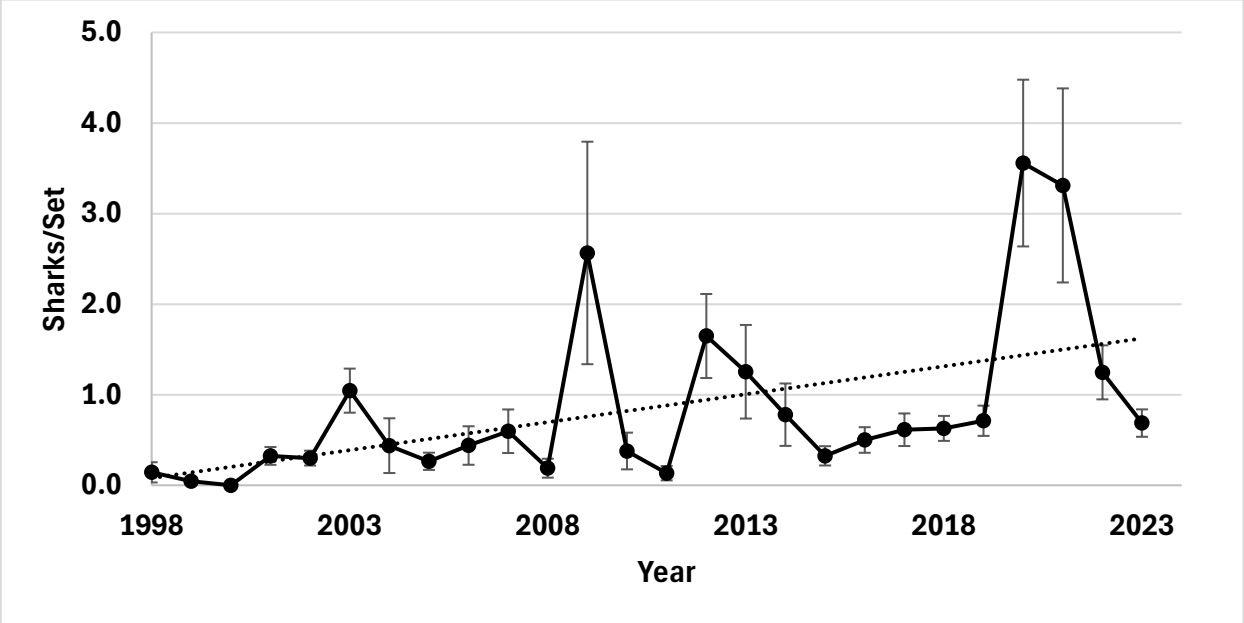

Figure 2. Catch per unit effort of young of year scalloped and Carolina hammerheads (sharks per set) from 1998 to 2023 in the South Carolina Cooperative Atlantic States Shark Pupping and Nursery Habitat gillnet survey. Standard error is denoted by error bars.

Data are comparatively lacking on great hammerhead abundance, especially in young of year and juvenile life stages, that said sufficient data were present to conduct a stock assessment with results showing the population is overfished, but no overfishing was occurring at the time of the assessment (SEDAR 77). Globally, there is significant concern for the great hammerhead with the IUCN Red List currently considering the great hammerhead critically endangered.

Data were acknowledged to be lacking in the assessment of the status of the smooth hammerhead and while robust recommendations could not be generated, the assessment indicated that the stock had been depleted in the past, reduced fishing pressure over the last 20 years had allowed the stock to begin rebuilding, and that rebuilding would likely continue to occur with the current management. Globally, the smooth hammerhead is considered vulnerable by the IUCN Red List, although their assessment notes that populations are declining.

POPULATION SIZE AND DISTRIBUTION

Bonnetheads are distributed in coastal and estuarine waters from North Carolina south through the Gulf of Mexico, Caribbean, and to Brazil (Compagno 1984). Within South Carolina waters, bonnetheads are found in high to moderate salinity estuarine waters (17-34 ppt) in the late spring through early fall (Ulrich et al. 2007). Females and males spatially segregated with females found primarily in estuarine waters, and males mostly found in coastal waters. A high degree of site fidelity by female bonnetheads has been observed through tagging studies, with individuals returning to the same estuary year after year (Driggers et al. 2013). This observed site fidelity could lead to localized exploitation of bonnetheads, resulting in a potential loss of genetic diversity. Recent research by Keller et al. (2021) found that bonnetheads are likely using geomagnetic features to migrate to and from Spring-Fall habitat.

Scalloped hammerheads are globally distributed in coastal warm temperate and tropical seas. Genetic evidence indicates 6 distinct population segments (Northwest Atlantic & Gulf of Mexico, Central & Southwest Atlantic, Eastern Atlantic, Indo-West Pacific, Central Pacific, and Eastern Pacific). Within South Carolina waters, adult and juvenile scalloped hammerheads are found primarily in coastal waters with estuaries, particularly Bulls Bay, serving as primary nursery areas for young of the year scalloped hammerheads. Juveniles and adults are found in nearshore and offshore waters year-round.

Recent research has shown Carolina hammerhead distribution is limited compared to the globally distributed scalloped hammerhead with Carolina hammerheads being limited to the western Atlantic Ocean (Barker et al. 2021). The center of abundance of young of year and early juveniles occurs in Bulls Bay, SC with decreasing abundance to the north and south. The species has been detected in waters off Brazil as well as in Trinidad and Tobago; however, it appears to be completely absent from the Gulf of Mexico (Pinhal et al. 2012). While estimates are preliminary, recent genomic work suggests the number of breeding Carolina hammerheads contributing to US East Coast nurseries is half that of scalloped hammerheads. Additional sampling is needed to fully assess the species range with samples needed from the Caribbean and eastern Atlantic to confirm presence/absence. Ongoing research is examining relative contributions of nursery areas to the adult population.

Great hammerheads are a circumtropical globally distributed species, in US waters they range from NC south through the Gulf of Mexico, primarily inhabiting coastal and nearshore waters, although they are known to make forays into deeper waters. Nurseries areas remain enigmatic, several neonates were captured alongside Carolina and scalloped hammerheads in Bulls Bay, and in scalloped hammerhead nurseries off the Big Bend of Florida (Barker et al. 2017); however, these are only a handful of encounters. More recently, a nursery area has been proposed for Biscayne Bay, FL; however, the great hammerheads captured there may be early juveniles (Macdonald et al. 2021).

The smooth hammerhead is distributed globally in temperate waters and is rarely encountered in tropical waters. In the western north Atlantic it is most commonly found from the Bay of Fundy to North Carolina and is infrequently countered off of South Carolina to Florida. Those animals that are encountered off South Carolina are typically mature and are found in nearshore waters. Juveniles and young of year smooth hammerheads are generally found in cooler waters off the mid-Atlantic bight.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In SC bonnetheads are commonly found on sandy and muddy bottoms in shallow estuarine and coastal waters, often aggregating in areas associated with oyster reefs or along sandy beach fronts. These areas are important foraging areas since the primary component of bonnetheads diet is blue crabs, comprising >95% of their diet. Females are more commonly found in estuarine habitats while males are more common nearshore (Ulrich et al. 2007)

Adult and juvenile scalloped hammerheads prefer nearshore coastal and oceanic waters, with adult hammerheads often associated with the gulf stream edge; however, they may make limited movements into the mouths of sounds and estuaries. Young of the year scalloped hammerhead and Carolina hammerheads are found in high salinity estuaries in areas with depths ranging from 1 to 10 m (3-33 ft.). They are often found over muddy bottoms in areas with high concentrations of prey items. Work by Galloway et al. (2024) suggests scalloped and Carolina hammerheads have a generalist diet with no resource partitioning between species. That said, stable isotope analysis (SIA) of neonate tissue suggests that there is either spatial or resources partitioning between mature female Carolina and scalloped hammerheads. These results have also been confirmed using trace elements, and SIA of eye lens and suggest that while nursery areas are shared, habitats in older life stages may not be shared.

Great hammerheads are mostly commonly captured in sounds and nearshore waters off South Carolina, their preferred prey is tarpon, blacktip sharks, and stingrays, and they are commonly found in areas where these prey species are dense. The majority of great hammerheads encountered in SC are mature, however small juveniles have been captured in high salinity sounds in Port Royal Sound and St Helena Sound, often associated with waters off of sandbars.

Smooth hammerhead habitat requirements in SC are poorly understood, catches have been historically low, but when encountered they were often in association with nearshore live bottom habitats.

CHALLENGES

The bonnethead is regularly captured as by-catch in commercial shrimp trawls, likely leading to a large source of mortality. Additionally, bonnethead are increasingly being targeted by recreational anglers and fishing guides as a sport fish. While the majority of these interactions are catch and release, some are harvested for consumption. The effects of increases in fishing pressure are unknown as limited data exist for catch and release mortality of bonnetheads. The capture of bonnetheads in August and September could have negative consequences for pregnant females with near full-term pups, as the stress of capture could lead to premature birth. Declines in abundance of their primary prey, blue crabs, have been observed. As this species represents >95% of bonnethead's diet, further declines in this important forage species could be detrimental to bonnetheads.

The scalloped hammerhead is facing severe population declines worldwide and is considered at risk for extinction in multiple distinct population segments. Multiple fishery independent surveys have reported large declines in abundance of scalloped hammerheads within the western North Atlantic and Gulf of Mexico segment, that said, populations appear to be recovering (Hayes et al. 2009; SEDAR 77). Complicating matters is that an unknown portion of these declines are Carolina hammerheads. Further, Carolina hammerheads may be experiencing declines in abundance through hybridization. Research by Barker et al. (2019) found unidirectional hybridization (scalloped hammerhead males mating with Carolina hammerhead females) which could eventually lead to reductions in the number of pure Carolina hammerheads; that said, to date there is no evidence of that occurring. Hammerheads experience significant mortality in commercial fisheries, primarily bottom and pelagic longlines (Branstetter 1987). Recently, the National Marine Fisheries Service reduced commercial quotas as well as increased recreational size limits; however, hammerheads may continue to have high mortality within these fisheries as they have high at-vessel and post-release mortality. Given the unknown distribution of Carolina hammerheads, it is possible that one species may be experiencing proportionally higher mortality due to fisheries interactions. There are no estimates of natural or catch and release mortality of young of the year scalloped hammerheads in the estuaries. Their natural mortality is thought to be relatively high, given the large brood sizes of female hammerheads.

CONSERVATION ACCOMPLISHMENTS

Recent funded C-SWG, and SWG research has led to increased knowledge on the distribution and trophic ecology of Carolina and scalloped hammerheads (Barker et al. 2017, Barker et al. 2019, Barker et al. 2021, Galloway et al. 2024) with additional

manuscripts in prep, but significant work remains.

CONSERVATION RECOMMENDATIONS

- Continue to monitor stock status of hammerhead sharks within SC waters through fishery-independent methods, primarily COASTSPAN, the Adult Red Drum and Coastal Sharks longline survey, and Trammel Survey.
- Monitor the community composition of scalloped and Carolina hammerheads utilizing SC estuaries as a primary nursery to track population stability.
- Investigate genetic variation of bonnethead sharks to determine if observed site fidelity has led to fine-scale genetic structure.
- Determine fine-scale movements of bonnetheads within South Carolina estuaries to investigate environmental drivers of movement within individual estuaries.
- Determine vertical and horizontal habitat use of Carolina and scalloped hammerheads across their range in the western North Atlantic.
- Collect and genotype tissue from hammerheads in the eastern Atlantic, Caribbean, and southwestern Atlantic to determine the geographic range of the Carolina hammerhead as well as to attempt to determine ancestral origins of scalloped and Carolina hammerheads.
- Conduct Close-Kin Mark Recapture studies to estimate population sizes of hammerheads.
- Generate species-specific life history data for Carolina and scalloped hammerheads.
- Determine vertical and horizontal movement patterns of smooth and great hammerheads.
- Investigate ecological processes that could have led to speciation in the scalloped and Carolina hammerheads.
- Improve the public's understanding of the importance of sharks in the ecosystem through outreach activities such as school programs, providing story opportunities for media, and educational brochures.
- The primary action at the State level is to ensure that overfishing is eliminated.
- Partner with law enforcement to ensure adequate compliance with regulatory actions implemented through the Federal management plan and subsequent amendments.

MEASURE OF SUCCESS

One of the most important measures moving forward will be determining the stock status of the population of bonnetheads residing in the US Atlantic. Within SC waters, tagging studies have documented that bonnetheads have a high degree of site fidelity. It will be important to document fine-scale movement within these systems as well as examine genetics to determine if populations are at risk for localized exploitation and loss of genetic variation. Success criteria would be an increase in our knowledge of utilization of habitat within South Carolina estuaries as well as knowledge of the genetic structure of this species.

Regional management efforts to maintain healthy, sustainable populations of hammerheads will require active participation from South Carolina due to its importance as primary and secondary nursery habitat for hammerheads. Expanding our knowledge of the importance of SC waters for hammerhead sharks is of the utmost importance. Currently, the primary nursery area for Carolina hammerhead sharks resides in SC (Bulls Bay). Moving forward, it will be important to document the relative importance of SC waters for the scalloped and Carolina hammerheads as well as the ecological processes that define these two species. A measure of success would be to increase our understanding of the relationship between these two species in juvenile and adult age classes, as most of what we know comes from young of year sharks. An integral component of measuring success will be the continued monitoring of SC sharks through fishery-independent surveys. The ultimate measure of success will be a stock status determination of not overfished with no overfishing occurring for all hammerhead sharks. Until then, particular attention should be paid to hammerhead sharks within SC waters.

Hogfish

Lachnolaimus maximus

Contributors:
Amy Zimney (SCDNR) & Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The hogfish commonly known as the "hog-snapper" is a member of the Labridae (Wrasse) family and order Labriformes (Page et al. 2023) with a maximum total length of ~82 cm (McBride and Murphy 2003), maximum observed age of 23 years (McBride and Richardson 2007), and world record total weight of ~9.95 kg (IGFA 2024). Hogfish possess a deep, compressed body and a long, pig-like snout. The first three spines of the dorsal fin are elongated, and a black spot is present at the base of the dorsal fin (Colin 1982). Hogfish coloration is variable depending on size, sex, and habitat, ranging from a mottled rusty brown, solid reddish orange, or whitish to pale pink (McBride and Johnson 2007). Mature male hogfish have a distinctive dark reddish-brown band from the tip of their snout to the top of their head (Colin 1982; McBride and Johnson 2007). The hogfish is a protogynous hermaphrodite starting life as a female (Colin 1982; McBride and Murphy 2003; McBride and Johnson 2007; Collins and McBride 2011; Seyoum et al. 2014; Towne et al. 2021), generally reaching maturity by age 3 (McBride and Johnson 2007; Towne et al. 2021) and transitioning to a male at age 3-5 (300-400 mm FL) after one or more spawning seasons (McBride and Johnson 2007).

Status

Two genetically distinct stocks exist along the southeastern United States Atlantic coast: the Florida Keys/East Florida stock and the Georgia to North Carolina stock (Seyoum et al. 2014, Cooper et al. 2014). A third stock exists in the eastern Gulf of Mexico (Seyoum et al. 2014). Results of the SEDAR 37 assessment (Cooper et al. 2014) suggest the Florida Keys/Eastern Florida stock is currently overfished and experiencing overfishing and the Georgia to North Carolina stock has been experiencing overfishing in recent years. The eastern Gulf of Mexico stock in not overfished or experiencing overfishing (Cooper et al. 2014). The hogfish is listed as Vulnerable by the IUCN (Choat et al. 2010).

POPULATION SIZE AND DISTRIBUTION

Hogfish are found in tropical, subtropical, and warm temperate waters along the United States Atlantic coast to the northern coast of South America and throughout the Gulf of

Mexico and Caribbean (McBride and Murphy 2003; Choat et al. 2010; Collins and McBride 2011; Cooper et al. 2014; Seyoum et al 2014; Towne et al. 2021).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Hogfish are associated with hard bottom and reef habitats (McBride and Murphy 2003; Choat et al. 2010; Collins and McBride 2011; Cooper et al. 2014; Seyoum et al 2014; Towne et al. 2021) from 3 to 40 m depth (Choat et al. 2010) and observed as deep as 69 m (Collins and McBride 2011). Juveniles inhabit nearshore environments including estuaries, seagrass beds, and shallow reef habitats (Colin 1982; McBride and Johnson 2007; Choat et al. 2010; Cooper et al. 2014). The hogfish diet is primarily benthic invertebrates (McBride and Murphy 2003; Cooper et al. 2014). One male has a harem of as many as 15 females (Colin 1982; McBride and Murphy 2003; McBride and Johnson 2007). Hogfish spawning occurs primarily during winter and spring (Davis 1976; Colin 1982; McBride and Johnson 2007; Cooper et al. 2014).

CHALLENGES

Hogfish are susceptible to size-selective fishing pressure (McBride and Richardson 2007; McBride et al. 2008; Towne et al. 2021). Demographic differences (e.g., size, age, fecundity, size and age at sex change) have been noted in hogfish between stocks with larger, older fish in the eastern Gulf of Mexico stock compared to the Florida Keys/East Florida stock (McBride and Murphy 2003; Collins and McBride 2011; Cooper et al. 2014; Seyoum et al. 2014), as well as, when comparing nearshore vs offshore habitats within the same region (Collins and McBride 2011, Seyoum et al. 2014; Collins and McBride 2015). There is a disproportionate higher removal of hogfish in areas with high human populations and/or relative accessibility (McBride and Richardson 2003) with larger and older hogfish in areas with less fishing pressure or in less accessible habitats (Seyoum et al. 2014; Collins and McBride 2015). Removal of males is particularly problematic because it could interrupt harems and reduce reproductive output (McBride and Murphy 2003; McBride and Johnson 2007; Towne et al 2021). Information on the Georgia to North Carolina hogfish stock is limited due to the species tendency to avoid trapping and hooked gears, which are the primary gears used for fishery-independent data collections. Data available from this stock are from fishery-dependent sources that catch larger, older males (Cooper et al. 2014).

CONSERVATION ACCOMPLISHMENTS

The South Atlantic Fishery Management Council (SAFMC) manages the hogfish fishery in federal waters off South Carolina. Commercial fishery regulations include a minimum fork length of 17 inches and a trip limit of 500 lbs whole weight. Recreational fishery regulations include a minimum fork length of 17 in and a 2 fish bag limit. There is no spawning season closure for the Georgia to North Carolina stock. Recreational fishing

vessels are required to have a descending device on board when fishing for species in the snapper-grouper complex, which includes hogfish.

CONSERVATION RECOMMENDATIONS

- Conduct life history studies across a range of sizes, ages, and stocks to test for differences between hogfish stocks.
- Investigate the contribution of males to spawning reproductive potential.
- Continue to monitor hogfish via fishery-dependent and fishery-independent surveys. Make improvements to existing fishery-independent surveys or develop new surveys to estimate hogfish abundance.
- Obtain length frequency and age samples via a consistent approach that are representative of each fishery and stock.
- Investigate spatial effects (nearshore vs offshore) on hogfish populations (Collins and McBride 2015).

MEASURE OF SUCCESS

The South Carolina Department of Natural Resources Southeast Reef Fish Survey (SERFS) collects data on the relative abundance, population demographics, and reproductive state of reef fish species collected in waters of the continental shelf and shelf edge between Cape Hatteras, North Carolina and St. Lucie, Florida. The SERFS detects hogfish primarily in video camera footage, providing an index of abundance. However, very few physical specimens are brought aboard research vessels, so population demographics and reproductive state are not currently assessed for the species. A measure of success would be for the video index of abundance to remain stable or increase in the region.

King Mackerel

Scomberomorus cavalla

Source: SAFMC

Contributors:
Joseph Cowan (SCDNR) & Pearse Webster (SCDNR)

Revised 2025:
Elizabeth Bullard and Tracey Smart [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

King mackerel, *Scomberomorus cavalla* (Cuvier 1829), are members of the Scombridae family, which includes a variety of mackerel, tuna, wahoo, and bonito, and the order Scombriformes (Page et al. 2023). The King mackerel is one of the three species in the Scomberomorini tribe (in addition to Atlantic Spanish mackerel and wahoo) that is frequently encountered off the coast of South Carolina (SC; Collette and Nauen 1983).

King mackerel have muscular, laterally compressed, fusiform bodies. Their body is tapered posteriorly, ending in a thin caudal peduncle, and they bare a powerful lunate tail. Two dorsal fins are followed by 7 to 10 small finlets, and the ventral side shows 7 to 10 small finlets also following the anal fin (Collette 2002). The body color is typically a dark blue to black dorsally with iridescent spots of a blue/green and a silver ventral side. Juveniles have yellow spots which fade as the fish ages, disappearing completely by maturity. These spots can cause juveniles to be mistaken for Spanish mackerel. However, the lateral line of king mackerel drops sharply towards the abdomen under the second dorsal fin jaw (Collette 2002), which allows for easy identification from Spanish mackerel who have a more gradual drop in the lateral line. King mackerel reach sexual maturity at 3-4 years, are gonochoristic (separate sexes), and can live more than 20 years. Maximum sizes can reach 6 ft and near 100 pounds (Finucane et al. 1986).

Status

The International Union for the Conservation of Nature (IUCN) lists king mackerel as a species of Least Concern. King mackerel had their last full assessment through the SouthEast Data, Assessment and Review (SEDAR) process in 2014, and SEDAR 38 was then updated in 2019. At that time, king mackerels were found to be not overfished nor undergoing overfishing.

POPULATION SIZE AND DISTRIBUTION

In the northwest Atlantic, king mackerel range along the US Atlantic coast, throughout the Gulf of Mexico and the Caribbean, and extend south into the coastal waters of Brazil (Godcharles and Murphy 1983). Large aggregations can be found off the coast of North

and South Carolina beginning in the late spring and continuing through the fall (Collette and Nauen 1983) as they typically occupy areas north of Florida during the warmer months of the year. Two separate migratory stocks are recognized between the Atlantic and Gulf of Mexico (GOM, Figure 1; SEDAR 2020). Although these migratory groups are managed separately, there is evidence of a winter mixing zone off Florida of these two stocks (Banks 2024).

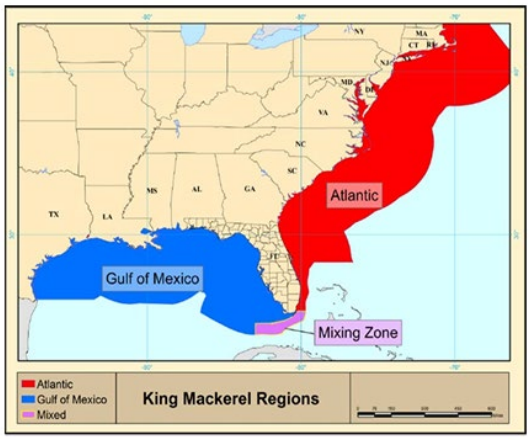

Figure 1: Map of king mackerel distribution through the stock boundaries, separating the Gulf of Mexico and Atlantic stocks while denoting a mixing zone between the two regions.

An estimate of absolute king mackerel population size in South Carolina waters is not currently available, but data reported from recreational and commercial fishing efforts on the Atlantic migratory group show a decrease in the number of pounds of king mackerel landed over the last decade commercially and recreationally (Figures 2 and 3; SAFMC 2018), continuing a decline that began in 1990 (NMFS 2014). The Coastal Trawl Survey (CTS) for the South Carolina Department of Natural Resources (SCDNR), a fishery-independent survey, encounters juvenile mackerel. The survey exhibits a high degree of interannual variability in abundance with a drop in catch per unit effort over the last 8 years (Figure 4).

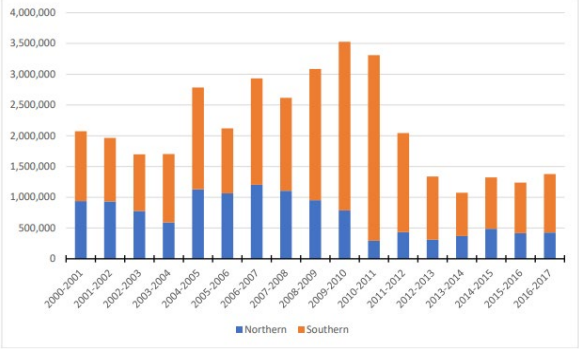

Figure 2: Commercial landings (pounds) of king mackerel from 2000-2017 separated by the northern and southern zone of the Atlantic migratory group (SAFMC 2018).

Commented [JB1]: Need to include a figure showing this!

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

King mackerel are epipelagic carnivores that inhabit offshore waters out to the continental shelf, but have been noted occurring closer to shore near inlets as well (Berrien and Finan 1977). They most often occupy waters with temperatures of 79-88°F. They prey on schooling finfish such as menhaden and anchovies, as well as invertebrates (Godcharles and Murphy 1986).

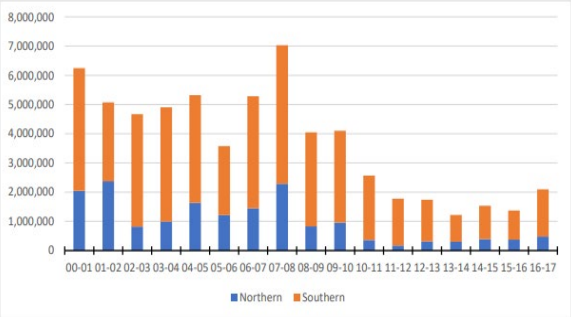

Figure 3: Recreational landings (pounds) of king mackerel from 2000-2017 separated by the northern and southern zone of the Atlantic migratory group (SAFMC 2018).

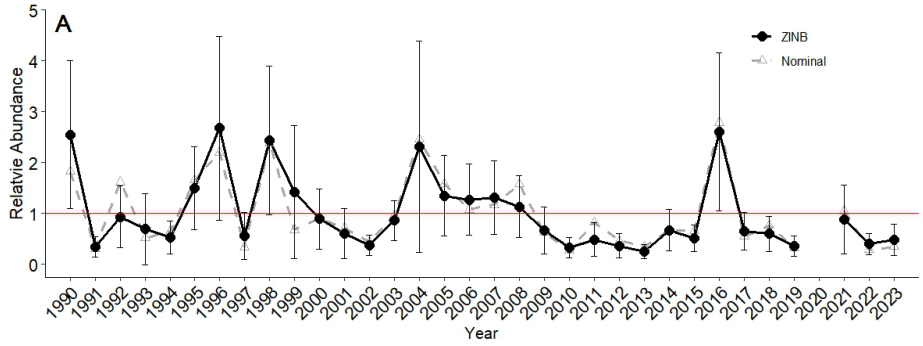

Figure 4: Nominal and ZINB standardized relative abundance of king mackerel normalized to the time series mean of the SEAMAP-SA Coastal Trawl Survey. Errors bars are representative of standard error.

Spawning occurs in coastal waters of the Southeast Atlantic and Gulf, with larvae being pelagic and found in the outer shelf region at depths of 41-200 meters (Finucane, et al. 1986). A concentration of larvae has been observed in the 32-33 degree latitudes in the vicinity of the Charleston Bump, suggesting the upwelling created by this geologic feature provides an important spawning and nursery habit for these fish (Collins and Stender 1987).

CHALLENGES

King mackerel remains a popular commercial and recreational fish and subsequently are certain to experience continued fishing pressure from both sources. SAMFC does not currently consider the Atlantic population to be overfished. However, the council also acknowledged the absence of fishery-independent monitoring data for adults of this species as a substantial challenge not only to determine appropriate management practices, but also to establish meaningful future population benchmarks for stock assessment (SEDAR 2009). Lucena-Frédou et al. (2021) expanded upon these gaps in information and knowledge for the species, discussing that more quantitative data is needed to evaluate populations successfully. It is thought that in recent years the number of recreational landings reported are severely underestimated in the Atlantic (Pons et al. 2019) and applying more quantitative data (such as length-based methods)

as a proxy for king mackerel stock status (ICCAT Manual 2021) could help to increase confidence in stock numbers.

With a separation of migratory groups, it is also vital to denote that the priorities of one group may not match that of another. Historically, the GOM population had been exploited at a higher rate than the Atlantic population with catch routinely exceeding limits (Banks 2024). Further evaluation of how these stocks function separately, and how certain environmental conditions may influence them individually and within the mixing zone, must be considered. Climatic conditions can result in these stocks increasing their overlap within the mixing zone or change the seasonality of mixing and therefore result in greater competition for resources and consequently enhanced competitive pressure on both stocks.

CONSERVATION ACCOMPLISHMENTS

The Fishery Management Plan for Coastal Migratory Pelagic Resources has developed substantially throughout its history and has been amended many times since its introduction in 1982 (FMP 1983). The introduction of permits for fishing, quota limits, size restrictions, landing limits, and mandatory reporting of commercial catches have all contributed to the beneficial management of king mackerel. Allowable Catch Limits (ACLs) have been set for both commercial and recreational sectors, and seasonal restrictions reduces potential impacts on mating and spawning fish. Geographic management boundaries have also been expanding to include as many members of the stock in management efforts as possible. Conservation efforts have also focused on the identification and protection of essential fish habitat throughout the coast with the goal of enhancing recruitment of juvenile fish into the stock.

CONSERVATION RECOMMENDATIONS

- Continue monitoring of commercial and recreational catches of king mackerel coupled with appropriately set ACLs that are maintained through enforceable regulation.
- Evaluate and update the effects of fishing and management plans on king mackerel stocks collectively and separately to determine where focus should be prioritized.
- Expand research and life history data collection from fishery-independent sources, particularly for adult fish which are rarely caught in current fishery-independent monitoring efforts and continue recruitment monitoring, which can be variable from year to year.
- Enhance research efforts focused on king mackerel diet.
- Further investigation of migratory patterns through tagging and otolith micro-chemistry to better define Atlantic and Gulf stock boundaries as well as the area of seasonal overlap.

MEASURE OF SUCCESS

The SEAMAP-SA Coastal Trawl Survey program monitors the relative abundance, population demographics, and reproductive characteristics of the Atlantic population of king mackerel, though they primarily encounter juveniles. Studying these metrics can help to detect when changes in these parameters occur relative to fishing pressures or current management efforts and can serve as early indicators of issues with the Atlantic stock. Utilizing sufficient fishery-independent data can help to generate stock estimates with more confidence. Increases in recruitment and abundance, expansion of size and age structures, and increases in spawning stock biomass (SSB) would indicate positive trends in the population. Ideally, stock structure would improve to a point where calculations of maximum sustainable yield (*MSY*) result in total allowable catch (*TAC*) levels that can accommodate demand for commercial and recreational harvest.

Lemon Shark

Negaprion brevirostris

Contributor (2025):
Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The lemon shark, *Negaprion brevirostris* is a member of the family Carcharhinidae and resides in the genus *Negaprion* (2 species). The lemon shark is a placentally viviparous shark (bears live young with a maternal connection). They are relatively large sharks reaching a reported maximum length of 284 cm TL (Castro 2011). The lemon shark is recognized by its pale yellow to olive gray coloring, blunt snout, equal sized first and second dorsal fins, and no inter-dorsal ridge. Life history information is lacking for lemon sharks, but they are generally thought to be slow growing and long lived. Male and female lemon sharks are thought to reach maturity around 12 to 13 years old at a length of 225 to 235 cm (89-93 in.) TL (Brown and Gruber 1988). Once mature, lemon sharks give birth to litters of 4-17 pups every 2 years (Gruber and Stout 1983; Feldheim et al. 2002). Maximum age is estimated as 20+ years old, however genetic data suggest a maximum age of 37 years (Brooks et al. 2016).

Status

Lemon sharks are classified as large coastal sharks (LCS) and are managed as a complex by the National Marine Fisheries Service (NMFS). Status determination for LCS is hampered by a lack of species specific data. The population of lemon sharks in the southeastern US were assessed independently (apart from the SEDAR process) by Hansell et al. (2021). Results of that assessment suggested there had been prior population depletion, but that the stock had been relatively stable since the mid-1990's. In early years, there had been overfishing occurring, but the conclusion was that in the most recent years the stock was not undergoing overfishing and was not overfished. The International Union for Conservation of Nature (IUCN) lists lemon sharks as "Near Threatened" listing evidence of decreasing populations. Lemon sharks are rarely captured in traditional longline gear, however they are seen in SCDNR trammel nets (primarily young of year), and on drumlines (large juveniles and mature lemon sharks), these catches suggest there are gear biases with traditional shark sampling gear (gillnets and longlines). Catch per unit effort data from the South Carolina Department of Natural Resources Coastal Longline survey suggest stable abundance of lemon sharks in estuarine waters (Figure 1); that said, catches of lemon sharks are low in this survey.

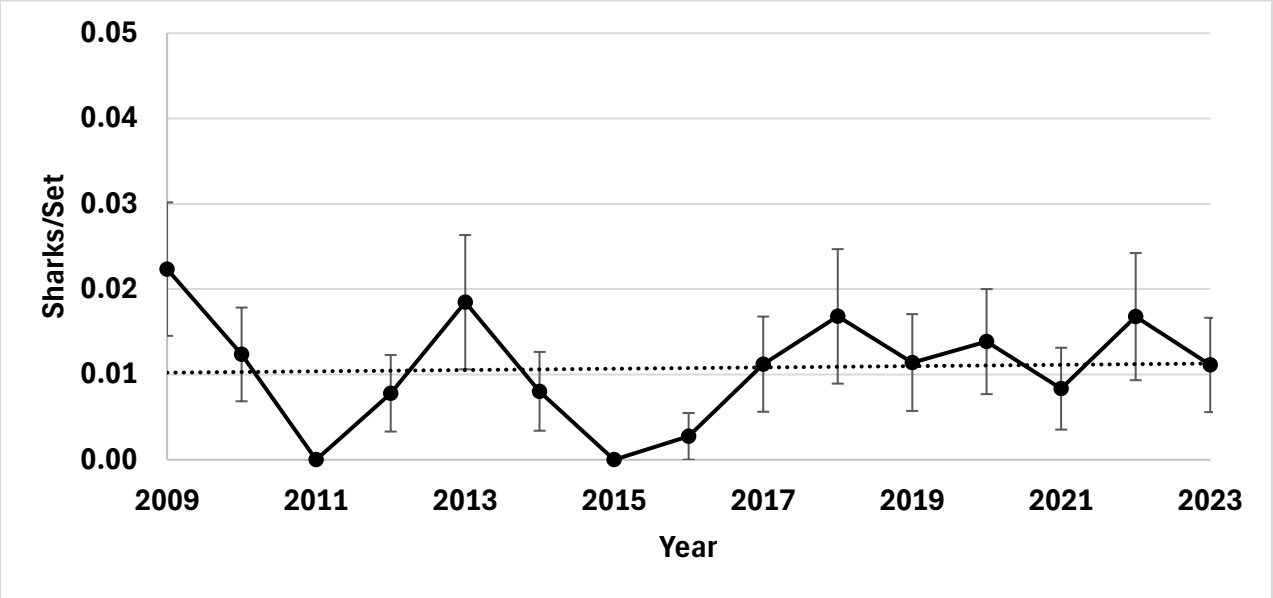

Figure 1. Catch per unit effort (sharks per set) of blacktip sharks from 2009 to 2023 in the South Carolina Coastal Longline Survey. Standard error is denoted by error bars.

POPULATION SIZE AND DISTRIBUTION

Lemon sharks are primarily found in the western Atlantic Ocean, although populations also exist in the eastern Pacific Ocean and the west coast of Africa. It is a coastal species, primarily occurring in shallow water. In US Atlantic waters, they are found from New Jersey south through the Gulf of Mexico with overwintering occurring in south Florida and the Bahamas. South Carolina waters may serve as nursery habitat for lemon sharks; however, young of year are found in lower abundance in South Carolina compared to nurseries in Florida, Georgia, and the Bahamas. All life stages of lemon sharks have been documented and they generally occur in salinities from 20-34 ppt (Ulrich et al. 2007).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Little is known about habitat requirements for lemon sharks as there is significant gear bias that prevents their capture in the numbers that are likely present. That said, young of year and juvenile lemon sharks are often see in shallow water over oyster reefs as well as along sandy front beaches. Large juvenile and adult lemon sharks are found in deeper estuarine waters, as well as at the mouths of sounds and bays. They are infrequently captured in nearshore waters, preferring to stick close to shore. Limited diet data suggest young of year and early juveniles prefer bony fish, while large juveniles and adults switch to a diet of bony fish and elasmobranchs including smaller sharks and stingrays.

CHALLENGES

The primary threat facing lemon sharks is development in critical habitat areas. In core nursery areas, lemon sharks are reliant on mangrove habitat for foraging and shelter from larger predators, In many parts of their range, these habitats are threatened by coastal development. While populations of lemon sharks appear stable threats to these nursery areas could impact these species. Lemon sharks display high site fidelity including natal philopatry, meaning it is pertinent to protect these nursery areas as future generations will return to use them. Management of lemon sharks is also hampered by a lack of life history data, despite being one of the most studied species of sharks in the world, there is a lack of data on reproduction and age and growth of the species, this lack of information undoubtedly hampers management.

CONSERVATION ACCOMPLISHMENTS

There are no conservation accomplishments specific to this species at this time.

CONSERVATION RECOMMENDATIONS

- Continue to monitor the stock status of lemon sharks within SC waters through fishery-independent methods, primarily trammel netting, drumlines and the Coastal Longline Survey.
- Investigate gear biases that may hamper monitoring of lemon shark populations.
- Partner with external collaborators to increase understanding of the life history of species lacking data.
- Use genomic methods to better understand site fidelity of lemon sharks to SC habitats as well as better understand the importance of SC as a nursery for lemon sharks.
- Use genomic methods such as Close Kin Mark Recapture to estimate population size.
- Investigate the use of non-lethal methods to age lemon sharks.
- Improve the public's understanding of the importance of sharks in the ecosystem through outreach activities such as school programs, providing story opportunities for media, and educational brochures.
- Continue to educate the public on the importance of species identification of sharks to ensure undersized and prohibited sharks are not landed.
- The primary action at the state level via law enforcement partnering is to insure adequate compliance with regulatory actions implemented through the federal management plan and subsequent amendments.

MEASURE OF SUCCESS

Regional management efforts to maintain healthy, sustainable populations of lemon sharks will require active participation from South Carolina due to its importance as habitat for all life stages. Expanding our knowledge on the life history and importance of SC waters for lemon sharks is important given potential impacts to nursery areas (especially in the Bahamas). Current population trends appear to be stable, but it is critical to maintain ongoing monitoring programs to generate indices of abundance to allow accurate regional stock assessments.

Hardhead

Gafftopsail

DESCRIPTION

Taxonomy and Basic Description

The marine catfishes, *Ariopsis felis* and *Bagre marinus*, belong to the family Ariidae. They lack scales but possess a forked caudal fin (tail), have an adipose fin anterior of the caudal peduncle, and have large, serrated spines on the three forward-most fins (two pectoral and the first dorsal). The spines can induce a painful injury and are covered in a slime that is mildly venomous (Halstead et al. 1990).

The common name for hardhead catfish is derived from the presence of a hard, bony plate extending rearward toward the dorsal fin from a line between the catfish's eyes.

The head is moderately flattened with the upper jaw forming a broad arc. One thread-like barbel is located on either side of the mouth just above the rear corners, and two pairs of white barbels are located on the chin. The rear dorsal (adipose) fin is fleshy and black, unlike the other fins which are membranous and translucent. The back of the fish is generally silvery with blue, green, or brownish tones, while the belly is generally white. The hardhead catfish has been reported at sizes up to 70 cm (27 inches; Acero 2002) and reaching 24 years of age in the Gulf of Mexico (Flinn et al. 2019), but it is more commonly found at sizes up to 36 cm (14 in.) in South Carolina's coastal waters (P. Webster, pers. obs.).

The gafftopsail catfish, *Bagre marinus*, is readily distinguished from the hardhead by long, thread-like extensions from its dorsal and pectoral fins and more strap-like, rather than rounded, barbels extending from the upper jaw. It has 22-28 anal fin rays and 11-14 pectoral fin rays, compared with 18-20 and 6-10, respectively, in the hardhead catfish. Gafftopsail catfish generally may reach greater lengths than hardhead catfish across both sexes (Flinn et al. 2019).

Status

On occasion, mass mortalities of marine catfish have been observed along the Gulf Coast. There have been no known directed fisheries for marine catfish in South Carolina, but both species have undergone a dramatic decline in numbers since the mid-1990s, and state regulations stipulate that any caught fish must be released alive immediately.

POPULATION SIZE AND DISTRIBUTION

South Carolina is well within the northern limits for the hardhead catfish and the gafftopsail catfish. *A. felis* has a coastal range from North Carolina to Florida and throughout the Gulf of Mexico to the Yucatán Peninsula (Acero, 2002); other sources indicate that the species may range as far north as Cape Cod at times (Jones et al. 1978). *B. marinus* ranges from Cape Cod, Massachusetts south through coastal Florida and the Gulf of Mexico to Panama (Muncy and Wingo 1983). Portnoy et al. 2024 suggests four genetically differentiated groups of the gafftopsail catfish, where three of these groups reside in the Gulf of Mexico and the remaining group represents the Atlantic population.

Hardhead catfish have been prominent in a number of mass mortality incidents in the Gulf of Mexico and appear to be in decline along the Southeastern Atlantic Coast (Wardle et al. 1998; SEAMAP unpub. data). As suggested by trawl surveys, abundance of the hardhead catfish in South Carolina experienced two drastic drops during the 1990s. Additional sampling along the Atlantic Coast of the Southeastern United States indicates that abundance remains depressed from North Carolina to Florida (SEAMAP unpub. data). However, since the decline occurred, sampling of coastal waters from Cape Hatteras, North Carolina, to Cape Canaveral, Florida, indicates that the decline in

abundance is most pronounced in the northern portion of this range. Gafftopsail catfish are generally less abundant than hardhead catfish, but they too have experienced a sharp and persistent decline in abundance (SEAMAP unpublished data). Contrary to the South Carolina population, the Gulf of Mexico population of gafftopsail catfish may be increasing in some areas (Cates et al. 2024).

Despite reduced abundance over the shallow coastal shelf, marine catfish may be encountered by anglers in estuaries, through the surf zone, and into near-coastal waters of the shelf. A true estimate of population size, considering abundance through all of these habitats, has not been calculated.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Marine catfishes are generalists, tolerating a wide range of salinities from open ocean to fresh water; however, their occurrence in fresh waters is less common. They are generally found over muddy bottoms, or at least in murky waters (Acero 2002).

Marine catfishes are mouth-brooders. Once spawning has occurred, the male will carry the eggs in his mouth until they hatch into larvae in about a month. He may then carry the young for a few more weeks until they are larger and stronger (Jones et al. 1978). Marine catfishes produce relatively large eggs and exhibit low fecundity (Merriman 1940; Ward 1957; Jones et al. 1978).

CHALLENGES

Mass mortalities of marine catfish have generally been ascribed to one of three causes: disease (R. Overstreet, USM, pers. comm., June 7, 2005), harmful algal blooms, and/or extremely low levels of dissolved oxygen (hypoxia; Wardle et al. 1998). It is unclear which, if any, of these agents is the cause of the recent declines of hardhead and gafftopsail catfish observed in South Carolina. A simple decline in abundance, as generally seen for these species in the Atlantic, does not tend to garner the immediate attention elicited by the mass mortalities witnessed along the Gulf Coast and in Indian River Lagoon, Florida.

Chemical contamination in the catfishes' environment provides two very different possible threats. Non-point source pollution may contribute to the occurrence of algal blooms, which, depending on the algal variety, may simply cause hypoxic events (Wardle et al. 1998) or may result in the release of deadly toxins (Steidinger et al. 1998). The second threat comes from contaminants accumulated in the muddy sediments with which this fish is associated. Metals, polycyclic aromatic hydrocarbons (PAHs), and pesticides all accumulate in muddy sediments (Sanger et al. 1999a,b) and have been shown to have detrimental effects on benthic creatures exposed to them.

While limited studies have been conducted on the effects of certain compounds on hardhead catfish (Steele 1983a,b), the effects of other pollutants and combination effects are not known. Catfish both live and feed primarily along the bottom, which increases their exposure to contaminants. This challenge is not unique to catfish. Bioaccumulation is a threat to the entire food chain, including humans.

CONSERVATION ACCOMPLISHMENTS

South Carolina state law prohibits the taking of marine catfish in an effort to preserve their declining populations.

CONSERVATION RECOMMENDATIONS

- Examine long-term trends in marine catfish population size and distribution and relate, where possible, to environmental variation.
- Identify causative factors in future marine catfish mortality events.
- Determine if latent pathogens exist in the marine catfish populations. Monitor the population to determine pathogen temporal prevalence and determine whether mortality events are triggered by pathogens themselves or by some other stressor.
- Investigate whether wild saltwater catfish are plagued by similar diseases to their captive freshwater relatives such as: visceral toxicosis, proliferative gill disease and enteric septicemia. If so, determine if effluent from aquaculture operations is a significant threat to the marine catfish.
- Develop the capacity to properly investigate possible harmful algal blooms and monitor for such blooms.
- Determine effects of pollutants on marine catfish reproduction, growth, and longevity.
- Determine marine catfish spawning seasons, spawning locations, and recruitment mechanism for the Atlantic Coast.
- Determine marine catfish predator/prey relationships and examine contaminant loads across these relationships.
- Monitor the effectiveness of existing Best Management Practices (BMPs) such as setbacks, retention ponds, and vegetated buffers for preventing nutrient and contaminant runoff into coastal waters.
- Apply and enforce BMPs, such as those utilized by proactive communities.
- Educate the public about the importance of the marine catfish in terms of ecological value. While these species are not commonly utilized as a food fish and it is generally maligned due to its pain-inducing spines, it does have a role to play in coastal ecosystems.

MEASURE OF SUCCESS

If stressors depressing abundance of marine catfish are identified, it may be possible to halt and reverse the downward trend. One indication of this would be a move toward abundance or density values at least approaching those seen in 1993 through 1995 by the SEAMAP trawl survey off of South Carolina. Future actions proposed to remove stresses on marine catfish will likely benefit other benthic organisms as well and thus could be quite valuable from an ecological and even a human health perspective.

Mobulid Guild

Giant Oceanic Manta Ray *Mobula birostris*
Lesser Devil Ray *Mobula hypostoma*
Devish Fish *Mobula mobular*

Contributors:
James Kilfoil and Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The giant oceanic manta ray (*Mobula birostris*), lesser devil ray (*Mobula hypostoma*), and devil fish (*Mobula mobular*) are members of the mobulidae family and reside in the genus *Mobula* (11 species), encompassing both manta and devil rays, and consists mostly of large species living in the open ocean rather than on the sea bottom.

Manta rays are easily recognized by their large, diamond-shaped bodies, elongated wing-like pectoral fins, gill slits positioned on their ventral sides, eyes on their lateral sides, and broad, terminal mouths. Unique among vertebrates, they have cephalic lobes located in front of their mouths that help channel water during feeding.

Giant oceanic manta ray

© NOAA/George Schmah

The giant oceanic manta ray is potentially the largest ray species, reaching a disc width (DW) of up to 700 cm, with some anecdotal evidence suggesting sizes up to 910 cm (Compagno, 1999; Alava et al., 2002). These rays are typically larger than their reef counterparts, characterized by a caudal thorn, rough skin, and distinct coloration patterns. Male giant oceanic manta rays mature at a disc width of 350–400 cm, while females mature at 380–500 cm (White et al., 2006; Last et al., 2016; Stevens et al., 2018). Their reproductive method is aplacental viviparous, meaning they give birth to a single large pup measuring 122–200 cm DW (White et al., 2006; Rambahiniarison et al., 2018). Though the exact reproductive cycle is unknown, it is estimated to be 4–5 years, similar to the closely related reef manta ray (*M. alfredi*). Females reach maturity around 8.6 years of age, but their first pregnancy might be delayed until 12 years due to food availability (Rambahiniarison et al., 2018). With a potential lifespan of up to 45 years, giant

oceanic manta rays have a generation length of approximately 29 years. They have a notably low reproductive rate, producing only 4–7 pups over their lifetime, which hinders their population recovery from over-exploitation and other threats (Dulvy et al., 2014).

Lesser devil ray

The lesser devil ray can grow up to 120 cm in disc width (DW), with some reports indicating sizes up to 230 cm DW in Venezuela (Ehemann et al., 2017). Males reach maturity at 114 cm DW, while females mature at 111 cm DW (McEachran and Carvalho, 2002). Their reproductive process is aplacental viviparous, typically producing a single pup ranging from 55 to 97 cm DW at birth (McEachran and Carvalho, 2002; Ehemann et al., 2017). Similar to other species in the mobulid family, lesser devil rays may have resting periods of 1–3 years between pregnancies (Marshall and Bennett, 2010; Deakos, 2011; Stevens, 2016). Although the precise age-at-maturity and maximum lifespan for lesser devil rays are not well-documented, they are estimated based on the spinetail devil ray (Mobula mobular), which matures at 5–6 years and can live up to 20 years (Cuevas-Zimbron et al., 2013; Pardo et al., 2016). This leads to a presumed generation length of about 12.8 years. However, since the spinetail devil ray grows considerably larger (520 cm DW) than the lesser devil ray (120 cm DW), this generation length may be overestimated.

Devil fish

The devil fish (Mobula mobular) is a large pelagic species, reaching up to 350 cm disc width (DW), and inhabits tropical and subtropical waters globally, from the surface to depths of 1,112 meters. This species is found in temperate and tropical waters across all oceans, with notable presence in the Mediterranean Sea, though it is absent from the Red Sea (Notarbartolo-di-Sciara, 1987; Notarbartolo di Sciara et al., 2017). Its distribution is sporadic, with patchy occurrences throughout its range (Lawson et al., 2017).

The devil fish grows to a maximum size of 350 cm DW, with significant geographical size variations (Notarbartolo di Sciara et al., 2020). Males reach maturity at 200–220 cm DW, while females mature at 215–240 cm DW. They reproduce aplacental matrotrophically, with a gestation period of 12 months, typically birthing a single large pup, though occasionally two pups per litter are born. The pups measure 90–160 cm DW at birth. The reproductive cycle ranges from 1 to 3 years, with some resting periods between pregnancies (White et al., 2006; Last et al., 2016; Rambahiniarison et al., 2018; Stevens et al., 2018). Females reach maturity at approximately 5–6 years of age, with a maximum lifespan estimated at 20 years, leading to a generation length of about 12.8 years (Cuevas-Zimbron et al., 2013; Pardo et al., 2016)

Status

Global status for three species are listed as "Endangered" by the IUCN Redlist, with population trends in decline. In 2018 NOAA Fisheries listed the giant oceanic manta ray as threatened.

POPULATION SIZE AND DISTRIBUTION

The giant oceanic manta ray is found circumglobally in tropical and temperate waters, inhabiting depths from the surface down to 1,000 meters (Last et al., 2016). They are distributed throughout the Pacific, Indian, and Atlantic Oceans in both coastal and pelagic waters. The global population size of the giant oceanic manta ray is not well-known, but local and regional populations have been estimated, generally numbering fewer than 500 individuals, with the exception of Ecuador, where the population is estimated to exceed 2,000 individuals. Population trends for the giant oceanic manta ray vary significantly across their range. In regions where they are protected, such as Hawaii (Ward-Paige et al., 2013) and Ecuador (Holmberg and Marshall, 2018), populations appear stable. However, in Ecuador, these rays migrate seasonally to Peru, where they face directed fishing pressures (Heinrichs et al., 2011). In areas where the species is frequently targeted or caught as bycatch, populations are likely declining. Globally, it is estimated that the population has decreased by 50–79% over three generations (approximately 87 years), with further declines anticipated over the next three generations (2018–2105) due to ongoing threats, exploitation, and reductions in their area of occupancy. In areas where manta rays are protected, their populations remain stable (Marshall et al. 2022a).

The lesser devil ray is endemic to the Atlantic Ocean, displaying a patchy distribution. In the Western Atlantic, it is found from North Carolina in the United States down to Argentina, while in the Eastern Atlantic, its range extends from Western Sahara to Angola (Mas et al., 2015; Last et al., 2016; Stevens et al., 2018).

This species is now absent from many areas that were once part of its historical range, with notably few sightings in countries such as Brazil. Genus-wide data indicate that populations of devil rays, including the lesser devil ray, have experienced significant declines of 51 to 94% over 10- to 15-year periods (~one generation length) in areas with intense fishing pressure. Similar declines are likely in West Africa due to comparable fishing pressures. An exception to these declines is observed along the east coast of the United States. From 1989 to 2005, the Southeast Area Monitoring and Assessment Program research trawl surveys recorded the lesser devil ray in 15 out of 17 survey years (n = 113). This suggests an estimated instantaneous rate of change of 0.105 (95% CI: 0.037–0.173), indicating a population increase in this region (Bizzarro et al., 2009).

The devil fish inhabits temperate and tropical waters globally, present in the Mediterranean Sea but notably absent from the Red Sea (Notarbartolo-di-Sciara, 1987; Notarbartolo di Sciara et al., 2017). Its distribution is uneven across its range (Lawson et al., 2017). There are no comprehensive estimates of the global population of the devil fish. Despite its extensive distribution, populations are sporadically distributed and vary greatly, likely influenced by food availability and fishing pressures (Marshall et al. 2022c). This species is often solitary but can gather in large groups for feeding or reproduction. In some regions, such as the northwest Mediterranean Sea, aerial surveys have estimated populations of up to 12,700 individuals (Fortuna et al., 2014; Notarbartolo di Sciara et al., 2015). In most areas, devil fish populations are declining due to targeted fishing and bycatch. These declines are inferred from decreased landings or sightings despite increased fishing efforts (Couturier et al., 2012; Ward-Paige et al., 2013; Croll et al., 2016). Reports from fishers and traders suggest that devil ray gill plates are becoming scarcer, driving up prices as supplies dwindle (O'Malley et al., 2017). Regional extinctions are suspected in areas with high fishing pressures (Lewis et al., 2015). However, in regions such as Australia, New Zealand, and some Pacific countries, the threat level is likely lower due to reduced fishing pressure and effective fisheries management in the former two countries (Marshall et al. 2022c)

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Although the giant oceanic manta ray is typically solitary, it congregates at cleaning stations and during feeding and mating events. Their diet mainly consists of planktonic organisms like euphausiids, copepods, mysids, decapod larvae, and shrimp, though they have also been observed consuming small to moderately sized fish. The giant oceanic manta ray demonstrates significant flexibility in its use of habitat depths. While they often feed in shallow waters less than 10 meters deep, tagging studies have shown that they can dive between 200 and 450 meters, and occasionally even deeper than 1,000 meters. This diving behavior is thought to be influenced by seasonal changes and shifts in prey location associated with the thermocline. These rays are found worldwide in tropical, subtropical, and temperate waters. They typically inhabit offshore oceanic regions and productive coastal areas but can also be seen in estuaries,

oceanic inlets, bays, and intercoastal waterways. They can tolerate cooler waters down to 19°C, with regional temperature preferences. For example, off the U.S. East Coast, they are frequently found in waters ranging from 19 to 22°C, while in regions like the Yucatan Peninsula and Indonesia, they prefer warmer waters between 25 and 30°C

The lesser devil ray is a pelagic species that inhabits coastal and oceanic waters, typically found from the surface to depths of 100 meters (Robbins et al., 1986; McEachran and Carvalho, 2002; Wiegmann, 2016). These rays often form schools, which can include up to 40 individuals, though they more commonly occur in smaller groups of 2 to 10. They primarily feed on zooplankton, including small crustaceans, but may occasionally consume schooling fish. They use their cephalic lobes to funnel prey into their mouth (source needed for feeding behavior details).

The devil fish is a pelagic species that primarily inhabits coastal and continental shelf waters. While it spends most of its time in waters shallower than 50 meters, it occasionally dives to depths of up to 1,112 meters (Canese et al., 2011; Croll et al., 2012; Holcer et al., 2013; Francis and Jones, 2017). This species demonstrates extensive movements, traveling up to 1,800 kilometers at minimum speeds of 63 kilometers per day, likely driven by seasonal prey availability (Freund et al., 2000; Canese et al., 2011; Croll et al., 2012; Francis and Jones, 2017).

CHALLENGES

Mobulids face significant threats from both targeted and incidental capture in various types of fisheries, including both industrial and artisanal operations (Couturier et al., 2012; Croll et al., 2016; Stewart et al., 2018). They are caught using an array of fishing gear, such as harpoons, drift nets, purse seines, gill nets, traps, trawls, and longlines. Their wide-ranging coastal and offshore habitats, combined with their tendency to form aggregations, make them highly susceptible to bycatch in purse seine and longline fisheries, as well as targeted capture in artisanal fisheries (Croll et al., 2016; Duffy and Griffiths, 2017). Their large size, slow swimming speed, and predictable patterns of habitat use further increase their vulnerability. These fisheries often meet the demand for gill plates in international markets, though some still focus on local use (White et al., 2006; Essumang, 2010; Rohner et al., 2017).

In addition to targeted capture, Mobulids are also caught incidentally as bycatch in at least 21 small-scale fisheries across 15 countries and nine large-scale fisheries in 11 countries (Croll et al., 2016). Even when caught unintentionally, their high market value often leads to them being retained. Those that are released alive frequently suffer from injuries and have high post-release mortality rates (Tremblay-Boyer and Brouwer, 2016; Francis and Jones, 2017).

While fishing remains the primary cause of population declines, other threats exist including entanglement in fishing gear, accidental hooking by recreational fishers, vessel strikes, and potential impacts from climate change, ocean acidification, oil spills, and pollution (Marshall and Bennett, 2010; Deakos et al., 2011; Couturier et al., 2012; Stewart et al., 2018). Additionally, the loss and degradation of shallow water lagoon habitats pose risks to juvenile rays (Stewart et al., 2018).

CONSERVATION ACCOMPLISHMENTS

In 2018, NOAA Fisheries listed giant oceanic manta rays under the Endangered Species Act. This species is further protected in over a dozen countries and territories (Lawson et al., 2017; Lawson and Fordham, 2018; Booth et al., 2020). All three species have been listed on Appendix I and II of Convention for the Conservation of Migrator species of Wild Animals (CMS). Mobula Species were listed on Appedix II of the Convetional on International Trade in Endageared Species (CITES) in 2016. In 2015, the Inter-American Tropical Tuna Commission prohibited Mobula species caught by large-scale fisheries in their Conventional Area form being retained or sold (whole or in part), requiring them to be released alive (Lawson et al., 2017; Lawson and Fordham, 2018).

CONSERVATION RECOMMENDATIONS

To facilitate the recovery of mobulid populations, it is recommended that landings of these species be banned, in accordance with various international agreements, for as long as their global numbers remain under threat. Furthermore, it is essential to enhance the collection and reporting of data on catches and discards. Additionally, implementing regional and national catch limits based on scientific recommendations or the precautionary principle, reducing bycatch mortality, establishing protocols for the safe release of caught individuals, and adopting codes of conduct for responsible tourism are crucial. Furthermore, it is important to fully enforce commitments made through international treaties. For more comprehensive guidance on priority conservation actions, refer to the IUCN SSG Global Devil and Manta Ray Conservation Strategy (Lawson et al., 2017).

MEASURE OF SUCCESS

- Reduced bycatch with and unwanted interactions with fisheries
- Reducing post-release mortality through gear modifications and establishment of safe handling and release practices
- Establishing population estimates and monitoring programs throughout distribution
- Understanding drivers of spatiotemporal patterns to reduce bycatch and identify critical habitat areas

DESCRIPTION

Taxonomy and Basic Description

The mummichog belongs to a group of fishes known as killifish, which are members of the family Cyprinodontidae. The mummichog was described by Linnaeus in 1766 as *Corbitis heteroclita*. He soon after created a new name for the species, *Fundulus heteroclitius*, which remains as the accepted nomenclature today. It is also thought that different "forms" of this species may exist. For example, *Fundulus heteroclitus macrolepidotus* is considered by some to be a northern form of the species that is distinguished from *F. heteroclitius heteroclitius* by egg structure and spawning behavior. The word "mummichog" comes from a Native American word meaning "going in crowds" and refers to its common schooling behavior.

The mummichog is a sexually dimorphic fish. Breeding males are easily distinguished from females by their more brilliant, intense pigmentation. Males also display vertical bars along the sides which the females lack. Females, in general, tend to be much paler than males. Very small fish of both sexes show dark transverse bars on their sides which are later lost. This species can vary in shade based on background surroundings (Bigelow and Schroeder 1953).

The mummichog is an omnivore, feeding on plant matter, small crustaceans, small mollusks, and fish. Adults are reported to reach sizes as large as 17.8 cm (7 in) with females growing larger than males. The mummichog is oviparous. Spawning takes place during the summer months during the new and full moon. Eggs are sticky, about 2 mm (0.08 in) in diameter, and sink after being spawned. Eggs then cling to the insides of mussel shells, oyster shells, and on vegetation. The eggs can develop out of water and typically hatch in 9 to 18 days after being submerged again in water during the following high tide. At 20 mm (0.8 in) the fry are fully developed and resemble adults (Bigelow and Schroeder 1953).

Status

The mummichog is not a state or federally listed species; however, is an extremely important food source for many larger fish as well as wading and sea birds. It is harvested commercially as bait and, because of its hardiness, is a favorite for biological experimentation and education. The species is also used as an indicator species in severely polluted systems and is sometimes the only species found in these areas. Significant levels of cancer and precancerous lesions have been found in the livers of small mummichogs. Scientists have correlated these to high levels of PAH in the mud associated with the wood preservative creosote (The Elizabeth River Project). Mummichogs have been known to consume as many as 2,000 mosquito larvae a day and can be used as a natural mosquito control in ponds and ditches.

POPULATION SIZE AND DISTRIBUTION

Mummichogs occur from the Gulf of St. Lawrence along the Atlantic Coast south to the Gulf coast of Texas. The mummichog has reportedly been introduced into Hawaii, the Philippines, Portugal, and Spain. It was also introduced to ponds in New Hampshire via bait bucket release and was later collected from the upper Ohio and Beaver River systems in far western Pennsylvania (Froese and Pauly 2004; Richart and Incze 2004; Fuller 2004).

The species is present year-round in South Carolina and is abundant in the state's estuaries and tidal creeks. One of the earliest records of the mummichog in South Carolina was collected on January 11, 1891, from the Ashley River (Anonymous 2001). Very little scientific information exists on abundance and distribution; however, it is assumed to be an abundant species. Cain and Dean (1976) sampled a high salinity creek in South Carolina and found mummichogs to be the most abundant (29.7%) species in their samples. The SCDNR electrofishing survey, that began in 2001 and continues to the present, has captured mummichogs in low salinity waters (<10 ppt) in each of the estuaries sampled along the coast (Winyah Bay system, Charleston Harbor system, ACE Basin system), with mummichogs representing the 6th most abundant species.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The mummichog is a benthopelagic, eurohaline species. They are commonly found in saltwater marshes, tidal creeks and in sheltered shores. The fish's upper salinity limit is reported to be 106 to 120.3 parts per thousand (ppt) (Abraham 1985). However, it is also reported that mummichogs living in Chesapeake Bay prefer to live in freshwater. This is an extremely tolerant species that can survive at very low oxygen levels and in heavily polluted ecosystems. It can also withstand temperatures as warm as 34^{o}C (93°F) and temperature fluctuations from 6^{o}C to 35^{o}C (43°F to 95°F). Because of the

hardiness of the mummichog, no specific critical habitats have been established. During cold weather months, mummichogs burrow into the mud to depths up to 20.3 cm (8 in.) to avoid freezing temperatures. In other cases, they may move to deep channels (Bigelow and Schroeder 1953).

CHALLENGES

In South Carolina, there is a commercial bait fishery that targets mummichogs. For a license fee of $25, an individual may have up to 50 pots with the option to pay $1 extra for each pot over 50. Another $25 license is required for the sale of mummichogs as bait. As of January 2010, commercial minnow trap license holders are also required to report monthly to the SCDNR on their catch and fishing effort. In January 2013, there had been 15 minnow trap licenses purchased for the 2013 fiscal year. Since reporting began in 2010, between 9,979-10,750 kg (22,000-23,700 lbs.) of mummichogs have been harvested; over half of this catch has come from creeks between James Island and Folly Beach (Charleston County) (Brad Floyd pers. Comm.). The gregarious nature of the mummichog makes it vulnerable to localized population depletion if heavily fished repeatedly in the same areas. More information on the impacts of localized population depletions due to harvest would be beneficial in describing potential ecological implications of mummichog removal (SCDNR final report).

CONSERVATION ACCOMPLISHMENTS

The mummichog bait industry is currently regulated through license sales and reporting requirements in South Carolina.

CONSERVATION RECOMMENDATIONS

- Continue to examine the mummichog bait fishery in South Carolina to collect fishery dependent data on catch and effort.
- Examine ways to use mummichog as an indicator species for water quality in South Carolina.
- Determine mummichog relative abundance and distribution in coastal waters.
- Track mummichog population trends including localized depletions related to harvesting for bait.

MEASURES OF SUCCESS

By implementing a monitoring protocol for mummichog in South Carolina, SCDNR will be able to infer water quality which, in turn, will benefit all marine life. Another measurement of success would be to document whether localized depletions of mummichog occur due to bait harvest.

Mutton Snapper

Lutjanus analis

Contributors:
C. Michelle Willis (SCDNR) & Julie L. Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Mutton Snapper are a large member of the family Lutjanidae found within the order Perciformes (Page et al. 2023). Their bright, distinctive coloration makes the species easy to identify. The back and upper half of their deep, laterally compressed body is olive green, while the body and fins on the lower half is red. A bright blue line is beneath the eye and other blue lines might be visible on the face. A distinct, small black spot can be seen under the dorsal fin and above the lateral line about midway down the body.

Mutton Snapper are gonochoristic, remaining the same sex from birth to end of life which may extend to 40 years of age. Little is understood about their reproductive strategy, but the species has been reported to congregate in large (tens of thousands) spawning aggregations, specifically in the Dry Tortugas National Park at Riley's Hump (Feeley, 2018; Domeier, 2004; O'Hop et al., 2015). While spawning may occur throughout the year, the primary spawning season for Mutton Snapper is between April and July. At approximately 15 inches total length (TL) and 2.85 years old, 50% of females are mature (SEDAR, 2023).

Status

Currently, the species is managed by the South Atlantic Fishery Management Council for the southeastern U.S. region (SAFMC 2023). As of the last SEDAR stock assessment, which included data through 2013, Mutton Snapper was not overfished nor was it undergoing overfishing (SEDAR 2015). A new stock assessment is under way, but results are not finalized as of this writing. Small numbers of Mutton Snapper are landed in South Carolina each year. Currently this species is not managed with any seasonal spawning closures, however fishing on some known spawning grounds is prohibited inside a special management zone (SMZ).

Worldwide, the species is listed as Near Threatened by ICUN as of October 2015.

POPULATION SIZE AND DISTRIBUTION

Mutton Snapper can be found in the western Atlantic Ocean from Massachusetts to southeastern Brazil, and in the Caribbean (Carson et al. 2011). Historically,

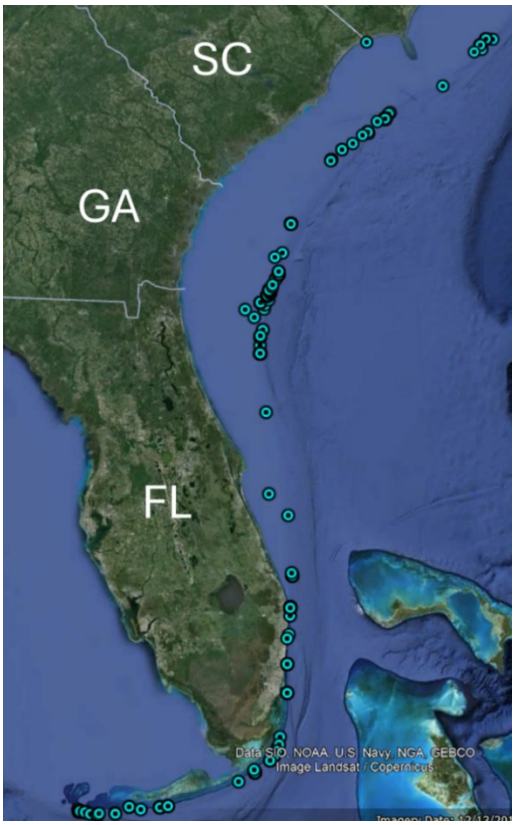

Figure 1: Mutton Snapper catch locations by SERFS and SADLS surveys from 1995-2023.

concentrations have been most dense off the eastern coast of Florida at Cape Canaveral and the Florida Keys, as seen in recreational landings data (Burton, 2002). Population size off South Carolina is unknown, however hook-and-line or longline efforts associated with the Southeast Reef Fish Survey (SERFS) and the cooperative South Atlantic Deepwater Longline Survey (SADLS) regularly encounter the species (Figure 1).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Mutton Snapper, like most reef fish, spend the first few weeks of life as planktonic larvae where challenges include starvation, predation, and movement away from appropriate settlement habitat (Houde, 1987, D'Alessandro et al., 2010). In the post-larval phase, juvenile Mutton Snapper settle onto seagrass beds and mangroves in Florida, but there is little published on juvenile settlement and habitat off the South Carolina coast (Burton, 2002). As they grow, Mutton Snapper move offshore and dwell on hard bottom habitats, coral reefs, ledges and rocky outcrops (Burton, 2002). In these environments, they serve as top predators, consuming smaller fish and invertebrates.

CHALLENGES

The challenges to achieving a sustainable Mutton Snapper population that support the commercial and recreational industries are similar to those of other reef fish species. Lack of data in the northern reaches of their distribution range makes it difficult to understand the status of the population. Slow growth and long lifespan make the species less resilient to disturbances than other community members. The species is also part of a reef fish complex that inhabits similar areas as other reef fishes and is pursued by multi-species fisheries. This means that post-release mortality, including barotrauma, may be an issue for the species.

CONSERVATION ACCOMPLISHMENTS

The SEDAR 15A update in 2015 determined the stock was not overfished or undergoing overfishing. However, analysts noted the stock was likely to be sensitive to fishing

pressure in the future. SEDAR 79 is currently ongoing and results of the assessment were not available at the time this document was compiled.

CONSERVATION RECOMMENDATIONS

Like other species in the snapper-grouper management complex, more data is the greatest need when considering best approach for species conservation.

Specific recommendations include:

- data collection focused on smaller individuals/juveniles in the population and primary habitat used in early life stages,
- focused effort on understanding seasonal migration patterns,
- increased dockside sampling and monitoring to improve data for areas and depths fished, as well as fishing effort employed, and
- focused effort on obtaining data about discard rates and discard mortality in both recreational and commercial sectors.

MEASURE OF SUCCESS

Because there is currently no fishery-independent measure of population size or trends off the South Carolina coast, fishery catch is the only available measure of success. If the hybrid SADLS project continues to produce the highest consistent abundance of Mutton Snapper for the region, then a stable population size and age structure would be a measure of success for fisheries management in the region.

Night Shark

Carcharhinus signatus

Photo: shark-references.com

Contributors:
Liz Vinyard (SCDNR) and Bryan Frazier (SCDNR)

Photo: Ashley Galloway

DESCRIPTION

Taxonomy and Basic Description

Night sharks are a slender, medium-sized species with an interdorsal ridge and distinctive large, green eyes. The first dorsal fin is small and originates over or behind the free rear tip of the pectoral fins. Body color is brownish to blueish gray above which fades to grayish white below, and the nose is long and pointed. The common name is thought to be a translation of the name Cuban fishermen gave the shark, *tiburon de noche*, which references the tendency to only catch them at night (Castro, 2011).

Photo: Ashley Galloway

Most sharks encountered are under 275 cm total length (TL), and maximum length is likely around 300 cm TL (Castro, 2011). While observed maximum ages determined by vertebral counts was 17 years old, back calculated ages using catch data indicated night sharks may live 31+ years (Santana and Lessa, 2004). Currently age and growth has only be studied in the southwestern Atlantic which reports life history parameters corresponding to slow to moderate growth rates (Santana and Lessa, 2004).

Females are thought to mature around 10 years old and size at maturity likely falls between 200 – 205 cm TL (Hazin et al., 2000; Santana and Lessa, 2004). Males are thought to reach maturity slightly younger at 8 years, corresponding to a size at maturity between 185 – 190 cm TL (Hazin et al., 2000; Santana and Lessa, 2004).

Like many Carcharhinids, they are viviparous placental giving birth to live young with a biennial reproductive cycle and a gestation period around 12 months. Gonadosomatic index values suggest copulation occurs during summer, and due to remarkable variability in embryo sizes collected from February to June, it is possible they have a

protracted parturition period lasting several months (Hazin et al., 2000; Santana and Lessa, 2004). Size at birth is presumed to be 60 – 67 cm TL (Compagno, 1984; Santana and Lessa, 2004) with litter sizes ranging from 4 to 18 pups (Hazin et al., 2000; Compagno et al., 2005).

Status

Due to declining abundance throughout their range, night sharks have an IUCN Red List status of Endangered. Night sharks are managed under the Atlantic Highly Migratory Species Fisheries Management Plan and retention has been prohibited in both recreational and commercial fisheries since 1999. An analysis of available abundance trends data produced conflicting results, warranting the continuation on the prohibited list as a precaution until sufficient data is collected to conduct a thorough stock assessment (Carlson et al., 2008).

POPULATION SIZE AND DISTRIBUTION

Night sharks are found in warm temperate and tropical waters of the western Atlantic ocean from Delaware to Argentina including the Gulf of Mexico, Bahamas, Caribbean, and Central America. In the eastern Atlantic, they occur from Senegal to northwestern Namibia (IUCN, 2021).

Information on demographics and movement patterns in night sharks is limited. Available evidence suggests significant declines due to high fishing mortality, with populations estimated to have declined 50-70% over the past three generations (IUCN, 2021). Several studies used marked recapture with conventional tags to document large scale movements upwards of 2,669 km and maximum reported time at liberty of 13.8 years, suggesting susceptibility to large scale pelagic longlining as well as regional artisanal fisheries (Kohler and Turner, 2001; Baremore et al., 2019).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Night sharks are a deepwater coastal or oceanic species residing offshore or along the outer continental and insular shelves in waters 50 to 100 m or deeper (Bigelow and Schroeder, 1948). They actively school and are known to conduct vertical diel migrations at night consuming a diet primarily of small active teleosts, squid, and shrimp (Compagno et al., 2005).

CHALLENGES

The night shark makes up a significant proportion of shark bycatch in pelagic longline fisheries off the southeastern U.S. Historically, they comprised a significant proportion of the artisanal shark fishery in Cuba; however, they are now rarely caught (Carlson et al., 2008). Despite being on the prohibited species list and are hence not targeted, some are likely retained by fisheries due to species identification issues as well as

lucrative demand for shark fins (Carlson et al., 2008). To monitor impacts of the demand for shark fins, genetic testing for prohibited species was conducted in fin markets in Hong Kong and Guangzhou; unlike many of the other prohibited pelagic species, they failed to identify any night shark fins (Fields et al., 2018; Cardenosa et al., 2020).

A study describing the demographics of night sharks captured in the longline fishery in the southwestern Atlantic ocean found the stock being targeted was over 89% juveniles. Recruitment to the fishery occurred around 5 years of age, however, age at maturity is not until 10 years for females. The high mortality rate of this fishery on individuals prior to reaching sexual maturity suggests significant reductions in the population is likely and unsustainable (Santana et al., 2009).

Life history information in the northwestern Atlantic is not available and very little is known about population size, productivity, or demographics. While significant declines in CPUE are reported to have occurred throughout the western Atlantic, it is unknown if observed changes are due to species identification, fishing tactics, market value or actual population declines (Carlson et al., 2008). Additionally, based on observer data, the average size of night sharks captured in pelagic longline fisheries has decreased approximately 40 cm TL since the 1980s. Whether this is due to changes in leader types and catchability, or a true decrease, requires additional research (Carlson et al., 2008)

CONSERVATION ACCOMPLISHMENTS

Some conservation sites have been identified over part of their range (IUCN, 2021).

While lacking comprehensive data for stock assessment, fishing has been restricted as a proactive management tool.

CONSERVATION RECOMMENDATIONS

- Explore ways to decrease fisheries bycatch and mortality in commercial and artisanal fisheries
- Improve monitoring and reporting in commercial and artisanal fisheries by international organizations and individual countries to improve estimates of catch and discards
- Improve knowledge and understanding of life history and demographics
- Improve knowledge and understanding of population status, abundance trends, and genetic structure

MEASURE OF SUCCESS

Removal from IUCN Endangered designation and an increase in abundance throughout their range. A first goal should be to collect sufficient data to conduct a thorough stock assessment.

Oceanic Whitetip Shark

Carcharhinus longimanus

Contributors:
Liz Vinyard (SCDNR) & Bryan Frazier(SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Oceanic whitetip sharks, members of the order Carchariniformes and family Carcharinidae (Page et al. 2023) are a large-bodied, stocky pelagic species with a distinctive pattern of mottled white on the tips of their dorsal, pectoral, and caudal fins. The first dorsal fin is broadly rounded while their pectoral fins are long and paddle-like (Compagno, 1984). It has black tips on the ventral surface of the pelvic and anal fins and the anal fin has a free rear tip that almost reaches the base of the caudal fin (Compagno, 1984). The nose is bluntly rounded, the eyes small and circular, and they may have a weak or occasionally absent interdorsal ridge (Castro, 2011). Body color can vary based on habitat but is generally olive gray to brown while their undersides are white to yellow tinged (Compagno, 1984). Small juveniles may have black blotched or black tips on their fins and black saddle marks on the dorsal surface between fins (Castro, 2011).

Most sharks encountered are under 300 cm total length (TL), and maximum length is likely around 325 cm TL (Lessa et al., 1999). While observed maximum ages determined by vertebral counts ranged from 12-18 years in the Pacific and from 13-19 years in the South Atlantic (Seki et al., 1998; Lessa et al., 1999), oceanic whitetip sharks are estimated to live up to 25 years with the potential that individuals may be considerably older, up to 36 years (NOAA, 2024). Studies conducted in the Northwest Atlantic and eastern Pacific indicate intermediate life history parameters with generally slow to moderate growth rates which may vary slightly between regions (Backus et al., 1956; Strasburg, 1958).

Females are thought to mature between 6 to 9 years which varies based on geographic location, and size at maturity likely falls between 180 – 200 cm TL (Lessa et al. 1999, Joung et al., 2016). Males are thought to reach maturity around the same ages and slightly smaller lengths between 175 – 189 cm TL (Seki et al. 1998, Joung et al., 2016). In a study from the equatorial Atlantic off North-Eastern Brazil, no difference in morphometrics or weights were observed between the sexes and the size at maturity ranged from 180-190 cm TL for both sexes (Lessa et al., 1999)

Like many Carcharhinids, they are placentally viviparous giving birth to live young with a biennial reproductive cycle and a gestation period of 10 to 12 months. Litters average 6 pups but can range from 1 to 14 pups with larger females producing more offspring. Size at birth is estimated between 65-70 cm PCL (Lessa et al., 1999; Castro, 2011).

Status

Due to declining global abundances, oceanic whitetip sharks have an IUCN Red List status of Critically Endangered and are currently listed under Annex II of the Protocol Concerning Specially Protected Areas and Wildlife of the Cartagena Convention (SPAW Protocol), Annex I of the Sharks Memorandum of Understanding on the Convention on Migratory Species (CMS), and effective September 2014, they were added to Appendix II of the Convention on International Trade in Endangered Species (CITES).

Stock assessments are only available in the Western and Central Pacific Ocean which conclude they are overfished and overfishing is occurring. While a formal stock assessment hasn't been completed in the US, management actions were implemented in 1993 as part of the Federal Fishery Management Plan for Sharks and subsequent regulations have been passed to further reduce fishing mortality (NOAA, 2006).

In 2018, NOAA Fisheries listed the species as threatened under the Endangered Species Act. They are currently managed under the Atlantic Highly Migratory Species Fisheries Management Plan, and retention is prohibited in both recreational and commercial fisheries in all U.S. Federal waters in the Atlantic, Gulf of Mexico, and Caribbean. In July 2024, the final Oceanic Whitetip Shark Recovery Plan was adopted by NOAA.

POPULATION SIZE AND DISTRIBUTION

Oceanic whitetip sharks are a circum-global, highly migratory species found in tropical and warm temperate waters. In the Atlantic Ocean, oceanic whitetip sharks are distributed from Maine to Argentina, including the Gulf of Mexico and Caribbean Sea but are uncommon in the U.S. Atlantic EEZ. In the Pacific Ocean, they are found from California to the tropics.

Global population data is lacking for the oceanic whitetip shark. Available evidence indicates significant magnitude declines due to heavy fishing pressure. Since the mid-1990s, their populations have declined approximately 80-95% across the Pacific Ocean, 88% in the Gulf of Mexico, and substantial declines are estimated in the Atlantic Ocean (Young and Carlson, 2020).

With declining populations, focus was placed on gaining insight into movement through use of conventional as well as pop-up and satellite archival tags. Patterns were consistent between studies and regions with large scale movements as well as evidence of philopatry which suggests potential depletions in localized abundance and genetic diversity due to overfishing (Kohler et al., 1998; Howey-Jordan et al., 2013; Camargo et

al., 2016). Several lines of evidence show declining median sizes for both sexes and this pattern in females is particularly concerning due to correlation between maternal length and litter size (Young and Carlson, 2020).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Oceanic whitetip sharks reside offshore in deep waters of the open ocean but are thought to spend most of their time in depths shallower than 100 m, primarily utilizing the upper mixed layer of the pelagic zone. While they are considered a surface-dwelling shark and prefer warm waters above 20^{o} C, they have been recorded making deep dives down to 1,082 m (Howey-Johnson et al. 2013; Young and Carlson 2020).

Major prey species include large epipelagic teleosts and squid, but they are also known to be opportunistic and will consume sea birds, other sharks and rays, marine mammals, and even garbage. They are considered a top predator and a stable isotope study conducted in the Southwestern Indian Ocean found significant dietary overlap with pelagic thresher sharks (*A. pelagicus*) and scalloped hammerheads (*Sphyrna lewini*) (Kiszka et al, 2015).

According to NOAA, critical habitat designation under the ESA is not possible at this time based on a comprehensive review of the best available scientific data (as of 2020). They determined there are no identifiable physical or biological features essential to the conservation of oceanic whitetip sharks within areas under U.S. jurisdiction.

CHALLENGES

Oceanic whitetip sharks are one of the most common pelagic bycatch species in gillnet, longline, and purse seine fisheries. While purse seine fisheries have historically had low bycatch rates, the development of industrialized seine fisheries targeting larger pelagic species has increased the likelihood of shark bycatch. To increase catches, fish aggregating devices (FADs) are frequently used prior to encircling with seine nets, and consequently, oceanic whitetip sharks are one of the predominant species associated with bycatch in these fisheries (Eddy et al., 2016). They are also the third most dominant shark bycatch species globally in pelagic longline fisheries and are frequently reported as being discarded alive (Abel and Grubbs, 2020).

Post-release mortality estimates for pelagic longline fisheries range from 5-20% (Abel and Grubbs, 2020), however, seine and FAD associated mortality rates are likely much greater and may be similar to their congener, *C. falciformis,* which has a seine mortality rate upwards of 85% (Filmalter et al., 2013; Poisson et al., 2014). Adding to concerns about fishing mortality rates, a recent study investigated the accuracy of shark bycatch estimations by onboard observers and found shark counts were underestimated for 50-100 percent of the sets with a mean underestimation at trip level ranging from 9 to 40

percent for onboard observers in the Pacific and Atlantic Oceans and 65 percent for electronic monitoring systems in the Indian Ocean (Forget et al. 2021).

In addition to concerns about fishing mortality, oceanic whitetip shark fins are in high demand in the global shark fin trade due to their large size. They are highly valuable and can sell for $45 to $85 USD per kg (CITES 2013). While retention of oceanic whitetip sharks has been prohibited by major tuna regional fisheries management organizations, genetic testing of fins in the Hong Kong fin market continued to detect their presence (Cardenosa et al. 2018).

Since oceanic whitetip shark abundance data is heavily reliant on fishery-dependent methods, variability in gear configurations and tactics has made the standardization of abundance trends for population assessments difficult (Young and Carlson, 2020). Additionally, vital information on location and timing of breeding, pupping, and nursery habitats are lacking. Identifying these areas and implementing protection measures could ensure increases in abundance and population recovery (Young and Carlson, 2020). Other emerging concerns include pollution with recent studies finding methylmercury levels in oceanic whitetips notably increased with fork length and were in high enough concentrations to have adverse health effects (Kiszka et al., 2015).

CONSERVATION ACCOMPLISHMENTS

While much work needs to be accomplished to allow the recovery of the oceanic whitetip shark, the recent adoption of the Oceanic Whitetip Shark Recovery Plan by NOAA is a strong step forward.

CONSERVATION RECOMMENDATIONS

- Explore ways to reduce bycatch mortality and assess post release mortality in longline fisheries in the Atlantic and Pacific Oceans.
- Develop methodology to quantify the percentage of fins in shark fin markets that can be assigned to oceanic whitetips with the goal of assigning fin samples to the basin of origin. This would allow for a better understanding of where IUU fishing is occurring.
- Improve knowledge and understanding of population status, abundance trends, and genetic structure.
- Improve knowledge and understanding of distribution, movement, and habitat use.
- Improve knowledge and understanding of demographics and life history.
- Minimize fisheries bycatch and mortality by determining frequency of capture and severity of interactions in commercial, artisanal, and recreational fisheries.

- Minimize fisheries bycatch and mortality in international fisheries and trade through enhanced coordination and collaboration with relevant international organizations.
- Determine effects of international shark fin trade on populations in all management units and take management actions to minimize or eliminate the quantity of fins in trade.
- Improve species-specific monitoring and reporting in commercial and artisanal fisheries by international organizations and individual countries to provide a better understanding of the effects of illegal, unreported, and unregulated (IUU) fishing, improve estimates of catch and discards, and measure progress towards recovery.
- Minimize fishing mortality through effective development, implementation, and enforcement of internation and domestic measures such as legislation and regulation.
- Develop and implement outreach and education strategies and programs to increase public and stakeholder awareness on status and recovery needs.

MEASURE OF SUCCESS

Increase population abundance to the level of removal from listing under the Endangered Species Act. Meet criteria listed in NOAA's Oceanic Whitetip Recovery Plan.

Pigfish

Orthopristis chrysoptera

Contributor (2025):
Sabrina Cobb (SCDNR)

Photo courtesy of Don Flescher and FishBase.org

DESCRIPTION

Taxonomy and Basic Description

Orthopristis chrysoptera, commonly known as the pigfish, is a member of the grunt family, Haemulidae. Haemulids encompass 17 genera and 150 species. They are distributed throughout the Atlantic, Indian, and Pacific Oceans and although most species are found in marine waters, some can be observed in brackish and freshwater (Ohs, Cortney L., et al. 2011). Haemulids are referred to as grunts because of the "grunting" or "chattering" sound that is produced when they rub their pharyngeal teeth together.

Key characteristics of the pigfish that help distinguish the species from others throughout their range include: a dorsal fin comprised of 12 to 13 spines followed by 15 to 16 soft rays, an anal fin with three spines and 12 to 13 soft rays. Both the dorsal and anal fin spines are covered by a scaly layer that is absent on the soft rays.

Pigfish have 53 to 58 lateral-line scales oriented in ten longitudinal rows above the lateral line and 15 to 19 rows below (Ohs, Cortney L., et al. 2011). Their body is elliptical in shape and significantly compressed, resulting in a body depth that is approximately 30 to 40 percent of their standard length (SL). Pigfish can grow up to 482 mm and weigh upwards of 10 kg (NCDEQ).

The overall coloration of the pigfish is greenish blue with iridescent highlights that gradually shade into silver ventrally. They have dark orange spots and irregular lines that cover the head and body. In addition, the upper body can have pale to dark grey bars and their fins are a yellow to bronze color with dusky margins.

Status

Pigfish are not a state or federally listed species; however, they are an important food source for Atlantic sharpnose *(Rhizoprionodon terraenovae)*, spotted seatrout

(Cynoscion nebulosus), and weakfish *(Cynoscion regalis)* (Radcliffe 1916; Hastings 1972; Darcy 1983).

POPULATION SIZE AND DISTRIBUTION

Pigfish occur predominately in the Gulf of Mexico from Florida to the Yucatan peninsula and along the Atlantic coast of the United States from the northern Bahamas to as far as New York, however they are uncommon north of Virgina.

The species is present year-round in South Carolina and is most abundant in the state's estuaries. Pigfish are often caught in SCDNR's estuarine based trammel net survey. Data collected from the survey shows year to year variability in abundances based on differences in recruitment and environmental variables (Figure 1). Overall, pigfish abundance appears consistent over the last few decades.

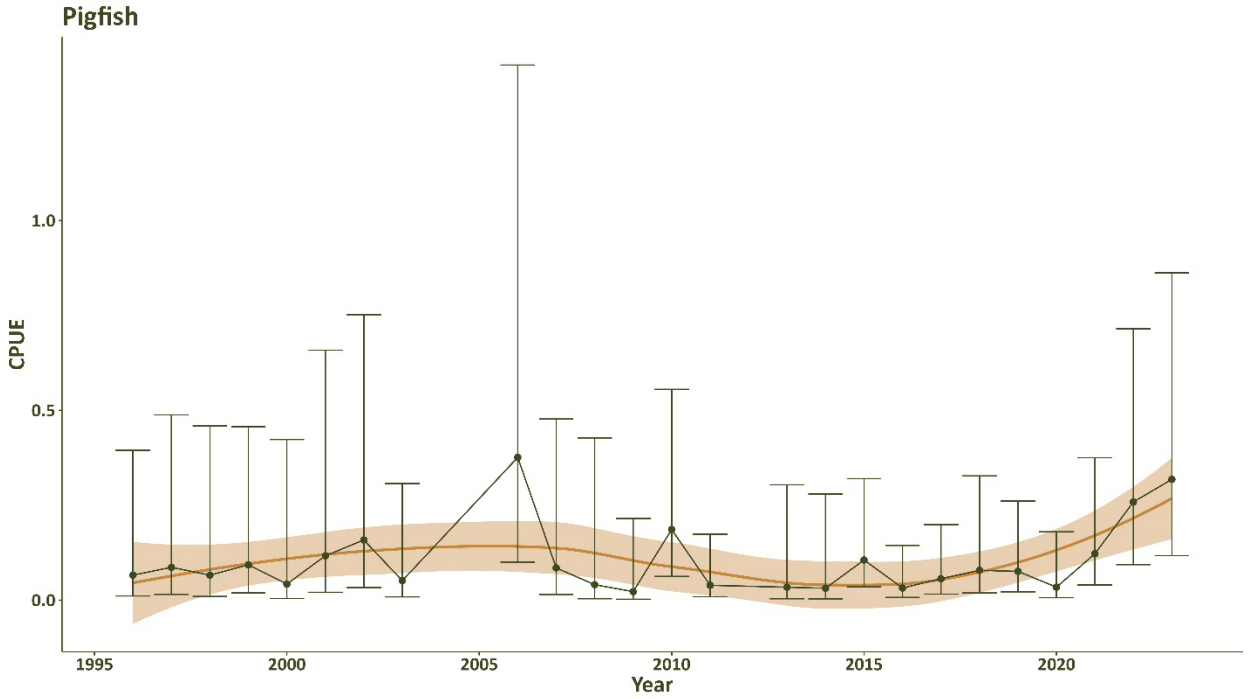

Figure 1. Pigfish mean annual standardized CPUE from SCDNR's trammel net survey.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Like many other species of grunts, juveniles will typically inhabit shallow waters near shore, often near vegetation, making South Carolina estuarian systems the perfect habitat to observe them. Adults can be observed over deep soft bottom flats, sandy and sparsely vegetated areas, and near mid-shelf reefs.

Pigfish can be found in water temperatures from 13.7 to 36.0 C but tend to prefer 23.9 to 26.7 C (Ohs, Cortney L., et al. 2011). This species is tolerant of salinities from 0 to 44.1 g/L however they tend to avoid waters with a salinity of 15 ppt or less (Ohs, Cortney L., et al. 2011). Pigfish have been historically collected from waters with a dissolved oxygen concentration of 2.1 to 11.8 mg/L (Schwartz et al. 1982).

Adult pigfish are primarily benthic carnivores, feeding on marine invertebrates, such as benthic worms, crabs and a variety of shrimp species; whereas young fish are planktivorous (Carr and Adams 1973; Darcy 1983). A shift in diet relative to increasing lengths was first documented from samples collected from Crystal River, Florida by Reid (1954). Reid's research showed pigfish between 25-50 mm total length (TL) consumed mostly copepods, while larger fish preyed upon amphipods, shrimps, and other benthic organisms. Juvenile pigfish diet in the Crystal River was also studied by Carr and Adams (1973). They observed fish 16-80 mm SL had two distinct feeding phases, planktivorous (consuming only copepods, mysids, and post larval shrimp), followed by a two-phase carnivorous stage in which marine invertebrates were the primary food target. Documented diet transition in the study began at approximately 26 mm SL and completed by 41-45 mm SL (Sutter and McIlwain 1987).

CHALLENGES

Some of the anthropogenic and environmental challenges pigfish are being faced with include increased fishing pressure and depletion of favorable habitat availability driven by climate change. As fishing efforts along our coast increase, the species becomes more susceptible to becoming bycatch which inadvertently could deplete local populations. Pigfish are caught by a variety of gear types including trawls, traps, and handlines, and currently have no commercial value in South Carolina. Along the Gulf of Mexico where the species is more prevalent, some are marketed as live bait but have little economic value (Darcy 1983). Commercial fishery statistics are not specifically reported for the species; however, overall catch data have been combined with other grunt species by the National Marine Fisheries Service and the Bureau of Commercial Fisheries (Sutter and McIlwain 1987).

Climate change poses a threat for pigfish by pushing their range north with increasing water temperatures and changing the macro habitat with increased, more intense tropical storms. This ultimately could decrease the preferred available habitat for the species and negatively impact their reproductive success.

CONSERVATION RECOMMENDATIONS

- Determine pigfish relative abundance and distribution in coastal waters.

- Track pigfish population trends in South Carolina including local depletions related to bycatch in fisheries.
- Explore the use of pigfish as bait in South Carolina after assessing population trends.

MEASURE OF SUCCESS

By implementing monitoring protocols for pigfish in South Carolina, SCDNR will be able to gain a better understanding of the species' life history, and their ecological role along the coast. In return, this will benefit targeted inshore fisheries such as spotted seatrout, that rely on the pigfish as a food source. Monitoring pigfish along our coast would also allow us to gain further insight to how climate change is affecting inshore fisheries and the implications it will have to our dynamic estuarine systems.

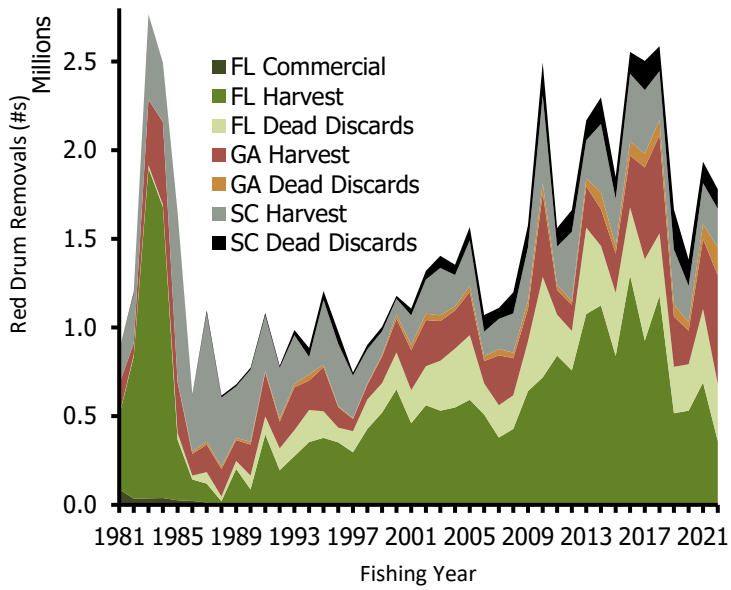
Red Drum

Sciaenops ocellatus

Contributors:
Joseph C. Ballenger (SCDNR)

DESCRIPTION



Taxonomy and Basic Description

Red drum are a large member of the order Perciformes and family Sciaenidae (Boschung & Mayden 2004; Carpenter 2002; Page et al. 2023) that are similar in body shape to Atlantic croaker but are not easily confused as they are the only local sciaenid possessing a conspicuous spot(s) on the caudal peduncle (Boschung & Mayden 2004). Their body is elongate, rather robust, with an inferior, horizontal mouth with chins not possessing any barbels (Boschung & Mayden 2004; Carpenter 2002). Their dorsal fin is long with two distinct sections: a spinous dorsal fin (15 spines) with a second dorsal fin (1 spine & 23-25 soft rays) separated by a very deep notch (Boschung & Mayden 2004; Carpenter 2002). Caudal fin shape changes with ontogeny, being rounded in young and becoming truncate to slightly concave in adults (Boschung & Mayden 2004; Carpenter 2002). Their coloration is distinct in the estuarine environment, with their body being iridescent silvery with a copper cast, being darker above and with age, with one to several black oscillated spots about eye size under the soft portion of dorsal fin to base of caudal fin (Boschung & Mayden 2004).

Red drum inhabit nearshore and estuarine waters of the U.S. Atlantic coast from Massachusetts (rare north of Chesapeake Bay) to Florida and the Gulf of Mexico from Florida to northern Mexico (Lux & Mahoney 1969; Mercer 1984). Management divides their population into two distinct stocks along the U.S. Atlantic coast (east coast FL to the north), one from the North Carolina/South Carolina (NC/SC) border north and the other from the NC/SC border south through the east coast of Florida, based on differences in life history (ASMFC 2022; SEDAR 2015), movement (ASMFC 2022; Bacheler et al. 2009; SEDAR 2015), and genetics (ASMFC 2022; Cushman et al. 2014; SEDAR 2015). South Carolina red drum belong to the southern population, which exhibit maximum observed sizes and ages of approximately 47 inches (120 cm) total length (TL) and 41 years old (SEDAR 2015). Red drum from the northern population reach slightly larger maximum sizes (55 inches (140 cm) TL) and older ages (62 years old; SEDAR 2015). In both areas, red drum exhibit extremely fast, strongly seasonal growth through ages 4-5 with evidence of changes in rates of approach to asymptotic sizes with age making their growth difficult to model with traditional growth models (e.g., von Bertalanffy growth model; ASMFC 2022; Cadigan 2009; Porch et al. 2002).

However, fast growth means harvest of red drum, which are managed through slot limits throughout their range, is primarily restricted to sub-adults between 1 and 3 years of age, though post-release mortality of catch-and-release fish occurs throughout their size and age range.

Despite their long life, southern population red drum mature early with 50% of females mature by 4.2 years old and 30 inches (76.6 cm) TL; similar ages- and sizes-at-maturity are observed for the northern population (3.5 years and 33 inches (83.6 cm) TL), keeping in mind the differences in size-at-age (J. Ballenger, pers. comm.). Spawning occurs in nearshore areas adjacent to channels and passes (Lowerre-Barbieri et al. 2008; Murphy & Taylor 1990; Wenner 2000) or near the mouths of high salinity estuaries along the coast (Beckwith et al. 2006; Johnson & Funicelli 1991; Luczkovich et al. 1999; Murphy & Taylor 1990; Nicholson & Jordan 1994; Woodward 1994) where adults form spawning aggregations during the late summer and early-fall months (August – mid-October; Lowerre-Barbieri et al. 2008; Luczkovich et al. 1999; Murphy & Taylor 1990; Ross et al. 1995). There is a slight latitudinal cline, with a 45-60 day spawning season shifted slightly later further south, with peak spawning in South Carolina from mid-August to September (J. Ballenger, pers. comm.). While adult fish participating in these spawning aggregations are protected from direct harvest due to slot limits, large-scale catch-and-release fisheries occur on and near aggregation sites resulting in post-release mortality of adult fish and potential sub-lethal effects affecting reproductive output.

There is growing literature that environmental factors affect the recruitment success of red drum (SEDAR 2015). In support, Goldberg et al. (2020) found a relationship between year class strength and ocean wind conditions promoting onshore movement of larvae during and after the peak spawning season. Similar environmental drivers are being identified for other species (e.g., Southern Flounder (Erickson et al. 2021)). Further exploration will likely result in the identification of other correlations between year class strength and environmental variables, though the relationship is likely complex making predictions difficult.

Status

The Atlantic coast southern population of red drum supports large scale recreational fisheries (Figure 1), though historic commercial fisheries were phased out in the region during the mid- to late-1980s when assessments indicated the stock was experiencing overfishing and in need of management protection (SEDAR 2015). The most recent regional assessment (ASMFC 2017; SEDAR 2015) of the southern population had high uncertainty in overfishing status, though point estimates suggested overfishing was not occurring during the terminal year, and additional concerns identified made use of the assessment for management purposes difficult. A subsequent state assessment in Florida found red drum in neither the northeast or southeast region of Florida were overfished nor experiencing overfishing (Addis 2020). In contrast, a state assessment in South Carolina suggested recruitment declined rapidly in the state after 2008 with abundance of sub-adults and adults following suit after 2010 with terminal year estimates indicating the population was experiencing overfishing (Murphy 2017).

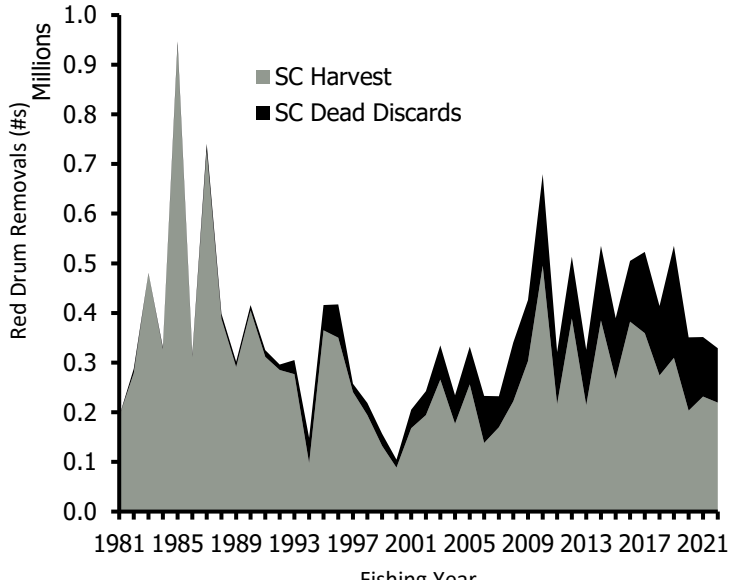


Figure 1: Red drum recreational (and commercial) removals from the southern population (top) and South Carolina specifically (bottom) for the 1981-2022 fishing years (Sept. 1 - Aug. 31). Shown are removals based on direct harvest and dead discards assuming an 8% discard mortality rate (ASMFC 2017; SEDAR 2015). Recreational harvest and discard data by state obtained from a Marine Recreational Information Program Query (NMFS. pers. comm.).

Currently, a new regional assessment of the southern population is being conducted through the SouthEast Data Assessment and Review (SEDAR) process by representatives of the Atlantic States Marine Fisheries Commission and Atlantic coast states. This assessment is scheduled for peer review in August 2024, with assessment results released for use by fisheries managers in late 2024. Data provided to the assessment suggests removals

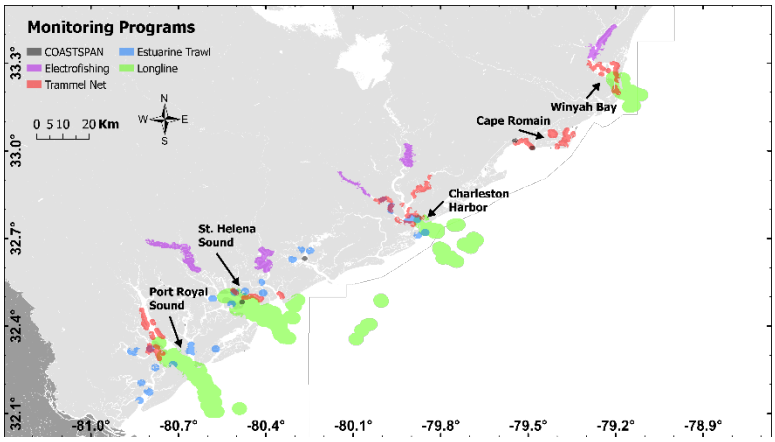

Figure 2: SCDNR Inshore Fisheries fishery-independent monitoring program survey areas.

in South Carolina and across the population have increased in recent years to levels observed in the early- to mid-1980s (Figure 1).

POPULATION SIZE AND DISTRIBUTION

Red drum are encountered by three SCDNR fishery-independent surveys operating in estuarine and coastal South Carolina waters, the SCDNR electrofishing survey, SCDNR trammel net survey, and SCDNR coastal longline survey. These surveys sample different habitats used by and life stages of red drum in South Carolina, with the electrofishing survey encountering primarily sub-adult (age-0 to age-3) red drum using upper estuary, low salinity (0-5 ppt), riverbank habitats during all months of the year (Figure 2). The trammel net survey also encounters sub-adults (age-0 to age-5) during all months of the year, though it samples lower estuary, salt marsh edge and oyster reef habitats (Figure 2). Adult red drum (ages 3+) are captured in the seasonal longline survey near the mouths of estuaries and in coastal ocean channel edge and live bottom/artificial reef habitats from mid-August through early-December.

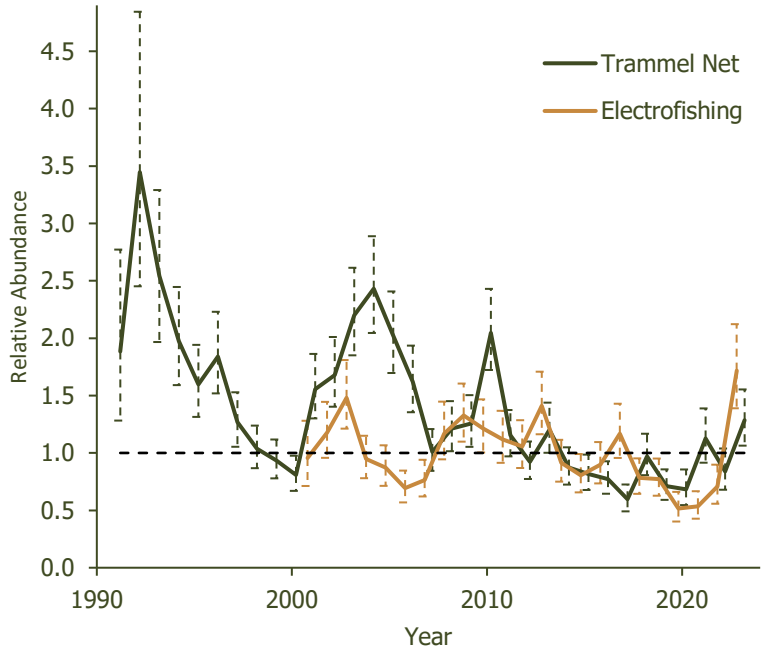

Figure 3: SCDNR Inshore Fisheries sub-adult (top) standardized indices of abundance for red drum. Provided are indices from the trammel net (green), electrofishing (gold). Error bars represent 95% CIs.

The two sub-adult surveys both indicate long term declines in abundance of sub-adult red drum across coastal South Carolina through the early-2020s, followed by a slight increase in recent years (Figure 3). For the trammel net survey, which has the longest time series, we observe a much larger decrease in relative abundance through time from highs in the early-1990s. The adult index has been much more stable through time, though there are indications of decreases in the last two years (Figure

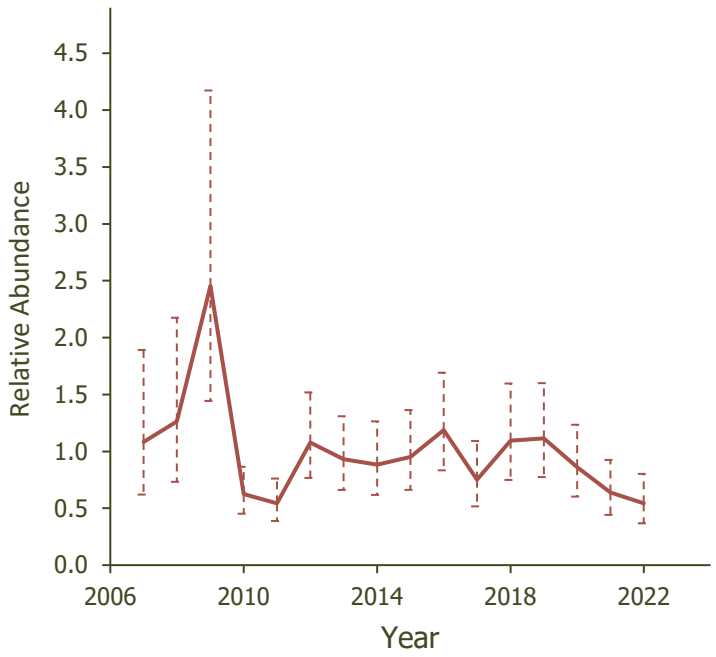

Figure 4: SCDNR Inshore Fisheries Coastal longline survey standardized index of abundance for adult red drum. Error bars represent 95% CIs.

4). This is expected given the integration of many year classes in the adult index, making it less responsive to population change.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Red drum can be found in most estuarine and coastal aquatic habitats found along coastal South Carolina, ranging from tidally influenced, oligohaline (0-5 ppt) riverine habitats to nearshore artificial reefs. While widely distributed, there are ontogenetic shifts in habitat use through time, resulting in different critical habitats throughout their life (ASMFC 2024; Odell et al. 2017). Adult red drum aggregate to spawn in a range of habitats, including estuaries, near inlets, and bay mouths, from late summer to late fall (Peters and McMichael 1987). Post-spawning, eggs and larvae are transported throughout estuarine environments, initially being found in high salinity (>25 ppt) waters adjacent to adult spawning habitats (Nelson et al. 1991; Reyier & Shenker 2007; Renkas 2010) but being found throughout estuaries, including low salinity nursery areas upon settlement where they tend to remain throughout early and late juvenile stages (Holt et al. 1983; Pattillo et al. 1997; Rooker & Holt 1997; Rooker et al. 1998; Stunz et al. 2002). Wenner (1992) indicated red drum juvenile habitats vary slightly seasonally in South Carolina; most often between August and early October red drum reside in main channels of rivers ranging in depths from 10 to 50 ft (3-15 m). Studies show red drum inhabiting non-vegetated sand bottoms exhibit the greatest vulnerability to natural predators (Minello and Stunz 2001). As juveniles transition to sub-adults (~200 mm+ TL), the distribution within estuaries varies seasonally as individuals grow and disperse. It is in the sub-adult stage red drum are most vulnerable to contemporary fisheries. Tagging studies indicate these fish remain in the vicinity of a given area (Beaumarriage 1969; Wenner et al. 1990; Troha 2023), with movements observed typically linked to changes in temperature and food availability (Pafford et al. 1990; Woodward 1994), increasing the risk of localized depletion.

CHALLENGES

Red drum along coastal South Carolina face a number of challenges, including increased fishing pressure, changing and increasingly stressful environmental conditions, loss and degradation of habitats critical to juvenile and sub-adult red drum, and other anthropogenic stressors such as contaminants and pollutants. In combination, these challenges are leading to long-term declines in sub-adult abundance (Figure 2) and recruitment (Murphy 2017; SEDAR 2015), evidence of size- and age-truncation and decreases in adult abundance (Figure 4) and documented overfishing conditions (Murphy 2017). Further, while population abundance trends and life history of red drum is well studied in South Carolina, major data gaps still exist, including the size composition of recreationally released fish (ASMFC 2022; SEDAR 2015); hence, the sizes and ages subject to post-release mortality and fishery selectivity, and the impact (lethal and sublethal) of catch-and-release fishing on adult red drum prior to , during and after the spawning season. Emerging challenges facing red drum, and many other estuarine species, include the impact of warming estuarine waters and marine heat waves during critical life history stages, phenological changes in weather patterns and food web dynamics, and increased variability in the climate. Finally, the impact of contaminants of emerging concern, such as per- and polyfluoroalkyl substances and microplastics among others, on the productivity of the population still needs investigation, particularly given recruitment appears closely tide to environmental conditions (Goldberg et al. 2020; SEDAR 2015).

CONSERVATION ACCOMPLISHMENTS

Red drum management in South Carolina began in the late-1980s as regional assessments (Vaughan and Helser 1990; Vaughan 1992; Vaughan 1993) suggested high fishing mortality and low escapement of red drum throughout the 1980s and into the early-1990s. This led to the adoption of fishery management plans by the Atlantic States Marine Fisheries Commission (ASMFC 1984) and the South Atlantic Fisheries Management Council, and the adoption of minimum size limits and a complete banning of commercial harvest in South Carolina by 1990. Later assessments (Vaughan 1996, Vaughan & Carmichael 2000), indicated overfishing continued on the regional population, leading to further management changes in South Carolina and other states intended to restrain harvest to sustainable levels. This led to a 15-24” TL slot limit and a 2 fish per person per day bag limit in South Carolina by 2001. Despite a short term increase in sub-adult abundance in the early-2000s, abundance trends in South Carolina (Figure 3) and state (Murphy 2017) and regional (ASMFC 2017;SEDAR 2015) assessments suggested continued overexploitation of the population, leading to management action resulting in our current regulations in South Carolina (15-23” TL slot limit, 2 fish per person per day bag limit, 6 fish per boat per day boat limit, and a prohibition on commercial harvest) which went into effect in 2018. Further, given the restrictive nature of the fishery and rise in population of catch-and-release fishing,

SCDNR has promoted the use of handling techniques and terminal tackle conducive to lower post release mortalities.

CONSERVATION RECOMMENDATIONS

Regional assessments have identified numerous research recommendations conducive to the effective assessment and management of the southern population of red drum, including the short term priorities:

- development of methods to estimate recreational discard catch length compositions coastwide,
- greater intensity of age sampling of adults to better characterize year class strength when size-at-age overlaps considerably,
- collect data to estimate movement rates of sub-adults in inshore waters to the adult population in offshore/nearshore waters for development of a multi-area assessment model,
- expand biostatistical sampling to better cover all statistical strata and collect more otolith ages proportion to lengths to support development of seasonal models,
- determine batch fecundity estimates of red drum to support fecundity-based assessment of reproductive potential,
- further study of post release mortality and sub-lethal effects of landings, particularly as impacted by fishing depth, fish size, fishing season, and the type of terminal tackle used,
- determine the contribution of stocked fish to wild populations and their impacts on stock status, and
- investigate appropriateness of reference points used for red drum management.

Longer term, research priorities identified in assessments include:

- expanding tag-recapture analyses to develop direct estimates of exploitation rates and apparent survival,
- incorporate tag-recapture data directly into integrated assessments for stock status determination, and
- identify impacts of water quality, environmental, ecosystem, and habitat changes on red drum stock dynamics and incorporate into our assessment of population dynamics.

MEASURE OF SUCCESS

The fishery-independent programs conducted by the SCDNR Inshore Fisheries research group annually monitors the relative abundance, population demographics (size- and age-compositions) and reproductive potential of estuarine finfish, such as red drum. These surveys can detect changes in those parameters, providing critical data for the

assessment of stock status and early detection of change (positive or negative) in abundance or population demographics. A sustained reversal of the twenty plus year decline in red drum sub-adult abundance and several years of above average recruitment would provide a tangible measure of management success.

Further, work identifying abiotic and biotic drivers of population fluctuations, in particular concerning recruitment, remain critical for projecting the response of red drum to future climate change, climate variability, and emerging contaminants of concern.

Red Grouper

Epinephelus morio

Contributors:
Margaret W. Finch (SCDNR) & Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Red Grouper, *Epinephelus morio*, is a medium-sized grouper of commercial and recreational importance in South Carolina. Adults are found on offshore reefs and man-made structures where they are top-level predators (Heemstra et al. 2002; Spanik 2018). The Red Grouper is a member of the family Epinephelidae (groupers) within the order Perciformes (Page et al. 2023).

The Red Grouper is a robust reddish-brown colored fish with body depth distinctly less than head length. The body is elongate and the head is pointed. The mouth is large and bright reddish orange in color with several fixed canine teeth. The scales are small and number from 112 to 128 in the lateral line series. The dorsal fin is continuous with 16 or 17 soft rays and 11 spines with the second or third spine being longer than the first. The anal fin has 3 spines and 8 to 10 soft rays. The caudal fin is convex in small fish (standard length less than 15 cm) but becomes truncate or slightly concave in larger individuals (Heemstra et al. 2002). The maximum adult total length (TL) for Red Grouper is at least 90 cm (35 in.) and the maximum weight is around 20 kg (45 lbs.; Heemstra et al. 2002).

Red Grouper color is a dark reddish-brown on the head and body and becomes lighter pinkish-red ventrally. The dorsal, caudal, and anal fins are dark on the edges with a thin white border. Red Grouper usually have dark spots on the nose or cheeks and the body has asymmetrical white spots and/or large pale patches (Heemstra et al. 2002).

Red Grouper are protogynous hermaphrodites, which means that they are born as females, subsequently changing sex from female to male. Females reach sexual maturity at around 48 cm TL and 2.8 years old. Sexual transition from female to male occurs when the fish are around 79 cm TL and roughly 7.7 years of age (Burgos et al. 2007; SEDAR 2010; SEDAR 2017).

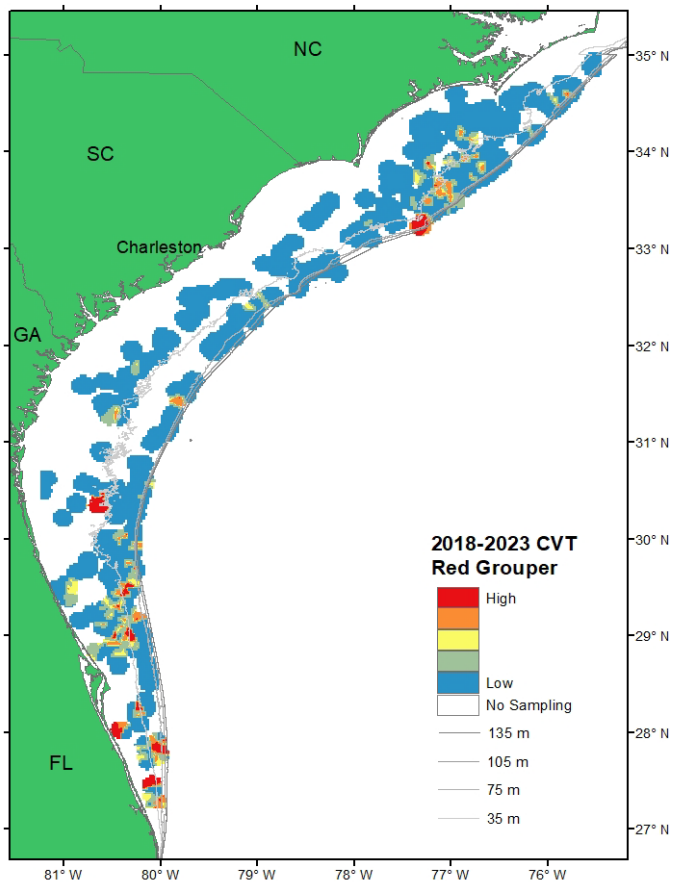
Status

The most recent stock assessment was completed in 2017 (with 2015 as the last year of data included) and results indicated the stock off the coast of the Southeastern US is overfished and that overfishing is occurring (SEDAR 2017). The stock of Red Grouper off the southeast Atlantic coast was listed in 2023 as overfished but not currently

undergoing overfishing under the Sustainable Fisheries Act (SFA) standards (NOAA Fisheries 2024a). Red Grouper are listed as Vulnerable by the IUCN.

POPULATION SIZE AND DISTRIBUTION

Red Grouper are found in the western Atlantic, primarily from North Carolina to Southern Brazil including Bermuda, the Gulf of Mexico, and the Caribbean, with juveniles occasionally reported as far north as Massachusetts. Red Grouper off the continental U.S. are managed as two separate stocks, the Gulf of Mexico stock managed by the Gulf of Mexico Fishery Management Council and the South Atlantic stock managed by the South Atlantic Fishery Management Council (SAFMC). However, there is evidence the two populations are genetically related via larval recruitment and gene flow (Bernard et al. 2020). Red Grouper off the Atlantic coast have a disjunct distribution, and are commonly captured off North Carolina, northern South Carolina and southern Florida, but are rare from southern South Carolina to northern Florida (McGovern et al. 2002; Figure 1). On the continental shelf off South Carolina, Red Grouper have been collected at depths from 22-101 m (72-331 ft.) by the Southeast Reef Fish Survey chevron traps (SERFS, see Figure 1).



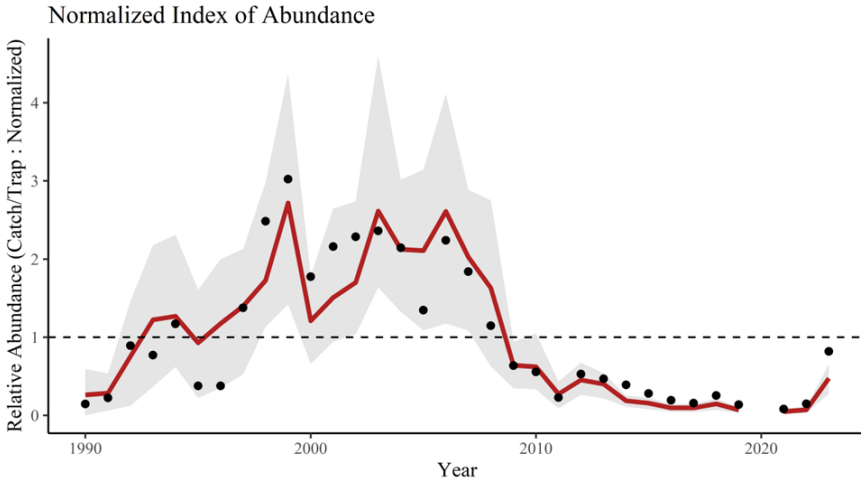


Figure 1: Distribution map of Red Grouper catches from SERFS Chevron Traps in 2018-2023 (Vecchio et al. 2024).

Two data sources suggest a decline in Red Grouper population off the Southeast U.S. Atlantic coast and were used in the most recent assessment. Fishery-independent data collected by SERFS (1990-present) indicates an overall decline in relative abundance since 2007 (Vecchio et al. 2024; Figure 2). A small uptick in the relative population estimate was seen in the 2023 data, but this increase does not rise to the level of the long-term average for the species. Southeast U.S. Atlantic coast commercial and recreational fisheries landings have also been in decline since around 2007 (NOAA Fisheries 2024b, ACCSP 2024; Figure 3).

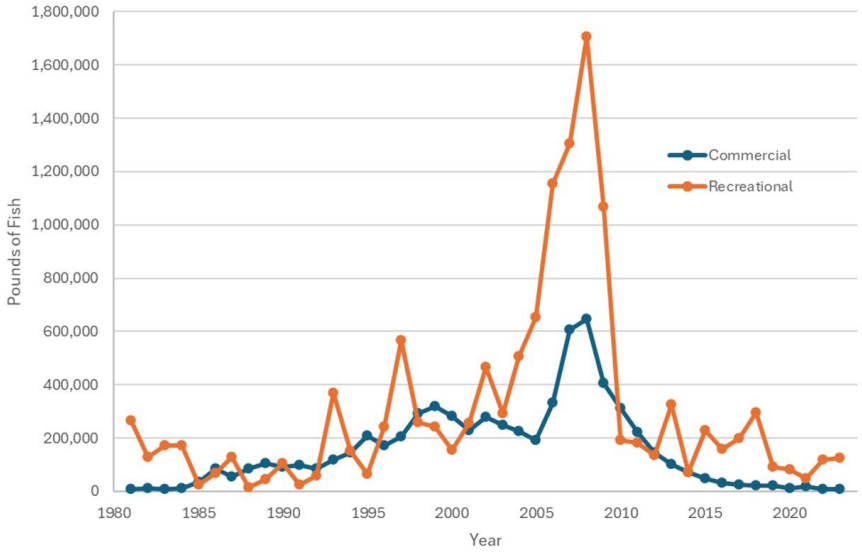

Figure 3: Commercial and recreational landings (in lbs) of Red Grouper for the South Atlantic Coast.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Red Grouper occupy offshore waters with rocky ledges/crevices and other live-bottom habitats with sponges, corals, algae, etc. (Heemstra et al. 2002). Red Grouper are known to create habitat for themselves and other marine species, both fish and invertebrates, by removing sand from rocky structures (Coleman et al. 2010; Ellis et al. 2017). It has been found that juvenile Red Grouper stay in shallower waters (< 40 m) until reaching maturity at which point they move into deeper waters for spawning. Transitioning and male Red Grouper have been found to inhabit deeper water (> 40 m) year round while females may move to shallower waters after the spawning season (Sedberry et al. 2006; Burgos et al. 2007). Off the southeast Atlantic coast, Red Grouper spawning occurs in deeper water (> 40 m) from February to June, peaking in April (Sedberry et al. 2006; Burgos et al. 2007; SEDAR 2010). Red Grouper exhibit an ontogenetic shift in diet with juveniles having a primarily benthic diet of crabs and other invertebrates while larger adults primarily feed on fishes (Spanik 2018; Vecchio and Peebles 2022).

CHALLENGES

Figure 2: Relative abundance of Red Grouper based on SERFS chevron trap catches. Red line is the modeled index of abundance. Gray shading is standard error Dotted line is the long term average value.

Red Grouper are vulnerable to heavy fishing pressure (Coleman et al. 2000; Sadovy de Mitcheson et al. 2020) and are considered to be overfished (SEDAR 2017). Because Red Grouper are long-lived (26 years), slow growing and late maturing (it takes 2.8 years for 50% of the female

population to become mature; Burgos et al. 2007; SEDAR 2010; SEDAR 2017), overfishing is a primary concern as such activity is likely to skew population demographics (size- and age-compositions) and reproductive ability of the population. Additionally, Red Grouper undergo sex reversal, which further results in skewed sex ratios under heavy fishing pressure; the largest fish are males and are selectively removed by the fishery (Huntsman et al. 1999; Coleman et al. 2000; Heppell et al. 2005). Red Grouper spawn in deep water (> 40 m; Sedberry et al. 2006; Burgos et al. 2007); if caught from these depths and subsequently released, mortality is high due to barotrauma from the resultant pressure changes. In addition, Red Grouper are larger in deep water and tend to be more sedentary with increasing depth, further increasing the vulnerability of males to fishing pressure (Burgos et al. 2007). Red Grouper have a minimum size limit and a spawning season closure in place to reduce fishing mortality. However, Red Grouper are also part of a multi-species fishery (snappers, other groupers, etc.), and so they are caught when not being targeted which increases the likelihood of regulatory discards and post-release mortality.

CONSERVATION ACCOMPLISHMENTS

The Red Grouper fishery off South Carolina is managed in federal waters by the SAFMC, which enacted several management measures to reduce fishing mortality. In the commercial fishery, a limited access snapper-grouper permit is required and there is a 200 lb gutted weight trip limit. There is a commercial and recreational minimum size limit of 20 inches (51 cm) T:. Red Grouper must be landed with the heads and fins intact to facilitate enforcement of regulations. Between January 1 and May 1, during the peak spawning period, there is a prohibition on recreational and commercial harvest and possession of Red Grouper and other shallow water groupers. Red Grouper harvest off the coast of North Carolina and South Carolina stays closed until June 1 while the fishery reopens May 1 off Georgia and Florida. Outside of the spawning season closure, longline use in areas shallower than 50 fathoms is prohibited and traps and trawls are banned for commercial use for Red Grouper. The recreational fishery is limited to 3 groupers (mixed species) per person per day including Gag, Black Grouper, Red Grouper, Scamp, Red Hind, Rock Hind, Coney, Graysby, Yellowfin Grouper, and Yellowmouth Grouper. Vessels fishing for snapper grouper species must have a descending device on board. In addition, the SAFMC established Marine Protected Areas (MPA) in the region in 2009 that are closed to bottom fishing year-round (SAFMC 2024).

CONSERVATION RECOMMENDATIONS

- Continue to evaluate the effects of fishing and management plans, especially MPA's that prohibit bottom fishing, on Red Grouper stocks.
- Initiate studies of the behavior, genetics and physiology of sex reversal, maturation and migration, timing of sex reversal, and movement of fish to spawning sites for Red Grouper.

- Establish a pre-recruit index of abundance by monitoring the abundance of juvenile Red Grouper off the southeast U.S. Atlantic Coast. Such an index could be used to evaluate recruitment success and predict trends in adult population size.
- More research on discard mortality, particularly the use and effect of descender devices, would benefit stock assessments of South Atlantic reef fishes.
- Evaluate the spatial structure of the stock along the southeast U.S. Atlantic coast to determine how to best assess and management Red Grouper since they display a disjunct distribution from North Carolina to Florida.

MEASURE OF SUCCESS

Measurement of management success is difficult in the absence of long-term historical data that precede expansion of the fishery in the 1970s; however, the SERFS program has monitored relative abundance, population demographics, and reproductive behavior of reef fish, including Red Grouper, since 1990. This survey can serve as an early warning sign of population recovery based on changes in abundance, size structure and sex ratio well before a full assessment can be conducted.

Red Porgy

Pagrus pagrus

Contributors:
Stephen Long (SCDNR) & Tracey Smart (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Red porgy, informally known as "Pinky" and commercially advertised as Pink Snapper, is a member of the family Sparidae within the order Perciformes (Page et al. 2023). They possess a known maximum total length (TL) of approximately 91 cm, maximum age of 25 years old, and world record weight of approximately 7.7 kg (SEDAR 2020, Carpenter 2002, IGFA 2024). Red porgy coloration is reddish silver, with yellow and blue hues, and a yellow pigmented eye (Carpenter 2002). Adult red porgy possess an oblong, compressed body with 11 to 12 spines and 10 soft rays along their dorsal fin, an anal fin with 3 spines and 8 soft rays, and a forked caudal fin (Carpenter 2002). They have molariform teeth and a rounded posterior nostril (Goldman et al. 2016, Manooch and Hassler 1978). Red porgy are protogynous hermaphrodites, starting life as female and transitioning to male at 3.7 years of age (377 mm TL; Daniel 2003). Spawning red porgy off the southeast U.S. Atlantic coast (i.e. NC, SC, GA, and FL) have been observed from January to April, although there is some variability among regional studies (Daniel 2003, Sedberry et al. 2006).

Status

Recreational and commercial landings of red porgy in the SEUS Atlantic peaked in the 1970s and 1980s, followed by a decline (NOAA Fisheries 2024). An assessment in the early 2000s determined the stock was overfished with overfishing occurring (SEDAR 2002). Subsequent updates and assessments continued to characterize red porgy as overfished and overfishing occurring through 2017 (SEDAR 2020). Despite these findings, IUCN characterizes Red Porgy as Least Concern.

POPULATION SIZE AND DISTRIBUTION

Red porgy are found from New York to Argentina, including the Gulf of Mexico and excluding Bermuda and the Caribbean, along the mid-to-outer continental shelf in hard bottom habitats (Carpenter 2002, Bubley et al. 2023). They occur at depths of 9-280 m worldwide (Carpenter 2002, Manooch 1976). Genetic data supports the distinction of a red porgy stock in the southeast US (SEUS) Atlantic (Ball et al. 2003, Ball et al. 2007). Red porgy off the SEUS inhabit hard bottom habitats along the mid-to-outer continental

shelf and shelf-break and are more recently concentrated in the middle to northern portion of the region (Figure 1; Grimes et al. 1982, Bacheler et al. 2016, Smart et al. 2020, Vecchio et al. 2024). A fishery-independent trap survey supports a continued decline of abundance in the region for all life stages encountered (Figure 2; Vecchio et al. 2024) and more specifically a reduction in recruitment of young fish in the region (Smart et al. 2020).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

SEUS Atlantic red porgy occupy natural and artificial reefs including wrecks, hard bottom, live bottom (e.g. sponges, corals), and habitats that provide bathymetric relief (e.g. rocky outcrops, rocky ledges), in temperatures of 57-77° F (Grimes et al. 1982, Harris and McGovern 1997, Manooch and Hassler

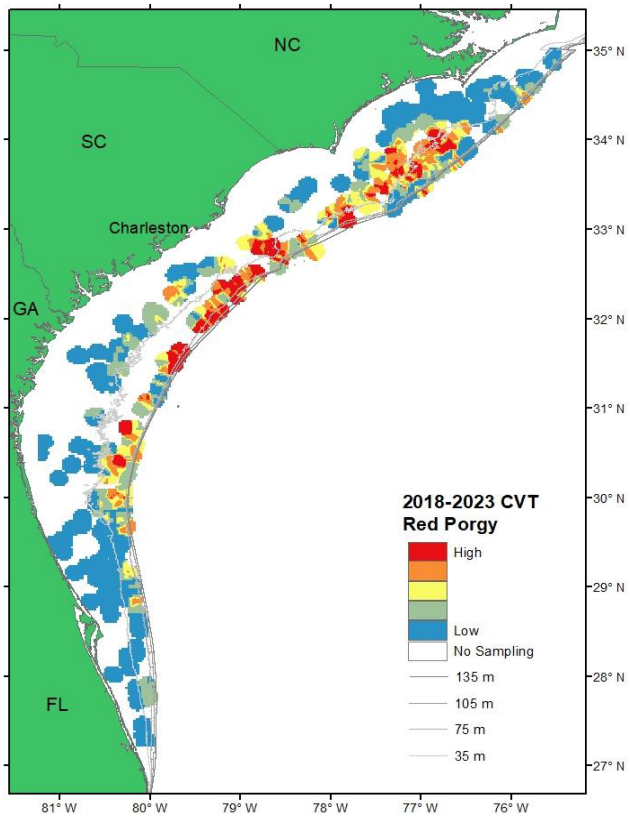

Figure 1: Figure from Vecchio et al. (2024) displaying Southeast Reef Fish Survey (SERFS) distribution of Red Porgy catches in Chevron Video Traps (CVTs) from 2018-2019 and 2021-2023, where red indicates the highest catches and blue to lowest.

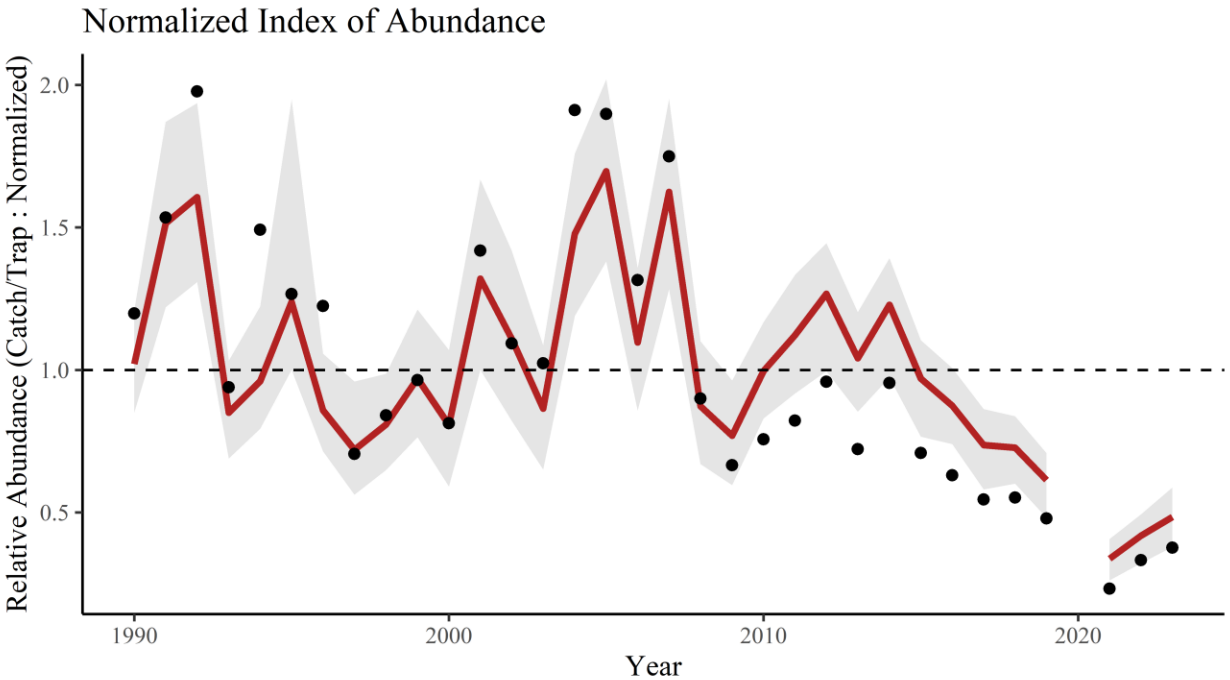

Figure 2: Figure from Vecchio et al. (2024) displaying index of abundance of Red Porgy over time from Southeast Reef Fish Survey (SERFS) Chevron Video Traps (CVTs).

1978). Juvenile Red Porgy are found in shallower depths, while mature Red Porgy are more frequently encountered in deeper water (Harris and McGovern 1997, Smart et al. 2020). Red Porgy are a relatively sedentary or non-migratory species and have a wide-ranging diet (Daniel 2003, Goldman et al. 2016, Harris and McGovern 1997, Manooch and Huntsman 1977).

CHALLENGES

Red porgy are part of a multi-species fishery, both recreationally and commercially. There is currently a spawning season closure, minimum size limits, bag and trip limits, and an annual catch limit for this species to reduce fishing mortality. However, the population continues to decline and has shown poor recruitment in the last decade. Because of the multi-species nature of the fishery, red porgy may still be caught and discarded during closures or because of size, which may lead to post-release mortality. Additionally, as protogynous hermaphrodites, red porgy males may be preferentially removed from the population due to their larger size, potentially leading to sperm limitation and reduced reproductive output. The drivers of low recruitment are currently unknown.

Red porgy in the SEUS Atlantic have been considered overfished since the mid-1990s and additionally, undergoing overfishing since 2000 (SEDAR 2020). This is a concern, as regardless of numerous regulation measures, the fishing pressure it has historically sustained has had a lasting effect (i.e. age composition bias and altering the reproductive ability of the population). Furthermore, at this time, no positive effect has been observed of the SAFMC Marine Protected Areas (MPAs) effectiveness on red porgy abundance (Pickens et al. 2021).

CONSERVATION ACCOMPLISHMENTS

The South Atlantic Fishery Management Council (SAFMC), which manages the stock, established a rebuilding timeframe in 2000. In the commercial fishery, a limited access snapper-grouper permit is required and there is a 15 fish trip limit. There is a commercial and recreational 14 in total length minimum size limit. Between January 1 and May 1, there is a prohibition on recreational and commercial harvest during their peak spawning period. Outside of the spawning season closure, longline use in areas shallower than 50 fathoms is prohibited and traps and trawls are banned for commercial use for Red Porgy. Recreational fisherman are limited to 1 fish per person per day. Vessels fishing for snapper-grouper species must have a descending device on board to reduce post-release mortality. In addition, the SAFMC established Marine Protected Areas (MPA) in the region in 2009 that are closed to bottom fishing year-round, however no positive effect has been observed for red porgy abundance (Pickens et al. 2021).

CONSERVATION RECOMMENDATIONS

- Initiate stock assessment update(s) by 2030.
- Re-assess the effectiveness of MPAs, as needed.
- Continue to monitor via fishery-dependent and fishery-independent surveys.
- Pursue non-lethal methods of determining age or reproductive condition
- Conduct a discard mortality study in conjunction with ongoing surveys.
- Investigate drivers of recruitment, including possibility of sperm limitation

MEASURES OF SUCCESS

The SCDNR Coastal Research Section monitors the economically important Snapper and Grouper fisheries off the SEUS Atlantic through the Southeast Reef Fish Survey (SERFS). The Survey, along with Federal partners, collects data on the relative abundance, population demographics, and reproductive state of these fish. With the information collected, the program can observe long-term trends and provide data needed by decision-makers for management regulations. The SERFS data can also serve as an early warning system for if management is leading to recovery or if there is a change in recruitment.

Red Snapper

Lutjanus campechanus

Contributors 2015:
Byron White (SCDNR)

Revised 2025:
Joseph Evans (SCDNR) & Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Red snapper, *Lutjanus campechanus*, is a large, fast-growing, early maturing, and long-lived member of the family Lutjanidae, themselves a member of the order Perciformes (Page et al. 2023). Maximum adult total length (TL) is 1.0 m (Smith 1997) with a maximum weight of 22.8 kg (IGFA 2001). The species has been aged to 51 years in the region of the Atlantic Ocean off the coast of the Southeastern U.S (SEDAR 2021). The species is gonochoristic, with separate males and females that remain the same sex throughout their life. The age at 50% maturity is 1.3 years (SEDAR 2021).

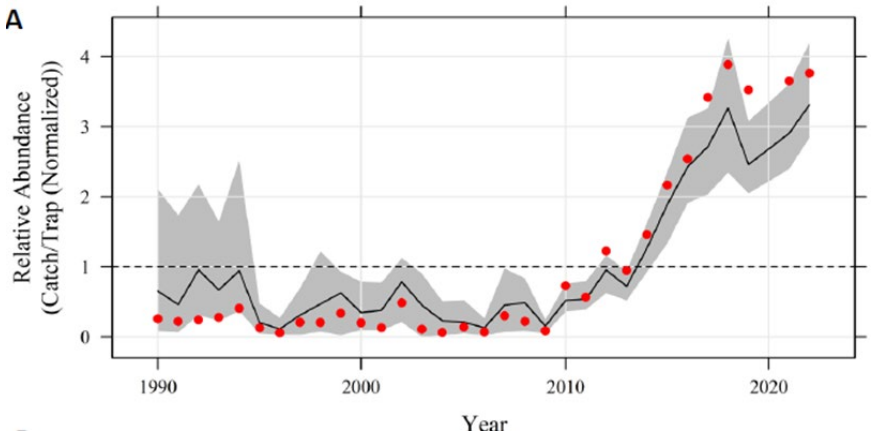
The Red snapper's body has a sloped profile, medium-to-large scales, a spiny dorsal fin, and a laterally compressed body. Red snapper have short, sharp, needle-like teeth. Coloration is light red, with more intense pigment on the back with a red eye iris. Individuals possesss 10 dorsal spines, 14 dorsal soft rays, 3 anal spines, and 8-9 anal soft rays. Red snapper under 30 to 35 cm TL frequently have a large, dark spot on the upper sides, located below the anterior soft dorsal rays.

Status

The latest stock assessment for Red Snapper off the Southeastern United States Atlantic (SEUSA) coast indicated the stock continued to be overfished and overfishing was occurring through 2019 (SEDAR 2021). In addition, IUCN lists the species as Vulnerable throughout the species range.

POPULATION SIZE AND DISTRIBUTION

Red snapper occur from North Carolina to the Yucatan Peninsula, including the Gulf of Mexico (Nelson and Manooch 1982; Manooch and Potts 1997) where they are commonly found near reef habitats consisting of limestone outcroppings, live-bottom habitat (Powles and Barans 1980), gas and oil platforms, and artificial reefs. Red snapper occur in depths ranging from a few meters as juveniles to 210 m as adults (Camber 1955; Bradley and Bryan 1975). On the continental shelf off South Carolina, they have been collected at depths from 7-74 m (Figure 1). The species is regularly encountered in the Southeast Reef Fish Survey (SERFS) using chevron trap gear, and total abundance has increased since the beginning of the time series (Figure 2).



HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Adult red snapper occupy natural and artificial reefs including wrecks, hard bottom, live bottom, shelf-edge scarps, ledges, sponge/coral habitat, and other habitats that provide vertical relief above the bottom. Juvenile red snapper under one year can be found on mud or sand flats in shallow coastal waters (Stender and Barans 1994; SEAMAP 2000). In the Gulf of Mexico, red snapper juveniles are frequently taken as by-catch in shrimp trawls, but are rarely encountered by these gears in the waters of the SEUSA (Bradley and Bryan 1975; Gutherz and Pellegrin 1988).

CHALLENGES

Red snapper are considered to be overfished and are experiencing overfishing in the SEUSA (SEDAR 2021). The primary driver of overfishing in recent years has been recreational discards because of high recreational fishing effort, a recovering (but not yet recovered) population, and the aggressive nature of the species when found on mixed-species reefs. Red snapper are frequently caught in deep water, 30+ m (98+ ft.); if caught from these depths and subsequently released, mortality can be > 20% due to barotrauma associated with pressure changes. In 2022 the South Carolina General Assembly passed legislation that allows for year-round harvest of up to two red snapper per person per day with a minimum size of 20 inches total length in state waters (SC Bill -S.980). However, due to the relative low numbers of large fish in state waters and sparse enforcement ability, it can be difficult to discern whether a fish is being landed legally.

Figure 1: Distribution map of Red Snapper catch from Chevron Traps in 2018-2023.

CONSERVATION ACCOMPLISHMENTS

The red snapper fishery off South Carolina is managed in federal waters by the South Atlantic Fishery Management Council (SAFMC 2013). In the commercial fishery, a limited access permit is required. There is currently a prohibition on recreational and commercial harvest and possession of Red Snapper in federal waters, except a brief open season that is announced annually by SAFMC. In addition, the SAFMC established Marine Protected Areas (MPA) in the region in 2009 that are closed to bottom fishing year-round (SAFMC 2013). As of July 2020, all recreational fishing boats were required to have a descender device rigged and ready to help mitigate discard mortality. The SEDAR73 stock assessment for red snapper in 2021 provided updated information as to the status of the population in the region. This assessment estimated that, since 2010, total abundance and spawning stock have been increasing at a relatively rapid rate, showing substantial progress toward rebuilding (Figure 3). Despite overfishing, this increase in abundance has been stimulated by higher-than-average recruitment.

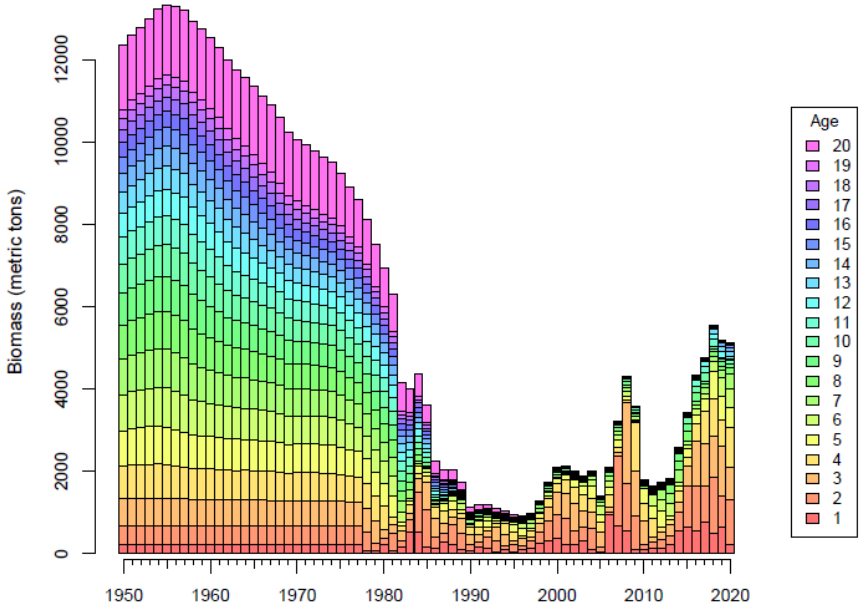


Figure3: Estimated biomass at age at start of year (SEDAR 2021).

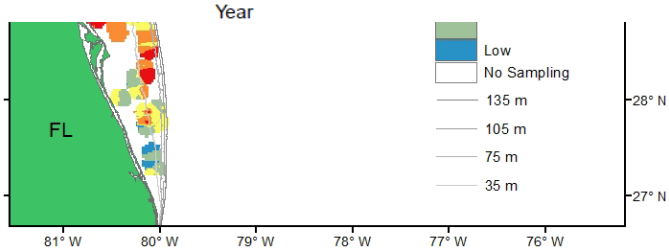

Figure 2: Chevron trap index of abundance for Red Snapper

CONSERVATION RECOMMENDATIONS

- Continue to evaluate the effects of management plans, including MPA's, on red snapper stocks.
- Continue to monitor red snapper populations via fishery-independent sampling.
- Initiate studies of the early life history, juvenile habitat preference, and spawning locations.
- More research on discard mortality, particularly the use and effect of descender devices, will improve estimates of discard mortality.

MEASURES OF SUCCESS

The SERFS program that annually monitors relative abundance, population demographics and reproductive status of reef fishes can detect changes in those parameters that result from management efforts. Measurement of management success is difficult in the absence of long-term historical data that precede expansion of the fishery in the 1970s; however, SERFS monitoring can detect changes in relative abundance and population demographics that respond to fishing pressure or management regulations. Increases in abundance, and size- and/or age-expansion in the population would indicate positive trends in the population.

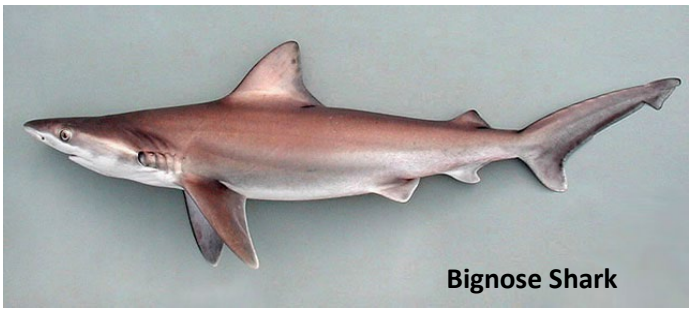
Ridge-back Shark Guild

Sandbar Shark *Carcharhinus plumbeus*
Dusky Shark *Carcharhinus obscurus*
Bignose Shark *Carcharhinus altimus*

Contributors (2025):
Bryan Frazier (SCDNR)



DESCRIPTION

Taxonomy and Basic Description

The sandbar, dusky, and bignose sharks are morphologically similar members of the family Carcharhinidae. All three species have a ridge between the first and second dorsal fin which is used for management purposes to define species that may not be taken recreationally. All are placentally viviparous (bear live young with a maternal connection) and are thought to be more sensitive to commercial and recreational harvest than other Carcharhinids. Sandbar sharks can be distinguished from dusky and bignose sharks using several characteristics. The dorsal fin on a dusky shark is smaller than bignose and sandbar sharks and originates behind the free rear tips of the pectoral fins, whereas the origin is over the pectoral fins in sandbar and bignose sharks. The sandbar shark has a shorter snout than a bignose, with bignose snouts being equal and greater than their mouth width; further, the dorsal fin on bignose sharks is smaller than found on sandbars.

Sandbar Shark

The sandbar shark is the most common member of the group and is a moderate sized shark reaching a maximum reported total length (TL) of 234 cm (Castro 2011). There is considerable debate on the reproductive periodicity of sandbar sharks with research indicating a biennial or triennial reproductive periodicity with an average brood size of 8 pups born in May to June at ~ 60 cm TL (Driggers et al. 2017). It is possible that both reproductive periodicities are present within the population as energy stores may control whether a female has a litter every two or three years. Maximum estimated age is 31 years with 50% maturity estimated at 13.1 for males and 14.1 for females (Hale and Baremore 2013). Tag and recapture data suggest sandbar sharks likely live longer than the reported maximum estimated age.

Bignose Shark

Bignose sharks reach slightly larger lengths than sandbar sharks, with a maximum reported length of 282 cm TL. The life history of this species is poorly understood; to date, no peer reviewed studies of age and growth or reproduction of this species in the western North Atlantic exist. Castro

(2011) reported a size at birth of 75 cm TL, with an average brood size of 7.

Dusky Shark

The dusky shark is the largest of these three species and is the largest member of the genus *Carcharhinus* with maximum reported lengths of 384 cm TL. Dusky sharks have a triennial reproductive cycle with an 18 month gestation period. Dusky shark pups are much larger than sandbar and bignose shark pups with an average size at birth of 95 cm TL (average brood size of 7.1) (Castro 2011). The maximum estimate age of dusky sharks is 39 years (Natanson et al. 2014).

Status

The above-mentioned species are classified as large coastal sharks (LCS) and are managed as a complex by the National Marine Fisheries Service (NMFS). Due to their similar appearance, they are managed as a subgroup of "ridgeback sharks" and recreational retention of all species are prohibited. Commercial retention of sandbar sharks is allowed; however, only be commercial fisherman participating in a highly controlled research fishery. Commercial retention of dusky sharks and bignose sharks is prohibited. All three species were heavily fished both recreationally and commercially prior to the implementation of management. This fishing pressure led to significant declines in abundance for all three due to the relatively low reproductive output of these species. The sandbar shark stock status has been assessed several times with the most recent assessment finding the stock is overfished, but overfishing is not occurring (SEDAR 54). Dusky sharks have also been assessed several times with the most recent stock assessment indicating dusky sharks are experiencing overfishing, and the stock is overfished. Dusky sharks suffer from high at-vessel and post-release mortality when captured as bycatch, and despite the ban on landings, the post-release mortality experienced by the population may be of large enough magnitude to keep the population in an overfishing occurring stock status (SEDAR 21). The International Union for Conservation of Nature (IUCN) Red List lists both sandbar and dusky sharks as endangered with decreasing populations (Rigby et al. 2019; Rigby et al. 2021). Bignose sharks have never undergone a stock assessment, they are primarily captured as bycatch within the commercial pelagic longline fishery, and there are no estimates of at vessel or post-release mortality rates for the species. The IUCN considers bignose sharks threatened with decreasing populations (Rigby et al. 2020).

POPULATION SIZE AND DISTRIBUTION

All three species have a circumglobal distribution although bignose sharks have a patchy distribution (Ebert et al. 2013). In US waters sandbar sharks are common from New England to Texas, with individuals commonly migrating between the Gulf of Mexico and the US Atlantic. All life stages of sandbar sharks are found in SC waters with SC estuarine waters serving as a nursery are for sandbar sharks (Ulrich et al. 2007). While SCDNR surveys generate ample data on young of year sandbar shark recruitment (Figure 1) and abundance of all life stages (Figure 2), dusky sharks are rarely captured. Dusky sharks have a similar distribution to sandbar sharks in US waters; however, they are not typically

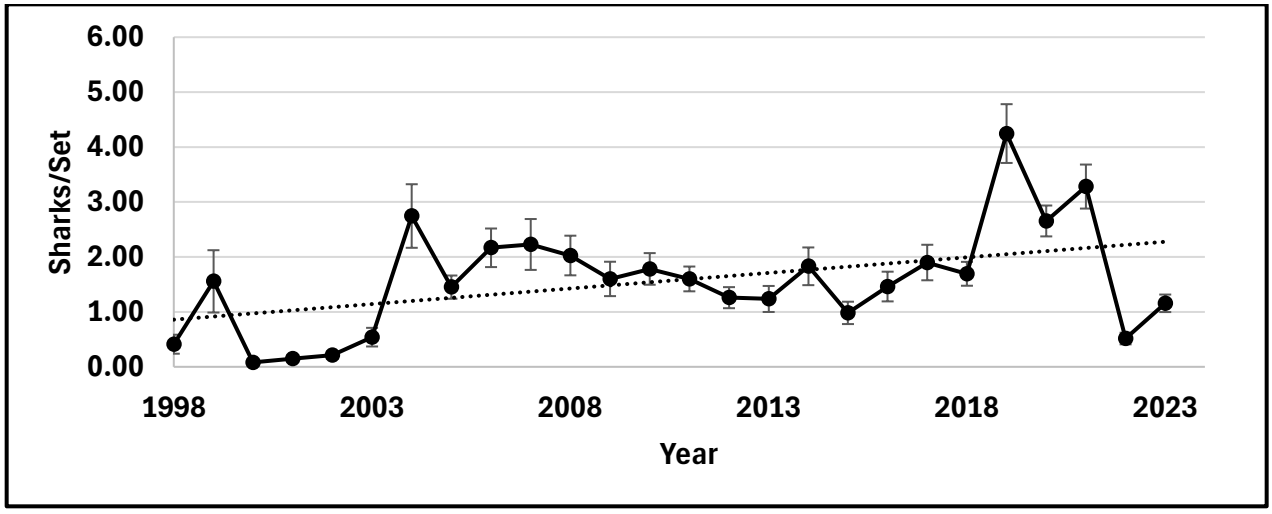


Figure 1. Catch per unit effort (sharks per set) of sandbar sharks from 1998 to 2023 in the South Carolina Cooperative Atlantic States Shark Pupping and Nursery Habitat Survey. Standard error is denoted by error bars. This survey primarily monitors recruitment of young of year sandbar sharks.

found in estuarine waters with young of year and juveniles preferring nearshore waters. Dusky sharks were more frequently observed in the early years of SCDNR monitoring; however, as the population was exploited, the populations center of abundance may have also shifted northward with most young of year and juvenile dusky sharks now found off of Maryland to North Carolina. Young of year dusky sharks are infrequently captured in SC waters, mature individuals are more commonly encountered in depths from 50 to 500 m. Off the US Bignose sharks are though to inhabit waters to a maximum depth of 840 m from Delaware to Florida, however they are rarely captured in fishery independent surveys and are considered data poor.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In South Carolina, young of year and juvenile sandbar sharks are commonly found in deeper sandy and muddy bottoms habitat in estuarine and coastal waters (Ulrich et al. 2007). While sandbar shark diet hasn't been formally quantified in South Carolina they are known to actively feed on a variety of bony fish (mostly benthic) before switching to larger teleosts and smaller elasmobranchs as large juveniles and adults (Shiffman et al. 2014). Adult sandbar sharks are primarily found in nearshore waters out to 100 m although they can be found in large abundance near the mouths of rivers and sounds. Port Royal Sound, St. Helena Sound, and Bulls Bay have been documented as primary nurseries for sandbar sharks.

Dusky sharks primarily utilize coastal to offshore waters. Young of year dusky sharks are infrequently observed in coastal SC waters; juveniles are rare. Adult dusky sharks can be found in coastal waters from 50m out to 500+ m, often associating with the shelf edge or live bottom habitats and gulf stream eddies. Little is known about habitat requirements for bignose sharks, as most catches are associated with pelagic longlines targeting swordfish.

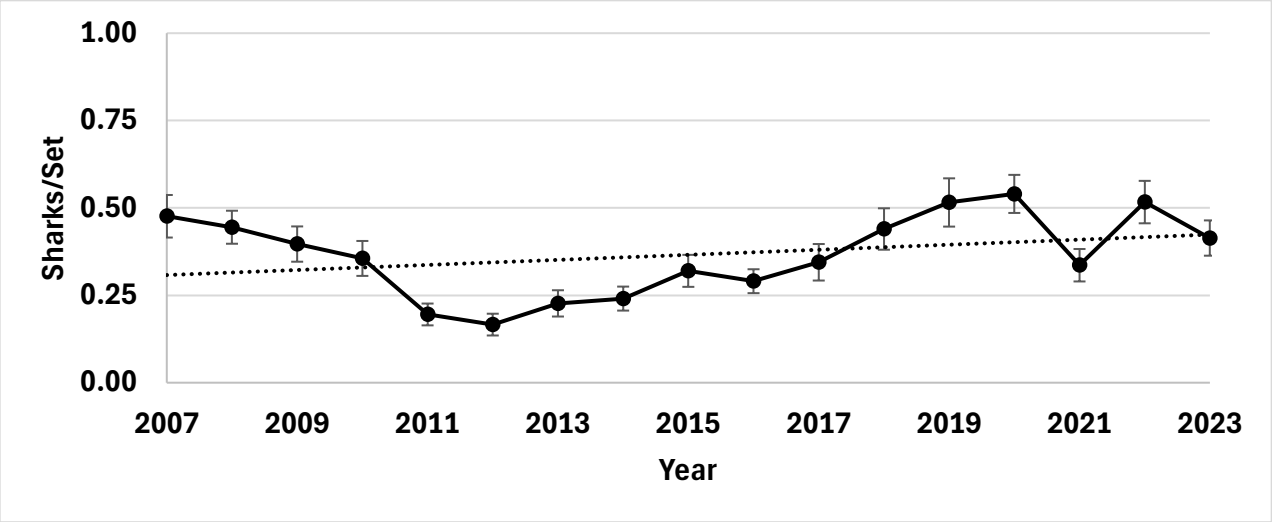

Figure 2. Catch per unit effort (sharks per set) of sandbar sharks from 2007 to 2023 in the South Carolina Coastal Longline Survey. Standard error is denoted by error bars. This survey monitors abundance of juvenile and adult sandbar sharks.

CHALLENGES

Large coastal sharks, specifically ridgeback sharks, have been shown to be the most affected species by the overfishing that occurred prior to implementation of a federal fishery plan for sharks. As such, these species are continuing to recover as their life histories only allow slow population growth. As such, they are particularly susceptible to fisheries interactions (i.e. bycatch and post-release mortality). As these species are easily confused it is imperative to promote safe handling and release of ridgeback sharks. In recent years, interactions between humans and sharks (in the form of depredation) has increased. These negative interactions have caused negative sentiment towards coastal sharks (in particular, sandbar sharks) potentially hampering recovery efforts of these species. Moving forward, it will be important to document as well as attempt to mitigate depredation of recreational and commercial catch by sharks.

CONSERVATION ACCOMPLISHMENTS

There are no conservation accomplishments specific to this species at this time.

CONSERVATION RECOMMENDATIONS

- Continue to monitor the stock status of ridgeback sharks within SC waters through fishery-independent methods, primarily COASTSPAN, and the Coastal Longline Survey.
- Increase collection of species specific-data to allow for future species-specific stock assessments.
- Implement genomic studies using Close-Kin Mark Recapture methods to estimate population sizes of ridgeback sharks (sandbar sharks in particular).
- Assess philopatry and fine-scale population structure in sandbar sharks
- Continue to study reproduction in sandbar sharks to define reproductive periodicity.
- Conduct large scale tagging of sandbar sharks throughout their range to better understand migration patterns of juveniles and adults.

- Develop methods of mitigating or preventing depredation or damage to recreational and commercial catch and gear.
- Partner with other federal, university and other southeastern states to increase understanding of the life history of species lacking data.
- Improve the public's understanding of the importance of sharks in the ecosystem through outreach activities such as school programs, providing story opportunities for media, and educational brochures.
- Continue to educate the public on the importance of species identification of sharks to ensure undersized and prohibited sharks are not landed.
- The primary action at the state level via law enforcement partnering is to insure adequate compliance with regulatory actions implemented through the federal management plan and subsequent amendments.

MEASURE OF SUCCESS

One of the most important measures of success will be the continued recovery of sandbar sharks and the recovery of dusky sharks, which seem to be lagging behind other coastal shark populations who are fully recovered or recovering (SEDAR 21). Regional management efforts to maintain healthy, sustainable populations of ridgeback sharks will require active participation from South Carolina due to its importance as nursery habitat. Maintaining ongoing monitoring programs to continue indices of abundance and trends over time is critical to the success of accurate stock assessments.

Sand tiger

Carcharias taurus

Contributors:
James Kilfoil and Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The sand tiger shark (*Carcharias taurus*), also known as the grey nurse shark or spotted raggedtooth shark, is a globally distributed species, occurring in all oceans except for the eastern Pacific (White et al. 2006, Ebert et al. 2013, SEAFDEC 2016, NFRDI 2017, White et al. 2017, Psomadakis et al. 2019, Tyabji et al. 2020). Characterized by a robust and bulky body, sand tigers reach a maximum length of approximately 325 cm (10.4 feet) total length (TL). It is distinguished by its two dorsal fins of nearly equal size, with the first dorsal fin situated just in front of the pelvic fin bases. Its caudal fin is short and asymmetrical, featuring a pronounced subterminal notch and a strong ventral lobe. The shark has five medium-sized gill slits positioned in front of the pectoral fin bases, lacks gill rakers, and possesses a short snout with small eyes that lack nictitating membranes.

The sand tiger shark's coloration includes a light grey-brown dorsal side with pale, yellowish blotches and a white underside. It has long, pointed teeth with small spine-like cusps on either side, and its body is typically adorned with reddish-brown spots, primarily on the posterior portion. The species' mouth extends beyond its eyes, and its caudal fin exhibits a long upper lobe, contributing to its strong heterocercal structure.

Sexual maturity in sand tiger sharks occurs at different sizes and ages for males and females. Males typically reach maturity at 190–200 cm TL, around 6 to 7 years of age, while females mature at 220–235 cm TL, between 9 and 10 years of age (Gilmore et al., 1993; Lucifora, 2003; Ebert et al., 2013; Weigmann, 2016). Reproduction in sand tiger sharks is adelphophagic viviparous. Females produce an average litter of 1–2 pups (due to intrauterine cannibalism), with a biennial reproductive cycle, although some studies suggest the cycle could be annual or triennial in certain regions (Cliff, 1989; Branstetter and Musick, 1994; Henningsen et al., 2004; Dicken et al., 2006; Gilmore et al., 2005; Bansemer and Bennett, 2009). The size at birth ranges from 85 to 105 cm TL. Age data for sand tigers have been validated to at least 40 years, and has an estimated 24.8 year generation length (Lucifora, 2003; Passerotti et al., 2014; Jakobs and Braccini, 2019).

Both juvenile and adult sand tiger sharks are generalist predators. Their diet includes a variety of prey such as bony fish, crustaceans, squids, skates, and small sharks. Common prey items are summer flounder, monkfish, sea robins, scup, spot, bluefish, butterfish, and tautog (Branstetter, 2002). Due in part to their size and demersal nature, sand tigers have few natural predators, though cannibalism has been observed (Branstetter, 2002).

Status

The sand tiger shark is globally recognized as Critically Endangered on the IUCN Red List (Rigby et al., 2021). The species has experienced a dramatic decline across much of its range, with populations in the southwest Atlantic and Mediterranean having decreased by over 80% over the past century, and in some areas, few or no individuals remain. In the western North Atlantic Ocean, estimates suggest a decline of 30–49% (Musick et al., 1993; Ha, 2006; Rigby et al., 2021). Conversely, in regions such as eastern Australia and South Africa, there are signs of population recovery following the implementation of management measures aimed at reducing fishing mortality. Overall, the sand tiger shark is thought to have experienced a global population reduction exceeding 80% over the past 74 years, which corresponds to three generation lengths. This severe decline underscores its critical conservation status.

POPULATION SIZE AND DISTRIBUTION

Sand tiger sharks are widely distributed and not restricted to any specific area, making them cosmopolitan. They are found across the Indian and Pacific Oceans and in the western North Atlantic Ocean, stretching from the Gulf of Maine to Florida and the northern Gulf of Mexico (Bigelow & Schroeder, 1948). In the western North Atlantic Ocean, sand tiger sharks are more abundant in warmer months, particularly in Delaware Bay, off North Carolina, and along Florida's east coast throughout the year. Adult sharks are commonly associated with wrecks off North Carolina, while juveniles are found from Massachusetts to North Carolina, predominantly in estuarine and coastal nursery habitats from late spring through October, with peak numbers in June (Bigelow & Schroeder, 1948; McCandless et al., 2007).

Adult sand tigers are present off Florida and in the Gulf of Mexico year-round, and they migrate as far north as the Gulf of Maine during the summer and fall (Branstetter, 2002; Carlson et al., 2009). Genetic research identified at least five distinct subpopulations of sand tiger sharks: western North Atlantic Ocean, Japan, west Australia, east Australia, and South Africa, with the latter possibly overlapping with Brazil and the Mediterranean (Stow et al., 2006; Ahonen et al., 2009; Fioravanti et al., 2019). These populations show low migration rates between regions and are genetically discrete from one another (Ahonen et al., 2009; Fioravanti et al., 2019).

The most comprehensive and recent population status assessment of sand tigers was conducted by Rigby et al. (2021), as a part of their IUCN Red Llist Assessment. The results of this assessment are summarized below.

In the IUCN Red List Assessment used data from three major sources: 1) western North Atlantic Ocean (Carlson et al. 2009, J. Carlson and C. McCandless unpubl. data 2020); (2) Western Indian Ocean (M. Dicken and H. Winker unpubl. data 2020); and, (3) east Australia (Reid et al. 2011). Trends in each data stream were analyzed covering three generations lengths within a Bayesian state-space framework (Sherley et al. 2020; Winker et al., 2020). Using this technique, Rigby et al., (2021) quantified the annual rate of change, a median change over three generation lengths, and the probability of the most likely IUCN Red List category percent change over three generation lengths. Based on these analyses, sand tiger sharks seem to be experiencing a decline throughout their entire range due to exploitation, with the exception of Western Australia. However, in areas where management measures that restrict retention or reduce fishing mortality have been implemented for some time—such as in the western North Atlantic Ocean, South Africa, and Eastern Australia—there are signs of potential recovery. The Eastern Australian subpopulation is estimated to have decreased by over 80% over the past three generations (74 years), while the western North Atlantic Ocean and South African subpopulations are believed to have declined by 30–49% over the same period. The species is suspected to be Critically Endangered in the western South Atlantic Ocean, Mediterranean, and Arabian Seas regions, with reductions exceeding 80% over the past three generations. In Southeast Asia and West Africa, where fishing pressure is high throughout their spatial and depth range, similar severe declines are suspected. Overall, it is believed that the sand tiger shark has experienced a population reduction of over 80% over the last three generations (74 years) due to exploitation levels.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Sand tiger sharks are primarily coastal and are typically found in waters from the surf zone down to approximately 23 meters deep. Their global range includes warm and temperate seas, excluding the eastern Pacific. They can also inhabit shallow bays, coral reefs, and extend to depths of 183 meters on the continental shelf. While they generally reside near the ocean floor, they have been observed throughout the water column.

In the western North Atlantic Ocean, sand tiger sharks occupy a variety of coastal habitats, including estuaries, nearshore areas, natural hard bottoms, artificial reefs such as shipwrecks, and the continental shelf. Their habitat preferences can vary based on factors like life stage, sex, and seasonal changes, making it crucial to understand the role of each habitat type.

Recent studies suggest that sand tiger sharks give birth along the Southeastern U.S. coast, with continental shelf waters off North Carolina playing a significant role in mating, gestation, and possibly pupping (Marens, 2021; Wyffels et al., 2022). They are reported to be present year-round in North and South Carolina coastal waters, frequently associating with artificial reefs and shipwrecks (Farmer, 2004; Schwartz et al., 2013; Paxton et al., 2019, 2020; Marens, 2021).

On the U.S. East Coast, certain areas are vital for various stages of sand tiger shark development, with some individuals demonstrating notable site fidelity. Kneebone et al. (2012) pinpointed key summer nursery sites for juvenile sand tigers in Plymouth, Kingston, and Duxbury Bay, Massachusetts. Their telemetry study from 2008 to 2011 showed that juveniles remained in these regions as late as October (Kneebone et al., 2013, 2014). Additionally, tagged sharks were tracked from the Gulf of Maine to Cape Canaveral throughout the year. While summer residency (May–October) was prevalent among these sharks in New England, juveniles were also observed off North Carolina and Florida during the winter months (November–April). Both juvenile and adult sand tigers have been known to return consistently to Delaware Bay, where they form aggregations based on maturity and show distinct habitat preferences within the bay and nearby coastal areas (Teter et al., 2015; Haulsee et al., 2016; Kilfoil et al., 2017; Haulsee et al., 2018; Roose et al., 2022).

CHALLENGES

The sand tiger shark's life history traits—such as slow growth, delayed sexual maturity, and low reproductive rates—render it particularly vulnerable to population declines (Goldman et al., 2006; Ha, 2006; Rigby et al., 2021). These characteristics, combined with ongoing bycatch and targeted catch-and-release fishing pressures in the U.S. (Kneebone et al., 2013; Kilfoil et al., 2017) and globally (Dicken et al., 2006; Lucifora et al., 2009), exacerbate the species' risk of decline (Carlson et al., 2009).

Sand tiger sharks face fishing pressure throughout their range, being caught as both target and bycatch in artisanal, recreational, and industrial fisheries using various methods such as longlines, gillnets, and trawls. They are often retained for their meat and fins, unless regulations prevent this. However, at-vessel mortality is reported as zero for demersal longlines, and the species shows high survival rates when released from longlines and rod-and-reel gear (Carlson et al., 2009; Kneebone et al., 2013; Ellis et al., 2017; Kilfoil et al., 2017). A recent vulnerability assessment rated sand tiger sharks as "High" in terms of biological sensitivity, climate exposure, and overall vulnerability (Hare et al., 2016). Additionally, their preference for inshore coastal environments makes them susceptible to habitat loss and degradation due to pollution, coastal development, and climate change.

CONSERVATION ACCOMPLISHMENTS

Species-specific protections for sand tiger sharks have been implemented in various countries and regions. In the United States, the species was listed as prohibited under the Fishery Management Plan for Atlantic Sharks in 1997 (Carlson et al., 2009). Several states have since adopted similar regulations. Additionally, the National Marine Fisheries Service (NMFS) identified the sand tiger as a candidate for listing under the Endangered Species Act (ESA) due to concerns over its low productivity and declines in abundance attributed to fishing pressures. On April 15, 2004, NMFS introduced a Species of Concern list, which included the sand tiger shark among other species, outlining factors considered for such designations (69 FR 19976). Although this status highlighted conservation concerns, it did not confer legal protection under the ESA and has since been discontinued. Other U.S. management strategies aimed at reversing the decline of sand tiger sharks include designating certain areas as Essential Fish Habitat (EFH) and Habitat Areas of Particular Concern (HAPC) within their range (NMFS, 2009, 2017).

CONSERVATION RECOMMENDATIONS

- Enacted species-specific legislative protections throughout range
- Increase studies of movement and habitat utilization to identify potential additional Habitat Areas of Particular Concern
- Explore gear modification to reduce bycatch and deleterious aspects of landing (e.g., gut hooking due to gulp-feeding mechanism)
- Increased capacity building throughout range and ongoing training to increase enforcement of existing protections
- Increased catch-monitoring to improve understanding of population trends
- Use new methods to determine census size such as close-kin mark recapture studies.
- Determine fine-scale population structure of sand tiger sharks in US waters.
- Explore non-lethal methods of age estimation to allow modeling of growth for the population.

MEASURE OF SUCCESS

- Decreased uncertainty in population trend estimates
- Reduced levels of bycatch and unwanted interactions with fisheries
- Potential increases in protected areas (Essential Fish Habitat, nurseries, spawning aggregations)

DESCRIPTION

Taxonomy and Basic Description

Scamp and yellowmouth grouper are part of the family Epinephelidae, themselves a part of the order Perciformes (Page et al. 2023) These species share a similar appearance that can be difficult to distinguish and along with the overlapping range throughout the Southeast United States (SEUS) presents a significant potential for misidentification (Burton et al. 2014). The high risk of misidentification in commercial and recreational landings compelled the SEDAR 68 Stock ID Workshop Participants and the Snapper Grouper Advisory Panel to recommend evaluating the two in a single stock assessment (SEDAR 2020). Following this logic, the two are combined here.

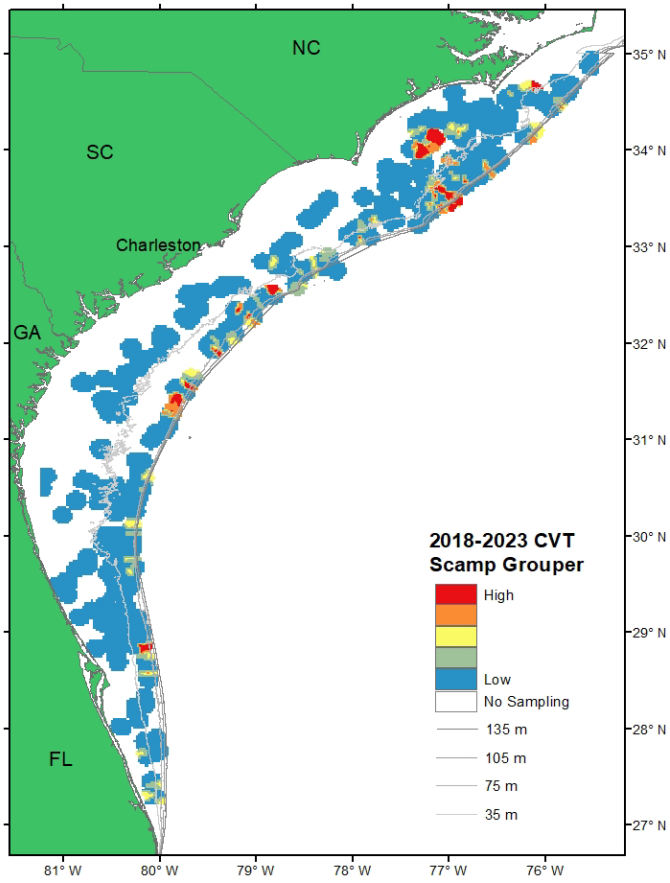
Both scamp and yellowmouth grouper are considered small to medium sized groupers. Yellowmouth grouper generally do not get as large as scamp, with a maximum size of approximately 30 inches and 20 lbs (SAFMC 2023). Scamp reach a maximum size of approximately 43 inches and 36 lbs (SAFMC 2023). Scamp are grayish brown in color with darker spots that appear blotched (sometimes described as "cat's paw" pattern) or lined. The corners of the mouth may appear slightly yellow, while the "broom-like" or raggedy appearance of the tail is different than that of other groupers (SEDAR 2020). Yellowmouth grouper are tan to brown with dark spots on the head and body. Like scamp, the corners of the mouth are yellow and there may also be yellow coloration around the eyes and at outer edges of the fins. The caudal fin has a similar filamentous appearance as scamp, but with minor differences that can be difficult to distinguish. Another indicator between species is the anal fin of adult yellowmouth grouper are typically more rounded than adult Scamp.

Their diets are similar, eating mainly fish and crustaceans. Both display behavioral color changes and are protogynous hermaphrodites (Burge et al., 2012; Gilmore and Jones, 1992). Scamp spawn from February to August with a peak from March to April, with spawning parameters having a dome-shaped relationship with age and size (Gamboa-Salazar et al., 2020). Yellowmouth Grouper are thought to spawn throughout the year, with peak from April to May (Bullock and Murphy, 1994). Results from the combined assessment indicate at least 50% of females from these species achieve reproductive maturity when they are close to 3 years of age (~15 inches total length), they transition

to males at about 10 years of age, and these species can reach a maximum age of 34 years (SEDAR 68, 2020).

Status

The combined assessment of these two species in the Atlantic waters off the southeastern U.S. determined the population in the South Atlantic region was overfished, but that overfishing was not occurring (SEDAR 2022). There is currently a commercial and recreational fishery for these species, with landings declining in both since the early 2000's (NOAA Fisheries 2024; pers. comm. from the National Marine Fisheries Service, Fisheries Statistics Division).



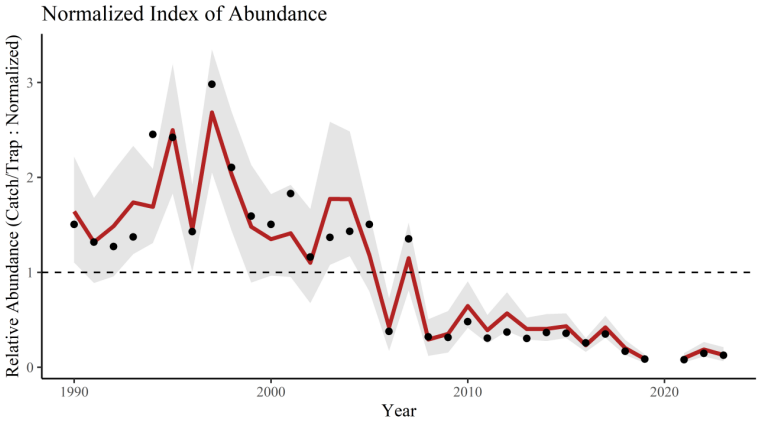


Figure 1: Distribution map of scamp catch from SERFS from 2018-2023 (excluding 2020).

POPULATION SIZE AND DISTRIBUTION

Scamp and yellowmouth grouper can be found along the Atlantic Coast of the US from North Carolina to Key West, FL, and throughout the Caribbean. Scamp's range further extends into the Gulf of Mexico to the Campeche Banks, while yellowmouth grouper's range extends further south to Brazil (Burton et al., 2014; Heemstra and Randall, 1993; Smith, 1978). The spatial distribution of scamp and yellowmouth grouper catches for the Southeast Reef Fish Survey (SERFS) is highest in the central to northern portion of the survey's sampling region (Fig. 1), which is also the northern end of geographical distribution for these species (Vecchio et al., 2024). Yellowmouth Grouper are seen by the survey but far less frequently.

Like many species in the region, scamp and yellowmouth grouper appear to be experiencing a decline in abundance and catch rates. Indices of abundance prepared annually by the SERFS using Chevron Traps indicate declining catch since 2007 (Fig. 2; Vecchio et al., 2024). Yellowmouth grouper catches are not high enough to create an independent index of abundance.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Scamp and yellowmouth grouper can be found in depths up to approximately 300 feet. They inhabit low-profile, hard-bottom areas within their geographic range. These live bottom areas are covered with hard and/or soft corals, sponges, and patches of macroalgae. While low profile habitat is generally the preferred habitat type, they also utilize ledges and high-relief rocky bottoms comprised of rocky outcroppings and ledges, or wrecks (Manooch et al., 1998; SAFMC, 2023).

CHALLENGES

Scamp, yellowmouth grouper, and other grouper species in the South Atlantic are experiencing similar challenges as other apex predators. Slower growing, long-lived species are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. Because both species are also sequential hermaphrodites, there is also disproportionate targeting of the larger sex (males) which has the potential to skew population demographics. As with many other reef fish species which have substantial overlap in habitat use, there is potential for mortality even when they are not targeted in this multi-species fishery. Additionally, changing climate, warming ocean temperatures, and habitat destruction might be contributing to low recruitment and a declining population.

CONSERVATION ACCOMPLISHMENTS

Because scamp and yellowmouth grouper are highly prized by both commercial and recreational fishers (Manooch et al. 1998), both species have undergone several management actions as a result. Historically, they have been managed in the South Atlantic under the Shallow Water Grouper Complex (SASWG). Under the SASWG, both species are currently subject to an aggregate grouper bag limit of 3 per angler per day, with a minimum size of 20 inches (508-mm) total length. There is also a spawning season closure from January 1 – April 30. Since 1992, permits were required to harvest them commercially. Hook use requirements and annual catch limits (ACL) have been enacted throughout the years to accompany bag/size limits and seasonal closures (SEDAR 68, 2020). In March 2024, the SAFMC's Amendment 55 moved scamp and

Figure 2: Chevron trap index of abundance for Scamp. Normalized nominal (black dots) and standardized abundance (red line) with 95% CI.

yellowmouth grouper to their own complex so that they might be managed independently of other shallow water groupers.

CONSERVATION RECOMMENDATIONS

The greatest need when considering effective conservation metrics for these species is more data. Stock assessment analysts are required to use proxies or less robust data to make decisions about natural mortality, reproductive biology, and juvenile cohorts within the population.

Specific recommendations include:

- practical applications for addressing data inadequacies identified in assessment modeling (SEDAR 2020),
- data collection focused on smaller individuals/juveniles in the population,
- development of artificial intelligence to automate the tools used in life history evaluation and underwater video analysis that can contribute to future stock assessments (SEDAR 2020),
- investigation into taxonomic status of yellowmouth grouper,
- incorporation of ecosystem considerations in management strategies, and
- more research into nonlethal opportunities for life history data collection.

MEASURE OF SUCCESS

A direct measure of success would be a steady increase in catch rates by fishery-independent surveys and/or expansions of population size- and age-structure.

DESCRIPTION

by Dianne Rome Peebles

Taxonomy and Basic Description

The sheepshead, *Archosargus probatocephalus* (Walbaum 1792), is a relatively large representative of the porgy family (Sparidae), most commonly found around hard bottom and structure occurring in South Carolinas estuarine and coastal waters.

The sheepshead is greenish-gray to silvery in color, with five to seven distinct vertical black bars and an oval shaped, laterally compressed, deep body (Manooch 1984; Smith 1997). The black bars remain very distinctive throughout the life of the fish. The mouth is of medium size, with prominent incisor-like teeth in the front and molars and grinding teeth in the rear. There are no barbels on the lower jaw. The posterior nostril is slit-like in appearance and the pectoral fins are long, extending beyond the anal opening when pressed close to the body (Böhlke and Chaplin 1993). The caudal fin is shallowly forked. The dorsal and anal fins possess strong spines, with the second spine of the anal fin being prominently enlarged (Robins and Ray 1986). Juvenile sheepshead are sometimes confused with young Atlantic spadefish (*Chaetodipterus faber*) or black drum (*Pogonias cromis*) when encountered in estuarine waters.

Adult sheepshead can attain a length of 76 cm (30 in.), and typically weigh from 2.3-6.8 kg (5-15 lbs.), though growth parameters vary by state (Adams et al. 2018). Fish in the 9-11.3 kg (20-25 lbs.) range are occasionally landed (Manooch 1984). The current recreationally landed record sheepshead in South Carolina is 7.4 kg (16 lbs., 6 oz.) (SCDNR 2012).

Sheepshead can have a total lifespan of 20 to 25 years, and can begin to sexually mature as early as age 1 (McDonough et al. 2011). Through fishery-independent and fishery-dependent collection of 509 sheepshead sampled for age-growth analysis in Georgia (Woodward et al. 2000), the maximum age through otoliths analysis was determined to be 17 years. In a similar effort conducted in South Carolina, the oldest individual sheepshead captured and aged by examination of otoliths was 26 years of age (Wenner 2004). Age-length data acquired by Wenner (2004) and McDonough et al.

(2011) for sheepshead in South Carolina show that fish on average reach about 25 cm (10 in.) fork length (FL) at the end of their first year, where about half of the fish remain sexually immature. Nearly all of the members of the population are mature at about 35 cm (14 in.) in length (FL), or 3 to 5 years in age (Wenner 2004; McDonough et al 2011). Sheepshead display a relatively rapid growth rate up to about age 6; size increases slowly thereafter with age.

Sheepshead are serial spawners; they spawn multiple times within a season. Females in South Carolina have been found to be capable of producing anywhere from 18,400 to 738,500 eggs per spawning event, depending on age and location (McDonough et al. 2011). This is much higher than the 1,100 to 250,000 per spawning event estimated in the Gulf of Mexico (Render and Wilson 1992; Tucker and Barbera 1987). Spawning has been documented to occur in coastal waters from late winter through early spring through the mid-Atlantic and Gulf of Mexico, with hatching of eggs occurring within 28 to 40 hours from time of fertilization, depending on water temperature. Estimates of spawning frequency determined by the presence of post-ovulatory follicles for sheepshead in South Carolina ranged from 2.5 to 20 days with an average of 7 days or once a week. With an approximate spawning season of 14 weeks (February-early May), total annual fecundity could range from 250,000 to 10,339,000 eggs per female per year (McDonough et al. 2011).

Sheepshead are an omnivorous species, feeding on a wide range of items including invertebrates, small vertebrates, and some plant material. Large juveniles and adults have been known to prey on small crustaceans, oysters, clams, and even smaller finfish (Bester and Robins 2005). Sedberry's 1987 analysis of the stomach contents of sheepshead taken from offshore hard bottom areas in the South Atlantic Bight demonstrated the importance of sessile invertebrates as an important dietary component for this species. Smaller sheepshead were found to have been feeding heavily on bryozoans, while larger specimens also included bivalves, echinoderms and ascidians in their diet. Both large and small sheepshead also feed to a lesser extent on barnacles, decapods, foraminiferans, cnidarians, polychaetes, gastropods and small arthropods as well.

The sheepshead's ability to maintain such a wide-ranging diet is supported by its rather unique dentition, as well as physical changes that can occur developmentally within its oral-jaw crushing musculature (Hernandez and Motta 1997; Cutwa and Turnigan 2000). Older fish, or fish that are in an environment where hard-shelled prey items are abundant have a much better developed feeding apparatus, capable of significant crushing power.

Sheepshead are most frequently encountered near some type of structure like pilings, jetties, oyster reefs, artificial reefs and coastal live bottom. Their close association with manmade reefs in South Carolina is documented as far back as the mid-1800s (Holbrook 1860). As a consistently popular species sought after by serious recreational

anglers, their year-round presence in South Carolina waters can be documented over time through various methods, including creel surveys (Table 1) and SCDNR's trammel net survey (Fig. 1). Creel surveys reveal the increase in catch-and-release fishing of Sheepshead over time, and the trammel net survey indicates fairly stable and consistent catches of Sheepshead since the early 1990's, though overall catches of Sheepshead in this survey are relatively low.

Table 1: Estimated number of Sheepshead harvested and released (in thousands of fish) in South Carolina by year, courtesy of the National Marine Fisheries Service (NMFS 2023).

	2011	2012	2013	2014	2015	2016	2017	2018	2019	2020
Harvested	458	128	66	169	141	136	204	118	164	135
Released	203	163	315	421	368	391	436	421	533	411

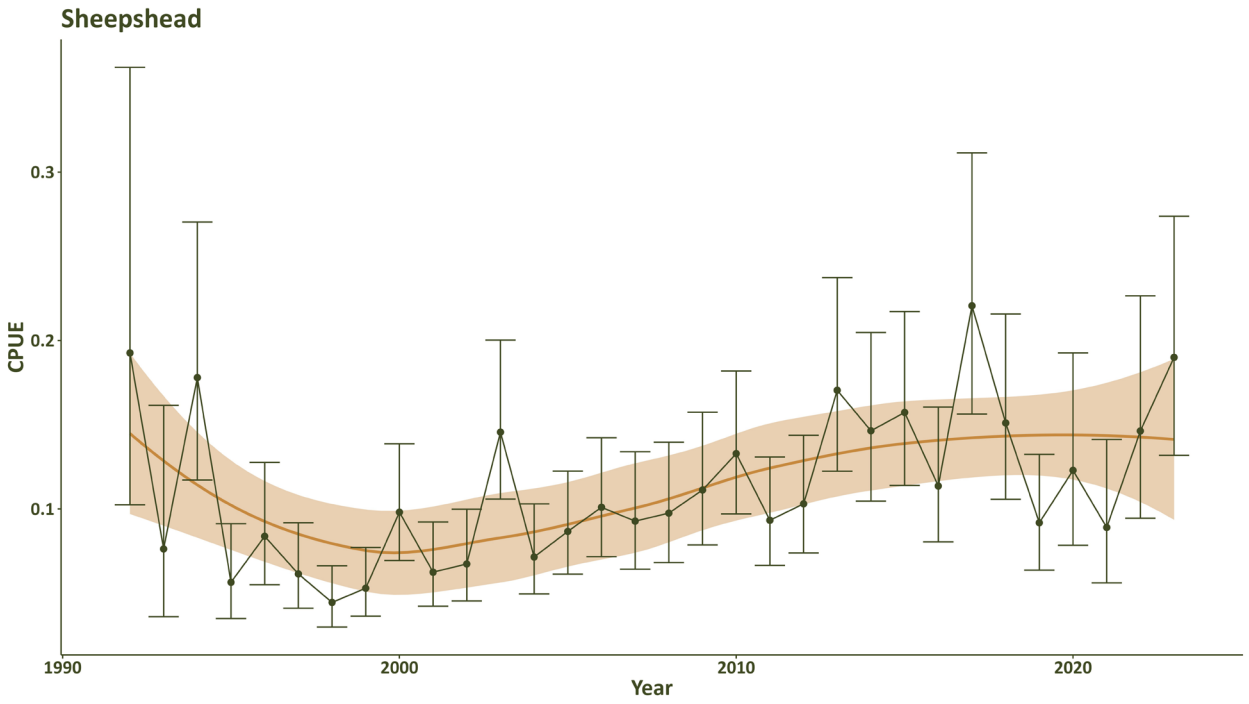

Figure 1. Sheepshead catch-per-unit-effort (CPUE) in SCDNR's trammel net survey.

While fish are present in the fishery every month of the year, there are peaks in landings in the spring and fall months. Examination of National Marine Fisheries Service (NMFS) Marine Recreational Fisheries Statistics Survey (MRFSS) data for the South Carolina sheepshead fishery shows clearly that the fishery is made up primarily of private boat anglers targeting the fish in inland and nearshore waters (NMFS 2005).

Status

The exact status and health of sheepshead populations in South Carolina's coastal waters is uncertain at this time. The species used to be federally managed as part of the South Atlantic Fishery Management Council's (SAFMC) Snapper Grouper Fishery Management Unit, but it was removed from this unit in April 2012 and is now managed by individual states. Of the states in the southeastern U.S., South Carolina has the most temporally expansive dataset on sheepshead catches with sampling dating back to 1985, whereas the next closest state (Florida) began collecting data in 2000 (Adams et al. 2018).

While sheepshead are targeted commercially to a limited degree in some areas, this species is typically recognized for its popularity among recreational anglers in coastal waters along the mid-Atlantic through Gulf of Mexico. In creel/angler surveys conducted by the South Carolina Department of Natural Resources (SCDNR) of saltwater recreational fishermen encountered at boat landings, sheepshead is the fifth most sought after species mentioned and ranks sixth in occurrence in the creels examined among this group (SC SRFSS data, 1991 through 2011). SCDNR's Marine Game Fish Tagging Program shows that sheepshead have averaged as the third most-tagged fish species by anglers in recent years (SCDNR 2024).

POPULATION SIZE AND DISTRIBUTION

Sheepshead are found in waters ranging from Nova Scotia to the Gulf of Mexico, and southward to Brazil (Manooch 1984). Populations of sheepshead occurring in South America and in parts of the Gulf of Mexico are regarded as two separate subspecies. Sheepshead are year-round residents from about South Carolina through the Gulf of Mexico, and most abundant to the north between April through November. They are found in coastal waters, bays and estuaries, and are tolerant of low salinity brackish waters as well.

Sheepshead are found in South Carolina's estuarine, nearshore and offshore waters throughout the year. Juveniles, and sub-adults are commonly found in the state's estuaries, bays, brackish rivers and creeks, and adults are typically encountered in nearshore and coastal waters, associated with hard-bottom habitat of some type. Spawning occurs in the early spring in offshore waters (Moore and Barkley 2005; McDonough et al. 2011). Adults and sub-adults of the species are commonly found around the State's marine artificial reefs out to depths of 30 m (100 ft.) (M. Bell, pers. obs.).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Sheepshead commonly occur in estuarine, nearshore, and coastal waters throughout the southeastern United States (Jennings 1985). They are encountered throughout a diverse range of ecosystems including brackish mangroves, salt marshes and nearshore waters, particularly around pilings, jetties and other structures. Recreational anglers fishing on manmade and naturally occurring reefs in nearshore and offshore waters

frequently target this species (Stanley and Wilson 2000). Juveniles are found predominately in estuaries and adults in offshore waters.

Sheepshead are taken in trawls, traps and other fishing gear used in tidal harbors, rivers and creeks in South Carolina waters. Their presence has been documented on subtidal and intertidal oyster reef habitats and on intertidal flats in the southeastern United States (SAFMC 1998). Adults are found in nearshore and offshore waters along the entire coast where suitable bottom habitat and structure exists. Grimes et al. (1982) noted their presence on shallow water live bottom habitats off North Carolina and South Carolina where limited vertical relief and a rich invertebrate community often exist.

Sheepshead readily recruit to South Carolina's marine artificial reefs, from 5 to 56 km (3 to 35 miles) offshore, but are most commonly noted by divers on reefs in the 9-18 m (30-60 ft.) range. Larger fish seem to move offshore as water temperatures drop in the fall and winter months and remain closely associated with reef structure (M. Bell, pers. obs.). It is not uncommon for divers to encounter very large sheepshead taking refuge or resting inside openings found in various reef structures.

CHALLENGES

Challenges for this species would most likely occur in the form of over-fishing, loss or degradation of essential fish habitat, degradation of estuarine water quality, or a combination of factors. Any of these problems, if materialized, could be initiated by multiple causative factors introduced in specific locales along the South Carolina coast, coast-wide, or even along larger spans of coast within the South Atlantic region.

While no directed commercial fishery for sheepshead currently exists in South Carolina, the species is popular with skilled recreational fishermen in inland and nearshore waters. Although the fishery is somewhat specialized and technique-dependent, anglers who know where and how to target the species may be very successful. Over-harvest of sheepshead that have yet to reach maturity in state waters could result in population problems for this species if the current harvest practices remain unchecked.

South Carolina NMFS-MRIP catch data for sheepshead from 2000 through 2011 indicate that 92% of the catch occurs in state waters, with an overall catch and release rate of only about 28% (NMFS 2012). However, the catch-and-release rate of sheepshead has increased since 2011, with every year since 2011 reporting significantly more releases than harvests (release rate of 73% post-2011; NMFS 2023). With removal of sheepshead from the snapper-grouper complex in 2012, new state regulations are currently relied upon to protect the species from overharvesting.

Any impacts to the health of South Carolina's estuarine habitats, or degradation of water quality in these areas, could also have negative consequences for the success of larval recruitment and settlement from coastal spawning populations of sheepshead or the health of juveniles and sub-adults inhabiting estuarine waters and bottoms.

Alterations to water quality parameters can impact the health of many marine-spawning species like sheepshead that can only be successful if they are physiologically, thermally and salinity adapted (Sea Grant 1976). Introduction of toxins and pollutants such as PCBs into coastal waters can also have a disruptive effect on juvenile fishes with potentially long-term impacts on life cycles (Thomas 1990).

CONSERVATION ACCOMPLISHMENTS

Sheepshead rely on a wide range of habitats throughout their life history, including estuarine oyster reefs, tidal flats, nearshore and offshore hard bottom reefs, manmade reefs, and other structure. In developing a comprehensive habitat plan essential to the health and success of all managed marine fishery species within the entire South Atlantic region, the South Atlantic Fishery Management Council (SAFMC) has characterized and documented the importance of the various habitat types essential to all managed finfish species within the region, including sheepshead (SAFMC 1998). In 2012, new size and bag limits were implemented in response to the removal of sheepshead from the snapper/grouper complex regulations. Currently, sheepshead must be a minimum of 14 inches total length to land, and there is a bag limit of 10/person/day, not to exceed 30/boat/day.

CONSERVATION RECOMMENDATIONS

- Quantify fishing mortality and catch per unit effort for the recreational sheepshead fishery off South Carolina.
- Determine age frequency, population trends, and significance of spawning activities of sheepshead occurring within the State's fishery.
- Examine the extent to which sheepshead occur as by-catch in commercial gear.
- Examine larval distribution, settlement and recruitment of sheepshead to estuarine systems and the importance of estuarine habitats in supporting sheepshead populations in South Carolinas coastal waters.
- Better define seasonal movement patterns and habitat utilization of sheepshead adults.
- Examine ability to use juvenile sheepshead as a finfish indicator species in monitoring the health of estuarine habitat.
- Examine possible impacts of degraded estuarine water quality on sheepshead.
- Determine emigration patterns of young sheepshead adults and recruitment to near/offshore habitats.
- Understand environmental factors that affect abundance and health of sheepshead stocks.
- Work with appropriate federal, state and local partners and stakeholders to better protect water quality by implementing better coastal planning policies, assessing current policies/regulations involving the introduction of various biocides and other potentially harmful chemicals into estuarine and coastal waters and requiring stricter monitoring and tighter restrictions on storm water runoff and wastewater treatment effluents.

- Work with appropriate federal agencies and others to develop realistic strategies, plans and policies to protect limited areas of essential fish habitat (EFH) as designated by the SAFMC Essential Fish Habitat Management Plan.
- Manage the use of marine artificial reefs in South Carolina's coastal and offshore waters to provide additional EFH where most appropriate to improve the chances of reaching fishery management and conservation goals established for applicable finfish species.

MEASURE OF SUCCESS

By protecting habitat, improving water quality, and actively managing the effects of recreational angler harvest on sheepshead populations, SCDNR will be able to encourage stable sheepshead populations within in the State's coastal waters, which will be documented by continuing current fishery-dependent and fishery-independent monitoring programs

Shortfin Mako and Longfin Mako

Isurus oxyrinchus & I. paucus

Contributors:
Claire Benson (SCDNR) & Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Shortfin Mako

The shortfin mako and longfin mako are members of the order Lamniformes and family Lamnidae (Page et al. 2023). These highly migratory, pelagic species are found in the Atlantic, Pacific, and Southern oceans (Compagno, 2001). Sharks of the family Lamnidae are predicted to be less resilient than other shark species in situations of high mortality rates due to their high longevity, late maturity and extremely low fertility and productivity rates (Stevens, 2008; Smith, 2008; Cortés et al. 2010, 2015).

The shortfin mako is considered the fastest shark in the world, able to reach max burst swimming speeds of 43 mph (69.2 kph; Diez et al. 2015). They have a bluntly pointed snout, large black eyes, and long gill slits. They are recognized by their metallic blue side coloring and white undersides with a distinct color break down its side. The tail has a high aspect ratio (ratio of height to length), which produces maximum thrust with minimum drag and provides almost all of the propulsion for the shark. The mouth is distinctly U-shaped (Compagno et al. 2005).

Shortfin mako sharks are a slow growing species. The average adult size is about 260-270 cm and 330 cm total length (TL) for males and females, respectively, with a reported maximum size of about 380 cm (13 ft) TL (Castro 2011). Size at birth is 60-70 cm TL. Age at maturity is between 7 and 9 years for males and 18 to 21 years for females (Cailliet et al. 2009). Shortfin makos are estimated to live 29-32 years (Bishop et al. 2006). Their slow growth and late maturity, along with a three-year reproductive cycle, renders makos vulnerable to overfishing.

Longfin Mako

Longfin mako have slimmer bodies and longer pectoral fins than the shortfin mako. The longfin mako has a slender, torpedo-shaped body with a moderately long conical snout. Like their congenger, they have elongated gill slits for more efficient gas exchange. The

mouth is shorter than it is wide with the lower teeth extruding. The eyes are large, and the pectoral fins are wide with a round tip. The pelvic fins are short with concave posterior margins. The first dorsal fin is large with a light free rear tip. Both anal and the second dorsal fins are small. There are strong keels on the caudal peduncle and short secondary keels on the caudal base. The caudal fin is semi-lunate, and the upper lobe is not much larger than the lower one. The terminal caudal lobe is not prominent, and the subterminal notch is well distinguished (Compagno, 2001; Castro, 2011).

The maximum size is believed to be 427 cm TL (168 inches; Castro et al. 1999, Compagno 2001, Castro, 2011). While age at maturity is not known, females have been reported mature at > 300 cm (>118 inches) TL and males at 229 cm (90 inches) TL (Castro, 2011). Longevity has not been studied to date. The longfin mako is ovoviviparous and fetuses are larger than those of the shortfin mako. Fetuses are believed to be cannibalistic in utero, consuming other eggs in the womb (Oophagy; Compagno, 2001). Females give birth to 2-8 pups measuring 122-135 cm (48-53 inches; Castro, 2011; Compagno, 2001; Manday, 1975). Reproductive periodicity and gestation times are currently unknown.

Status

Worldwide, the shortfin mako is considered overharvested due to direct targeted fishing and as by-catch associated with tuna and swordfish fisheries. The U.S. National Marine Fisheries Service (NMFS) includes the shortfin mako on their list of managed pelagic sharks. This species is also listed under the 1995 UN Agreement on the Conservation and Management of Straddling Fish Stocks and Highly Migratory Fish Stocks (UNFSA), which requires all fishing states implement measures to conserve the species. Unfortunately, a lack of scientific data, underreported catch data and the large-scale nature of their movement patterns, has made it challenging to collect accurate information about the status of their populations globally. Genetic work has identified three distinct subpopulations of the shortfin mako. These are assessed separately under the IUCN (Cailliet et al. 2009).

Most information available on the population status and trends consists of fisheries catch data and is therefore either not species-specific or focuses primarily on shortfin mako. The population structure of the longfin mako is widely unknown due to a paucity of data. However, it is suspected populations in the Atlantic Ocean and the Indo-Pacific could be isolated (Reardon et al. 2006). ICCAT assessed the status of shortfin mako in the North Atlantic and South Atlantic. Stock units have not been defined in the Pacific Ocean. The current IUCN Red List status for the global population of shortfin mako and longfin mako is 'Endangered' (Rigby et al. 2019). More details of the population status and trends can be found in the IUCN assessment.

The conservation status of the longfin mako is uncertain. Longfin mako are thought to have a very low, minimum population with a doubling time of more than 14 years. The ICUN lists longfin makos as "Vulnerable" due to their increasing rarity due to fisheries bycatch and the shark fin trade (Amorim et al., 1998; Compagno, 2001).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The shortfin mako is a pelagic species with a worldwide distribution. They are primarily resident in oceanic waters but can also be found near the coast where the continental shelf is short. They occur from the surface to about 500 m (1640 ft) and usually inhabit waters that are above 16°C (60°F; Calliet et al. 2009, Compagno et al. 2005).

There is little data available on the habitat and range of the longfin mako but they are most often seen in tropical and temperate waters. As in other Lamnids, the longfin mako has counter current vascular heat exchange, allowing the musculature, eyes, brain and viscera to be heated. They are often observed at the surface, but specimen's stomach contents include deepwater squids suggesting a broad range of habitable depths for the species (Compagno, 2001; Castro, 2010).

CHALLENGES

In terms of fisheries, both species are caught in pelagic longlines, drifting or set gill nets and in hook-and line fisheries (Stevens 2008). Shortfin mako constitute a larger proportion of bycatch in longline fleets than the longfin (Reardon et al. 2006).

There are also challenges related to the international trade of shark meat and fins. The shortfin mako is a higher value shark species for meat products. Clarke et al. (2006) found fins of shortfin mako entered the international fin trade, where they account for approximately 2.7% of the fins traded. Longfin mako are mostly sold in the same category with shortfin mako or thresher fins due to a similarity of appearance and market value. Challenges for the longfin mako include the rarity of this shark, limited knowledge of its biology, slow life history, and occurrence as a limited but complementary bycatch of high-intensity oceanic fisheries targeting shortfin makos, other sharks, and pelagic scombroid fishes.

Other challenges exist with a general lack of management actions for makos that have been implemented by regional fishery management organizations. National fishery or conservation measures have been limited. Full stock assessments have only been conducted for the two Atlantic shortfin mako stocks, excluding the Mediterranean. The assessment for the south Atlantic stock was considered to be highly uncertain. Finally, critical habitats have not been identified and delineated and fishery data (landings, discards, size frequency, catch and effort) are lacking in some areas.

CONSERVATION ACCOMPLISHMENTS

Currently, there are no species-specific conservation measures in place.

CONSERVATION RECOMMENDATIONS

There is a need to improve the understanding of mako sharks through research, monitoring and data exchange, including data collection of biological and distributional data and population status. Steps towards accomplishing this include:

- Identifying critical sites of mako shark abundance and seasonality.
- Filling data gaps in life history parameters of shortfin mako.
- Investigating life history of longfin mako.
- Improve understanding of post-release survivorship of mako sharks to enable improved handling and release protocols.
- Initiate necessary collection of fishery data (including landings, discards, size frequency, catch and effort where needed).
- Research into ways to reduce bycatch and improve survivorship of makos, including gear modifications and fishing practices (soak time and safe release handling guidelines).

MEASURE OF SUCCESS

Mako sharks are heavily overfished in the Atlantic. As such, the primary measure of success would be the rebuilding of populations and implementations of international fisheries management measures allowing the stock to be sustainably fished once recovered.

Silky Shark

Carcharhinus falciformis

Contributors:
Liz Vinyard (SCDNR) and Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The silky shark is large and slender, deriving its common name from the smooth appearance of its skin relative to other shark species. Body color is usually bronze-brown to grey-brown with an inconspicuous pale flank band and white underside. The nose is blunted and shorter than the mouth width. The first dorsal fin is low and sloping and originates behind the free rear tips of the elongated pectoral fins. It has an interdorsal ridge and the second dorsal fin is small with a very long free rear tip approximately 2.5 times the vertical height of the fin (Castro, 2011).

The species was originally thought to be two separate species, *C. falciformis* based on a description of one embryo, and *C. floridanus* based on morphometrics from two adults. The two species were determined to be the same by Garrick et al. (1964) and combined. Frequent confusion with night sharks (*C. signatus*) and dusky sharks (*C. obscurus*) contributed to misidentification for decades (Castro, 2011).

Most sharks encountered are under 250 cm total length (TL), and maximum length is likely around 332 cm TL (Joung et al., 2008). Observed maximum ages determined by vertebral counts ranged from 11 to 16 years for females (Indian and eastern Pacific oceans, respectively) and 14 years for males in both regions (Clarke et al., 2015). Observed maximum ages from studies in the Gulf of Mexico and Atlantic were slightly older and varied from 13 years to 22 years (Branstetter, 1987; Bonfil et al., 1993). Silky sharks are estimated to live up to 32 years with the potential individuals may be considerably older (Clarke et al., 2015). Age and growth studies conducted throughout their range suggest intermediate life history parameters with slow to moderate growth rates which may vary slightly between regions (Joung et al., 2008; Clarke et al., 2015; Santander-Neto et al., 2021).

Females are thought to mature between 9 to 15 years which varies based on geographic location and size at maturity likely falls between 190-220 cm TL (Bonfil, 2008; Joung et al., 2008; Clarke et al., 2015; Santander-Neto et al., 2021). Males are thought to reach maturity around 9 to 13 years and slightly smaller lengths between 180 to 212 cm TL (Bonfil, 2008; Joung et al., 2008; Clarke et al.,2015; Santander-Neto et al., 2021).

Like many members of the Carcharinidae, themselves members of the order Carcharhiniformes (Page et al. 2023), they are placental viviparous giving birth to live young and likely have a biennial reproductive cycle with a gestation period around 12 months although it may vary between regions (Castro, 2011). Litters average six pups and can range from 2 to 18 pups. Size at birth has been reported to vary between regions as well and ranges from 65-85 cm TL (Bonfil, 2008; Joung et al., 2008).

Status

Due to declining global abundances, silky sharks have an IUCN Red List status of vulnerable and are currently listed under Appendix II of the Convention on the Conservation of Migratory Species (CMS) of Wild Animals, and Appendix II of the Convention on International Trade in Endangered Species (CITES) as of 2016 (NMFS, 2022).

The first stock assessment on silky sharks was conducted in the western and central Pacific Ocean in 2012; however, it was rejected by the scientific committee who recommended further modeling. In 2013, the assessment was again attempted with additional data sets and longer time series, and due to consistent declines in size composition data, increased fishing mortality, and declining CPUEs, they conclude silky sharks are likely overfished and experiencing overfishing although there was still a great deal of uncertainty in the models (WCPO, 2013).

A stock assessment in the Indian Ocean also contained a great deal of uncertainty about the relationship of abundance to nominal CPUE series but an ecological risk assessment determined they were highly vulnerable due to their low productivity and high susceptibility to longline and purse seine fisheries. Therefore, the IUCN status was changed to a Near Threatened status in the western and eastern Indian Oceans (FAO, 2022).

Silky sharks have not been assessed in the U.S. but are managed under the 2006 Consolidated Highly Migratory Species (HMS) Fisheries Management Plan (NMFS, 2006; NMFS, 2022). Retention is prohibited in recreational fisheries and by the commercial Caribbean Small Boat permit. However, they are allowed to be landed by the Atlantic directed commercial shark fishery which has no limit on pelagic sharks (other than shortfin makos) and the Atlantic Incidental Permit which has a limit of 16 combined pelagic and small coastal sharks/vessel/trip (excluding shortfin mako). Several states within the U.S. have regulations allowing some landings of silky sharks within their waters, but most follow the federal guidelines prohibiting recreational landings.

Sharks captured domestically in association with the International Commission for the Conservation of Atlantic Tunas (ICCAT) fisheries using pelagic longline gear are required to follow ICCAT recommendations. Since 2012, these include prohibiting retaining, transshipping or landing silky sharks.

POPULATION SIZE AND DISTRIBUTION

Silky sharks have a circum-global distribution in tropical waters and are found in both oceanic and coastal-pelagic zones. In the western Atlantic, they are distributed from Massachusetts to southern Brazil, including the Caribbean Sea and Gulf of Mexico. They are also found in the central Atlantic, eastern Atlantic from Spain to northern Angola, the Indian Ocean, and throughout the equatorial regions of the Pacific Ocean.

Their population structure is not fully understood, but there is evidence of multiple stocks. Initial work in the Indo Pacific suggested there were potentially up to three groups within the region while a later study using larger sample sizes concluded there were at least five genetically distinct populations globally: western and eastern Pacific Oceans, Indian Ocean, Red Sea, and the western Atlantic Ocean (Aires da Silva et al., 2014; Clarke et al., 2015). Clarke et al. (2015) found the greatest divergence between the western Atlantic Ocean and the Indo-Pacific specimens. The Indo-Pacific had significantly less genetic diversity relative to the western Atlantic but still showed evidence of genetic differentiation, suggesting less connectivity among regional populations than expected (Clarke et al., 2015). Interestingly, the opposite was observed in the western Atlantic samples which suggests gene flow and a lack of female philopatry between the western North Atlantic and western South Atlantic (Clarke et al., 2015).

Although catch data in all regions have been too variable to conduct stock assessments, declines in CPUE were observed and estimates of fishing mortality exceeded estimates of sustainable yields (IOTC, 2013; WCPO, 2013; Aires da Silva et al., 2014). In the Gulf of Mexico, research surveys and observer data suggested their abundance declined 91% since the 1950's and declines in CPUE in the Atlantic regions were between 46-50% from 1992-2005 (Cortes et al., 2007). Cortes et al. (2007) estimated over three generations, silky populations in the Atlantic were reduced by 95-98%. Assuming evenly distributed silky populations, authors estimated global population declines over three generations of 47-54% (Cortes et al., 2007; WCPO, 2013; Lennert-Cody et al., 2016).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Silky sharks are most often found near the edge of continental and insular shelves at depths 200 m or more or offshore in the epipelagic zone from the surface to 500 m (Last and Stevens, 2009). They are also associated with deepwater reefs and insular slopes near islands and prefer warmer waters above 23°C.

Their diet consists of large squid, pelagic fish and pelagic crabs (Kiszka et al., 2015). While they are commonly observed following schools of tuna, they were found to occupy the lowest trophic position relative to several other commonly encountered pelagic shark species (Kiszka et al., 2015).

Ontogenetic shifts in habitat usage have been observed in the western Atlantic with neonates and early juveniles occupying coastal waters on the continental shelf, which suggests the potential for localized nursery grounds (Yokota and Lessa, 2006; Bonfil, 2008). Adults and older juveniles are more likely to be found in deeper water off the continental shelf or open ocean waters (Bonfil, 2008). Unlike some other species of pelagic sharks, silky sharks are known to aggregate in mixed sex and size groups, frequently around floating aggregation devices (FADs) and following schools of tuna (Castro, 2011; Filmalter et al., 2013).

CHALLENGES

Silky sharks are one of the most common pelagic bycatch species in gillnet, longline, and purse seine fisheries. While purse seine fisheries have historically had low bycatch rates, the development of industrialized seine fisheries targeting larger pelagic species has increased the likelihood of shark bycatch. To increase catches, FADs are frequently used to increase catches prior to encircling with seine nets, and consequently, silky sharks are one of the predominant species associated with bycatch in these fisheries (Eddy et al., 2016). They are the second most dominant shark bycatch species globally in pelagic longline fisheries and are frequently reported as being discarded alive (Abel and Grubbs, 2020).

Post release mortality estimates for longline fisheries range from 5-20% (Abel and Grubbs, 2020), however, seine and FAD associated mortality rates are much greater and may be upwards of 85% (Filmalter et al., 2013; Poisson et al., 2014). In many instances drifting FADs may have old nets attached to them and silky shark entanglement and associated mortality in the combined structure has been estimated to be five to 10 times the actual bycatch associated with the seine fishery (Filmalter et al., 2013).

Adding to concerns about fishing mortality rates, a recent study investigated the accuracy of shark bycatch estimations by onboard observers and found shark counts were underestimated for 50-100 percent of the sets with a mean underestimation at trip level ranging from 9 to 40 percent for onboard observers in the Pacific and Atlantic Oceans and 65 percent for electronic monitoring systems in the Indian Ocean (Forget et al. 2021)

Consequently, pelagic species like silky sharks are one of the most predominant in the global shark fin trade and as such, are listed under CITES Appendix II to ensure international trade does not threaten their survival. Despite this designation, genetic testing of fins in the Hong Kong fin market found silky shark fins were the second most traded species (Cardenosa, 2018).

Accurate estimates of population sizes, demographic structure, and fishery data is severely lacking and urgently needed to generate data necessary for regional stock

assessments so that sustainable levels of fishing pressure and spawning stock biomass can be determined (CMS, 2018).

CONSERVATION ACCOMPLISHMENTS

Bycatch rates by depth were investigated in pelagic longline fisheries targeting multiple species. Comparisons between global pelagic longline fisheries suggested shark bycatch was lowest while targeting tuna at deeper depths and highest in fisheries targeting species in shallower depths or closer to shore (Abel and Grubbs, 2020). Increasing hook depth to 150 m or more has been shown to significantly reduce the bycatch rate of Silky sharks.

Following recommendations adopted in the North Atlantic Ocean, the Indian Ocean Tuna Commission passed a resolution to fully utilize entire shark catches by restricting finning at sea for fresh landed sharks, limiting the proportion of fins by weight of frozen sharks, encouraging the release of live sharks (particularly juveniles and pregnant females), and improving collection of accurate data while setting a firm date for annual reporting of landings (IOTC, 2022).

CONSERVATION RECOMMENDATIONS

Improve knowledge of population sizes and demographics

Improve knowledge and understanding of critical habitat use areas outside of seamounts

Improve knowledge on key biological and ecological parameters, life history and behavioral traits, and migration patterns

Identify shark mating, pupping, and nursery areas

Identify effective approaches to reduce bycatch including gear modifications and handling practices to maximize post release survival

Enhance and develop collection of fishery data (landings, discards, size frequency, catch and effort)

Support increased multilateral cooperation, management plans, and conservation measures

MEASURE OF SUCCESS

Gather enough information to effectively conduct stock assessments by region

Increase population abundance

Reduce bycatch mortality

Smalltooth Sawfish

Pristis pectinata

Contributors:
Bryan Frazier (SCDNR) & Hayden P. Bessette (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Smalltooth sawfish are a chondrichthyan species belonging to the sub-class *Elasmobranchii*, the order *Rhinopristiformes* and the family *Pristidae* (Page et al. 2023). Within this family, there are two genera, *Pristis* and *Anoxypristis*, which contain the 6 extant species of sawfish. These species are most closely related to the order *Rajiformes*, which is composed of skates and rays.

The smalltooth sawfish shares a distinguishing characteristic with the other sawfish species, a long snout-like protrusion lined with teeth, called the rostrum. This rostrum contains 22-29 teeth along its edges, which are unique from many elasmobranch teeth, given they are not replaced after falling out. Smalltooth sawfish differ from other *Pristidae* through several features. They have longer, narrower rostra with smaller, more numerous teeth. Their caudal fin lacks a lower lobe, and the front of the dorsal fin is located in line with the posterior end of the pectoral fins. The smalltooth sawfish has an olive-brown dorsal coloration and a white ventral coloration.

Smalltooth sawfish reproduce via internal fertilization and are ovoviviparous. They are born in broods of 7-14, with stretched total lengths (STL) of 64-81 cm at birth (Brame et al., 2019). Sexual maturity is reached at 7-11 years old, at lengths of 340 cm STL in males and 370 cm STL in females. They can reach lengths of 700 cm STL with a longevity of approximately 36 years in the wild (Kyne et al., 2021).

Status

Smalltooth sawfish are currently listed as an endangered species under the Endangered Species Act. They were the first marine fish to receive federal protection under this act. The International Union for the Conservation of Nature Red List lists them as critically endangered (Carlson et al. 2022). It is estimated populations have declined by up to 95%, with their geographic range declining by greater than 80% (Norton et al., 2012; Dulvy et al., 2014). Few data exist that describe total abundance levels in either stock.

POPULATION SIZE AND DISTRIBUTION

Historically, smalltooth sawfish occupied neritic environments from the Gulf of Mexico to North Carolina. There are generally believed to be two distinct populations, with one in south Florida and the other in The Bahamas. The core of the current population resides in south Florida, although in recent years, as the population has slowly increased, sawfish have been observed as far up the east coast as South Carolina, and as far as Mississippi in the Gulf of Mexico.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Young of year and juvenile sawfish inhabit riverine and estuarine areas, with several critical habitats established in Florida (Norton et al., 2012). Density in these environments has been associated with habitat structure, including correlations with mangrove density (Guttridge et al., 2015). Habitat utilization expands as smalltooth sawfish develop, with adults occupying areas composed of seagrass beds and reef structures further offshore (Hollensead et al., 2018). However, typical distributions remain nearshore, and individuals demonstrate high site fidelity (Carlson et al., 2014). Their general diet consists mainly of teleost and elasmobranch fishes throughout all life history stages (Poulakis et al., 2017). Behavior and morphology suggest most of prey items occupy benthic or epibenthic areas. Smalltooth sawfish rely on the rostrum to stun or immobilize prey items. Ampullae of Lorenzini allow sawfish to locate buried prey items through the emission of electrical impulses.

CHALLENGES

Traditional threats to the smalltooth sawfish include bycatch through non-discriminate fisheries such as gill netting, shrimp otter trawls, and longlining due to increased vulnerability based on morphology and distribution relative to these types of fisheries. Responses to physiological stressors vary over ontogeny, with young of year individuals demonstrating the highest sensitivity. However, resilience is relatively high across all life history stages (Prohaska et al., 2018). Smalltooth sawfish are also vulnerable due to habitat loss, as development continues to threaten nursery areas such as red mangrove forests. There is currently a large-scale mortality of smalltooth sawfish occurring in the Florida Keys, research into the cause is ongoing with initial results pointing towards ciguatoxins (Poulakis pers comm).

CONSERVATION ACCOMPLISHMENTS

Numerous regulations have been put in place across several US states, including a ban on gillnet fishing in Florida waters. Information on safe-handling practices for both commercial and recreational fisheries is available from multiple agencies. A recovery

plan implemented by NOAA Fisheries under the Endangered Species Act was published in 2009 and is currently being adapted as information develops. The main goals of this recovery plan were to

1. minimize human interactions and associated injury and mortality,
2. Protect and/or restore smalltooth sawfish habitats, and
3. ensure smalltooth sawfish abundance increases and the species reoccupies areas from which it had previously been extirpated (NOAA Fisheries).

In addition to this recovery plan, several areas of critical habitat have been established. Smalltooth sawfish, along with the other Pristis species, were listed in Appendix I of the Convention on International Trade in Endangered Species (CITES: 2007, The Hague, Netherlands). This restricts the commercial trade of the species. In addition, all five species were listed under Appendices I and II of the Convention on Migratory Species (CMS: 2014, Quito, Ecuador). Smalltooth sawfish are also listed as endangered under the Endangered Species Act (NMFS, 2003, ESA Listing Rule for the U.S.A. DPS, Federal Register 68 FR 15674).

CONSERVATION RECOMMENDATIONS

- Continued research on life history including investigations into non-lethal methods of age determination
- Use genomic methods to estimate population size using Close Kin Mark-Recapture methods
- Increased observer coverage to document sawfish interactions in the shrimp otter trawl fishery
- Protection of sawfish in the Bahamas
- Continued electronic tagging and monitoring of sawfish to monitor habitat expansion and continue defining critical habitats.
- Protection of habitats most important to the recovery of the smalltooth sawfish

MEASURES OF SUCCESS

The ultimate measure of success for this species would be recovery of the population allowing removal from ESA protections, that said, this measure is in the distant future. More achievable measures would be the protection of critical habitats, recovery of the species from the ongoing unusual mortality event, and protection of sawfish populations in the Caribbean (including the Bahamas).

Snowy Grouper

Hyporthodus niveatus

Contributors:
Kevin Kolmos (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Snowy grouper, *Hyporthodus niveatus*, are a commercially valuable deepwater grouper species in the family Epinephelidae, themselves members of the order Perciformes (Page et al. 2023). Their coloration changes with the size of the fish. Juveniles have brownish coloration with coin-sized white spots along their sides, giving them their "snowy" look and name. A black saddle shape is present on the caudal peduncle and extends below the lateral line. Larger individuals usually lose their white spots with the top of the dorsal fins having a black margin. Snowy grouper have 11 dorsal spines and 3 anal spines.

Snowy grouper are a relatively long-lived, protogynous hermaphrodite whose spawning season spans late January – October, with a peak in May – August (Kolmos et al. 2019). Kolmos et al. (2019) found max ages of males and females in the South Atlantic (SA) to be 32 and 35 years, respectively, with a max length of 1137 mm total length (TL). Spawning events vary by size, increasing as the individuals grew (Table 1).

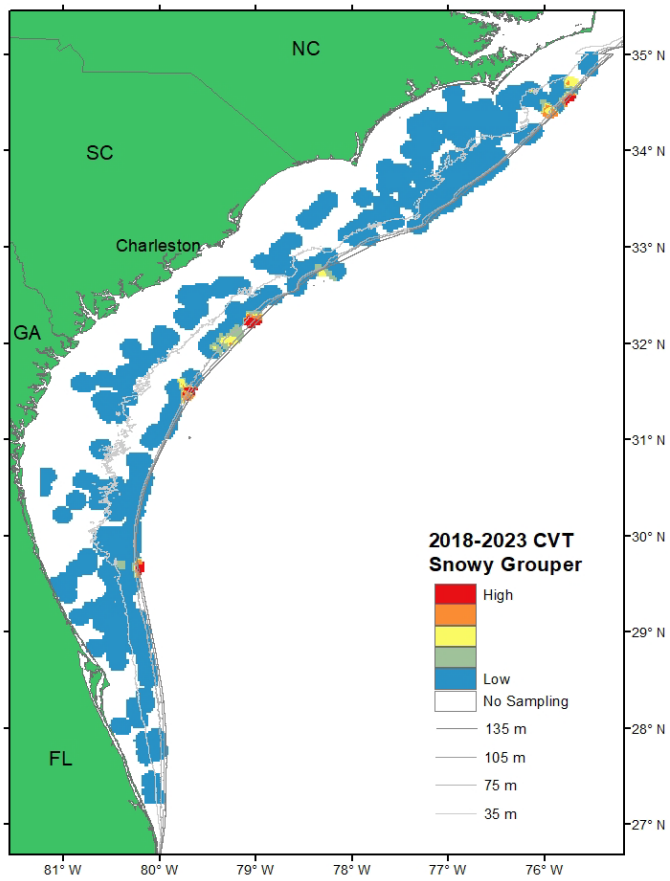

Table 1: Proportion of adult female (active and inactive) snowy grouper that were spawning daily, by 100 mm TL bin. Specimens were collected during spawning season (April – September) off North and South Carolina in 1979-2012. Spawners had at least one indicator of imminent spawning (i.e., oocyte maturation, ovulated eggs, or postovulatory complexes). Sampling period is the time (in days) from which representative samples of data were taken. Values of spawning proportion have been proportionally reduced to a 24-h period. (Table 6 in Kolmos et al. 2019).

Total Length (mm)	Adult Females (*n*)	Spawning Proportion (24 h)	Sampling period (d)	Spawning season duration (d)	Spawning interval (d)	No. of batches
501–600	130	0.06	178	139	17.1	8
601–700	326	0.13	178	153	8.0	19
701–800	325	0.14	178	177	7.0	25
801–900	94	0.17	175	163	6.0	27
≥901	26	0.18	171	129	5.4	24
Total	**901**	**0.13**		**152**	**7.8**	**19**

The length and age at 50% female maturity in the SA was 596 mm TL and 5.8 years, respectively (Kolmos et al. 2019). Snowy Grouper are a protogynous hermaphrodite where individuals start off as female and transition to male around the age of 17 years old or 900 mm TL (Kolmos et al. 2019). Very few males have been captured less than 800 mm TL.

Status

Snowy grouper in the U.S. are managed as two stocks within different jurisdictions, a Gulf of Mexico stock and a SA stock, which is supported by recent otolith microchemistry research that suggests little mixing between the two regions (Sanchez et al. 2022). The SEDAR 36 Update completed in 2020 confirmed SA snowy grouper were both overfished and experiencing overfishing.

POPULATION SIZE AND DISTRIBUTION

Snowy grouper occur in the western Atlantic from Massachusetts to Brazil, including Bermuda, Cuba, the Bahamas, and the Gulf of Mexico with some occurrences off the cost of Canada (Scott and Scott 1988; Heemstra et al. 2002). Along the coast of the southeast United States, adult snowy grouper are found predominantly on the upper continental slope (> 75 m) at depths of 116-302 m (Figure 1; Low and Ulrich 1983; Moore and Labisky 1984; Parker and Ross 1986; Kolmos et al. 2019) whereas juveniles are more common at shallower depths (Moore and Labisky 1984, Wyanski et al. 2000).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Snowy Grouper are found on the continental slope out to 300+ m depths along rocky outcroppings, ledges, and cliffs (Matheson and Huntsman 1984). Juveniles can typically be found in shallower waters than adults.

Figure 1: Regional distribution of snowy grouper from the SERFS chevron traps from 2018-2023 (excluding 2020).

CHALLENGES

Deepwater species are usually harder to monitor based on the logistical challenges associated with weather, gear, currents, and depth in capturing these individuals. Slower growing, long-lived species are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. Because snowy grouper are sequential hermaphrodites,

there is also disproportionate targeting of the larger sex (males) potentially skewing population demographics. As with many other reef fish species which have substantial overlap in habitat use, there is fisheries related mortality even when they are not targeted in this multi-species fishery. As a deepwater species (≥30 m), snowy grouper are highly susceptible to post-release mortality (e.g. barotrauma). Fishery-dependent data is minimal, sporadic, and/or confidential (NOAA Fisheries 2024) due to regulations and limited participants in both the commercial and recreational fisheries. Overall gear encounters with snowy grouper by the fishery-independent SERFS chevron traps is relatively low, with catches not significant enough to create an index of relative abundance (Bubley et al 2023). Because snowy grouper continue to be overfished and overfishing is occurring, this necessitates monitoring on a consistent basis crucial to properly managing this stock, which can be challenging for the reasons stated above.

CONSERVATION ACCOMPLISHMENTS

There are seasonal closures for snowy grouper from July 1-April 30 as well as a 3-bag aggregate limit per vessel during the open season. There have been periodic decreases in the total allowable catch for Snowy Grouper since 2006 with additional deepwater MPAs established off the southeast coast of the US. After the results of the SEDAR 36 Update, Amendment 51 was proposed and is still going through the review process to determine the best course of action to sustainable manage the snowy grouper stock. Kolmos et al. (2019) indicated the population off NC and SC has started a slow recovery from an overfished status with age and growth, sex composition, and maturity all indicating a positive response to regulations to reduce fishing effort.

CONSERVATION RECOMMENDATIONS

- Increase fishery independent information to develop reliable indices of abundance
- Collect more age samples from the recreational sector with more spatial coverage
- Creating finer scale spatial structures to better assess the population
- Investigate sexual transition for temporal patterns as well as incorporating the dynamics of sexual transition in assessment models
- Use the updated information from Kolmos et al. (2019) to better estimate spawning potential

MEASURE OF SUCCESS

The South Atlantic Deepwater Longline Survey (SADLS) continued in 2023. SADLS was recently developed to address data deficiencies for deepwater species such as golden tilefish, blueline tilefish, and snowy grouper in the region. Protocols and locations were developed based on a workshop held in February 2020 and sampling commenced in

August 2020. Sampling is primarily conducted through cooperative efforts with commercial fishers and onboard observers. These collaborations are vital to the continued monitoring of our valuable deepwater species.

Southern Flounder

Paralichthys lethostigma

Contributors:
William A. Roumillat (SCDNR)

Revised 2015:
William A. Roumillat (SCDNR)

Revised 2025:
Joseph C. Ballenger (SCDNR) & Amy Zimney (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The southern flounder, *Paralichthys lethostigma* (Jordan and Gilbert, 1884), is a member of the order Carangiformes and family Paralichthyidae, or left-eyed flounders (Page et al. 2023). Diagnostic characters of this bottom dwelling predator include a rather large mouth with large, sheathed teeth, an arch in the lateral line over the pectoral fin, and no ocellated spots on the pigmented side. The southern flounder is the most abundant of the four species of the *Paralichthys* genus found in South Carolina estuarine and near shore waters, occurring from freshwater-tidal riverine systems to higher salinity seawater (Wenner et al. 1990). This species is often confused with the summer flounder (*P. dentatus*) or the gulf flounder (*P. albigutta*), from which it can be differentiated by comparing counts of vertebrae, fin elements, gill rakers, and body pigmentation (Wenner and Archambault, 2005). The fourth species, the large-tooth flounder *P. squamilentus*, is found on South Carolina beachfronts only as juveniles (Anderson et al. 1977). Although the South Carolina state record southern flounder weighed 8 kg (17 lbs., 6 oz.; SCDNR 2024a), this species occurs much more abundantly up to about 2.3 kg (5 lbs.) in local waters.

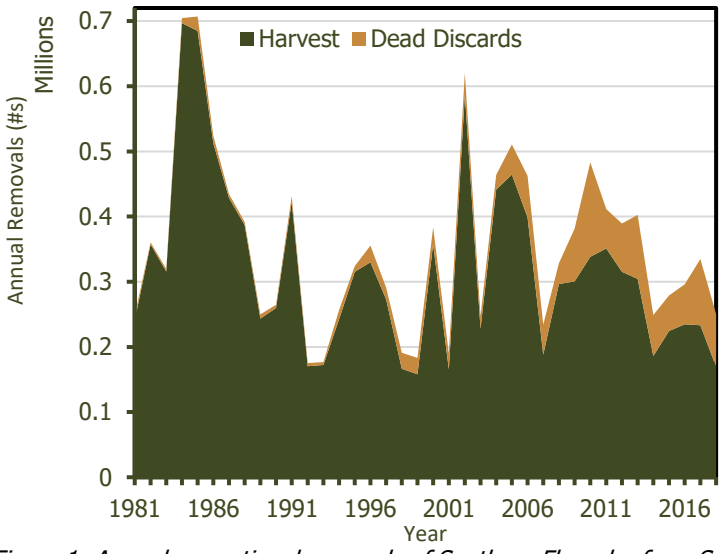

Figure 1: Annual recreational removals of Southern Flounder from South Carolina based on Marine Recreational Information Program estimates from 1981-2018. Removals represent direct harvest (green area) plus dead discards assuming a 9% post-release mortality rate (orange area).

Status

Annual removals of southern flounder in South Carolina have remained relatively stable since the mid-early 2000s, though

annually a greater share of removals is comprised of dead discards due to post-release mortality (Figure 1; NOAA, Office of Fisheries Statistics, pers. comm.)

A regional stock assessment of southern flounder, finalized in 2019, integrated available data from the east coast of Florida, Georgia, South Carolina and North Carolina to assess the status of the stock across the region (Flowers et al. 2019). The assessment suggested long-term declines in recruitment, chronic overfishing of the stock since the late-1980s, and spawning stock biomasses (SSB) below threshold levels (i.e., overfished) throughout the assessment time series with further rapid declines since the mid-2000s (Figure 2), and to end overfishing and allow the stock to rebuild to the target SSB in ten years a 72% coastwide reduction in annual removals was necessary.

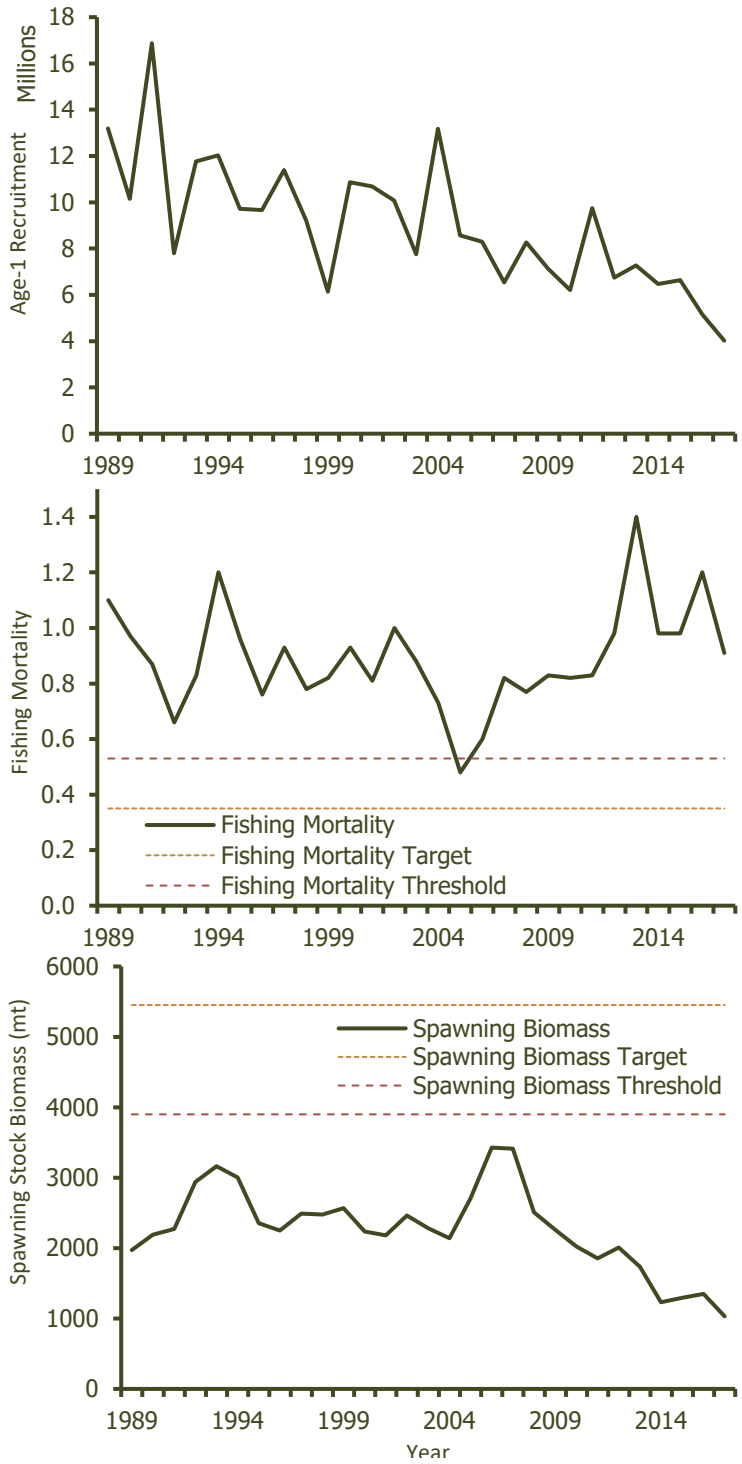

Figure 2: Time series of recruitment (top), fishing mortality (F; middle) and spawning stock biomass (SSB; bottom) as estimated in the regional assessment (Source: Flowers et al. 2019).

Currently, a second update to the regional assessment is being finalized with data through a 2022 terminal year. Results of the update assessment are expected to be available for management use in the fall of 2024.

POPULATION SIZE AND DISTRIBUTION

South Carolina falls within the northern limits for this species, which has a range from North Carolina to eastern Florida on

the Atlantic coast, and from southwestern Florida through the Gulf of Mexico to the Yucatan peninsula (Munroe 2002).

Tagging efforts have been conducted in South Carolina estuarine waters (Hart 2018; Wenner 1990), with the resultant data indicating limited movement and perhaps residence of southern flounder in estuarine systems, promoting the possibility of localized depletion. Three South Carolina Department of Natural Resources (SCDNR) fishery-independent monitoring programs routinely encounter southern flounder in South Carolina estuaries, namely the trammel net, electrofishing, and estuarine trawl surveys (Figure 3). The electrofishing and trammel net surveys both suggest steep declines in abundance through the late-2010s, with the decline more apparent in the longer trammel net time series which suggests declines of approximately 75% across coastal South Carolina since the early-1990s (Figure 3). The short estuarine trawl survey suggests generally increasing abundances from the early-2010s through 2020, followed by a rapid decline the last couple of years (Figure 3). These surveys also allow for a tracking of changes in population demographics through time using size- and age-compositions (Figure 4).

Figure 3: Standardized relative abundance of southern flounder as observed in the SCDNR trammel net (green line), electrofishing (gold line) and estuarine trawl (red line) surveys. Trammel net catches are normalized to average catches from 2010-2023, while electrofishing and estuarine trawl catches are normalized to their entire time series. The horizontal line represents average catch over the respective normalization period (survey specific) with points above the line indicating above average catch in that year and vice versa if below.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Immature southern flounders remain in the estuaries throughout the year. Adults migrate from estuaries during colder months to spawn offshore, though growing evidence suggests some adults may overwinter and spawn in estuarine waters (Midway

et al. 2024). Larvae are transported by ocean currents into the estuaries, finally reaching their

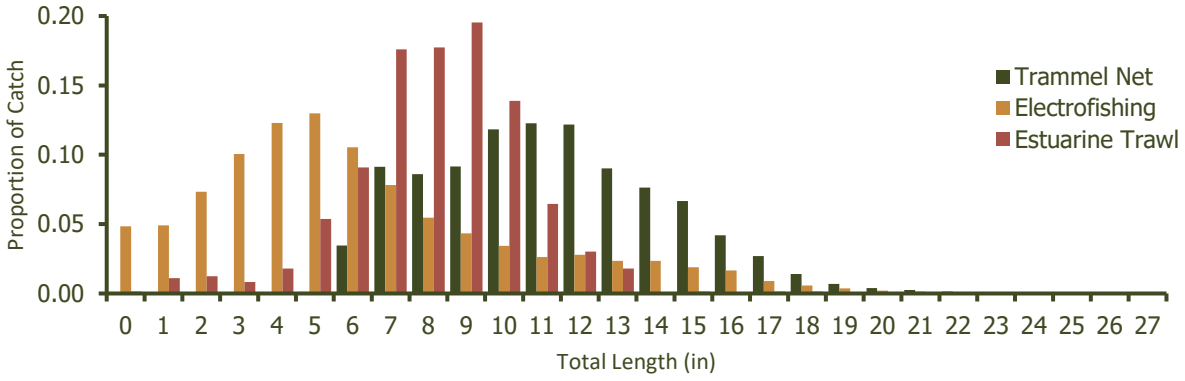

Figure 4: Percent frequency, across all years, of southern flounder by length captured in the SCDNR trammel net (green bars), electrofishing (gold bars), and estuarine trawl (red bars) surveys.

nursery habitat as small juveniles (1.3 cm or 0.5 inches) in the upper reaches of South Carolina estuaries. It is believed the majority of both sexes reach maturity by age-2, though females are much larger than males at that time (Midway et al. 2024). In South Carolina, at age 2, males are approximately 20 cm or 8 in. while females measure approximately 33 cm or 14 in. Females not only grow faster than males, but also live longer (Midway et al. 2024; Wenner et al. 1990), with maximum age of males and females in South Carolina waters of 3 and 6 years old, respectively.

Diet information for the southern flounder was investigated by Wenner et al. (1990) for adults and by Fernandez (1991) for juveniles. Prey items reflected the habitat location of this species during growth. Small flounders fed on copepods and opossum shrimp found in the upper reaches of the estuaries (Fernandez 1991). As the flounders grew and moved down the estuaries into higher salinities, their diet changed to include larger crustaceans and small fishes (Wenner et al. 1990). Larger southern flounders primarily consumed fishes and small blue crabs found in the shallow waters near the marsh edge in the higher salinity/lower reaches of South Carolina estuaries (Wenner et al. 1990).

CHALLENGES

The increase in the human population along the coast of South Carolina is disproportionate to the general demographics of the nation as a whole, and a concomitant increase in fishing pressure on flounder stocks in local estuaries has resulted (Flowers et al. 2019). The regional assessment suggested regionally the flounder population had been overfished and experiencing overfishing since at least the late-1980s (Flowers et al. 2019), with evidence of large declines in relative abundance along coastal South Carolina. Further, the potential for more limited movements of juvenile and adults across state boundaries (Midway et al. 2024), enhances the risk of

localized depletion due to fishing and habitat degradation. There is also mounting evidence of broadscale impediments to recruitment due to climate change (Erickson et al. 2020) or other factors (Midway et al. 2024).

Chemical contaminants and other emerging contaminants of concern, especially those that precipitate and incorporate into the sediment, pose a great threat to this species because of its close and persistent contact with the estuary bottom. Metals, polycyclic aromatic hydrocarbons (PAHs) and pesticides were shown to accumulate in the muddy sediments with which this fish is closely associated (Sanger 1998); these were shown to be detrimental to the benthic creatures exposed to it. Similar concerns are now arising regarding per- and polyfluoroalkyl substances (Fair et al. 2019; Thornton 2024) and microplastics (Parker et al. 2020) There is presently no routine testing of southern flounders for any of the above contaminants, except for the heavy metal mercury. Fortunately, samples of southern flounder fillets regularly examined since 2001 have not indicated any harmful build-up of the highly toxic methyl-mercury that can be found in South Carolina waters (SCDHEC 2024).

Preliminary investigations have shown various amounts of naturally occurring southern flounder parasites in different South Carolina estuarine systems. Since there is a history of industrial discharge in the Winyah Bay and Charleston Harbor estuarine systems, the potential of a positive correlation with parasite loads and pollution needs to be further investigated, especially in these two areas. Understanding the affects of parasite loads on natural populations of southern flounders, especially in reference to contaminants in the estuaries, could assist in circumventing future population problems.

CONSERVATION ACCOMPLISHMENTS

Because southern flounder are such a highly sought-after species, the State of South Carolina instituted harvest restriction on both the commercial and recreational fishery. Harvest of this important species is currently regulated by law with a 16-inch total length minimum size and 5 fish per angler per day, not to exceed 10 fish per boat per day for both the commercial and recreational fishery. The southern flounder does not enjoy gam fish status, so there are no restrictions on commercial capture except harvest must abide to the minimum size and possession limits for the recreational fishery. Further, the recent regional assessment led to changes in flounder regulations in North Carolina and Florida to work towards reducing coastwide removals by 72%.

CONSERVATION RECOMMENDATIONS

- Examine long-term trends in southern flounder population size, abundance and relative distribution; relate these dynamics to fishing pressure, climate variation, pollution affects, and parasite load and disease.

- Determine effects of pollutants on southern flounder reproduction, growth, and longevity.
- Determine the seasonality and potential estuarine hotspots of parasitic infections on southern flounder; relate these to growth and reproductive dynamics.
- Monitor the effects of recreational fishing stress on the existing population of southern flounders.
- Monitor the effects of marine pollutants on fish.
- Test for benthic contaminants. Acquiring this knowledge could benefit a great number of species that associate closely with the estuarine bottoms in addition to southern flounders.
- Continue exploring environmental drivers of recruitment success, particularly in the context of projected climate change impacts along coastal South Carolina.
- Further work is needed to elucidate the rates of coastal mixing of juvenile and adult flounder throughout the region.

MEASURE OF SUCCESS

By monitoring and reacting to a potential decline of this species due to increased angler harvest, parasite load, or environmental contaminants, SCDNR will be able to maintain adequate stocks. A measure of success would be to see sustained improvements in relative abundance as observed in various SCDNR fishery-independent surveys and future assessments showing rebuilding of the regional population to target levels and an ending of overfishing.

Southern Kingfish by Diane Peoples for Florida Department of Wildlife and Conservation.

DESCRIPTION

Taxonomy and Basic Description

Kingfishes are members of the drum family of fishes and are related to such species as spotted sea trout (*Cynoscion nebulosus*), spot (*Leiostomus xanthurus*), Atlantic croaker (*Micropogonias undulates*), red drum (*Sciaenops ocellatus*), black drum (*Pogonias cromis*), and others. In South Carolina's waters, there are three different species of kingfishes: the Gulf kingfish (*Menticirrhus littoralis*), the southern kingfish (*Menticirrhus americanus*), and the northern kingfish (*Menticirrhus saxatilis*); however, only the southern kingfish is encountered with any regularity. On occasion, all three species will be found together. Along the East Coast of the United States, the common name for the kingfishes varies by location. In South Carolina, they are called "whiting" whereas in North Carolina they are "sea-mullet."

The southern kingfish can be distinguished from the other two species by pale angular bands and a short first dorsal spine. The northern kingfish has dark, angular bands along the sides of their body and a long first dorsal spine. The Gulf kingfish has a silvery color as well as a darker area on the tail fin (mainly on the dorsal lobe or the top portion), and much smaller scales than the southern kingfish.

Both commercial and recreational fishers harvest the southern kingfish throughout this species' range. It is difficult to obtain reliable estimates of the landings because neither group of fishermen separates landings by species. For example, all three kingfishes are listed as "king whiting" in the commercial statistics of the National Marine Fisheries Service (NMFS Commercial Fisheries Statistics 2005) for the East Coast. The recreational statistics are also problematic due to confusion of the species by port samplers and creel clerks. Port samplers view the commercial catch and obtain catch statistics (amount of catch, species, and individual fish size). Creel clerks interview recreational anglers at boat landings, piers, beaches, and marinas to obtain information on recreational catch. Additional training for individual samplers has minimized this problem in the recreational fishery; however, data from the early years of the survey are suspect (NMFS Marine Recreational Fisheries Statistics Survey 2024). Figure 1 represents the collective recreational catch (# of fish) of southern kingfish in South

Carolina, which has experienced a downward trend after peaking in 2006.

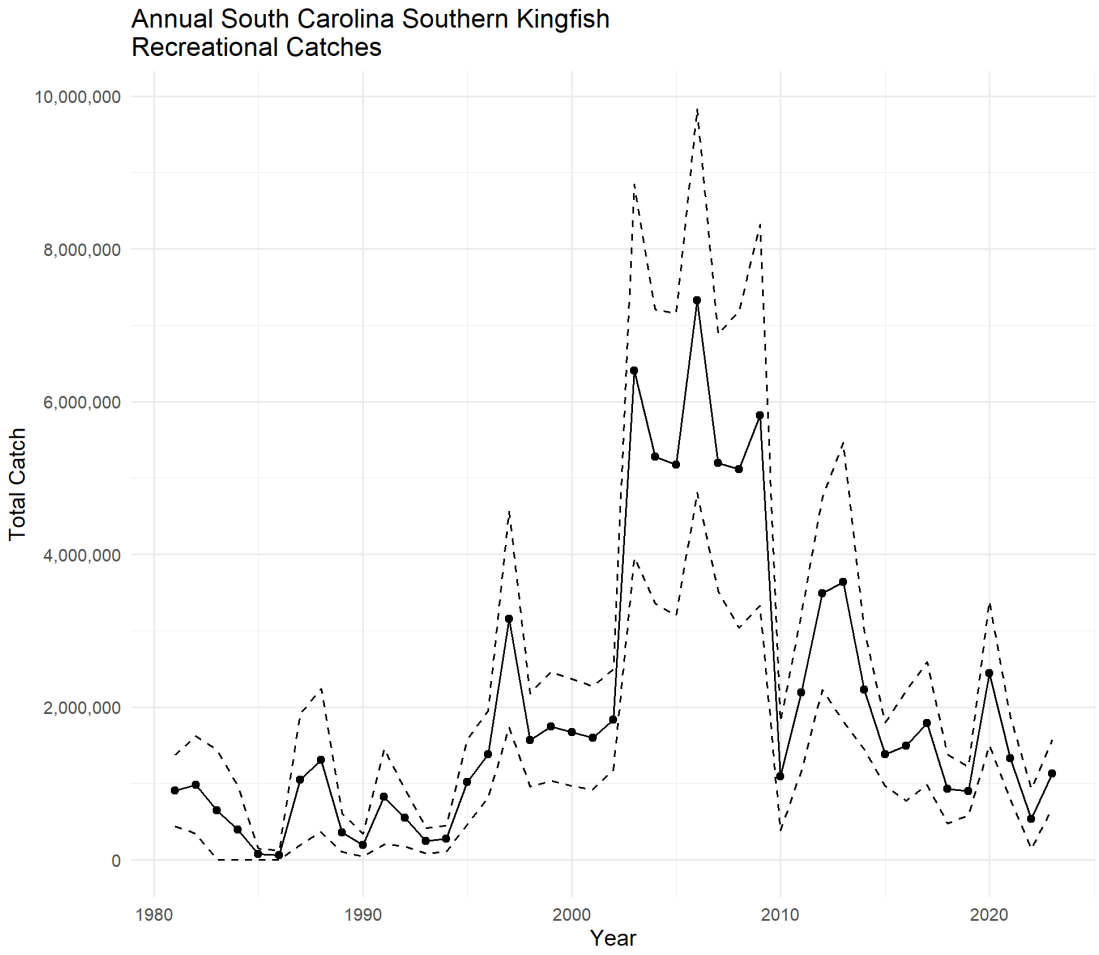

Figure. 1: Recreational catch (number of fish) of southern kingfish in South Carolina (NMFS 2024). Black solid line represents total catches, and grey dashed line represents the 95% confidence interval around those catch estimates.

Status

None of the kingfishes are considered threatened or endangered; however, there are concerns in South Carolina regarding by-catch mortality. Although the population status of kingfish in general appears to be stable in South Carolina, the difficulty in separating these three species in order to detect population trends for each is a cause for concern.

The prevalence of kingfish in near shore, shallow, coastal waters make these species excellent indicators of the health of this ecosystem. In addition, kingfish are a forage item in the near-shore oceanic waters for another species of conservation concern, the bottlenose dolphin.

Southern Kingfish are present in South Carolina estuaries year round but are more abundant during June-September (Fig. 2).

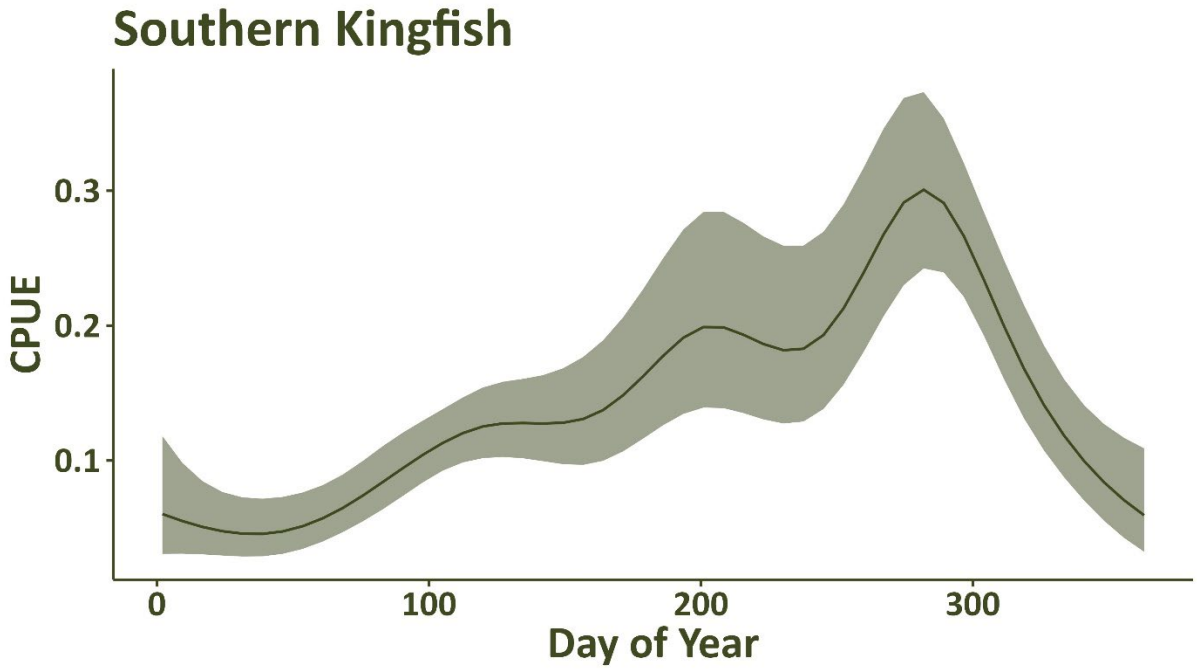

Figure 2. Southern Kingfish catch per unit effort in the SCDNR's Inshore Fisheries trammel net survey by day of the year.

The SCDNR fishery independent trammel net survey (1990-present) has caught southern kingfish at steadily increasing numbers over the last 34 years (Fig. 3), though declines have been observed since 2021.

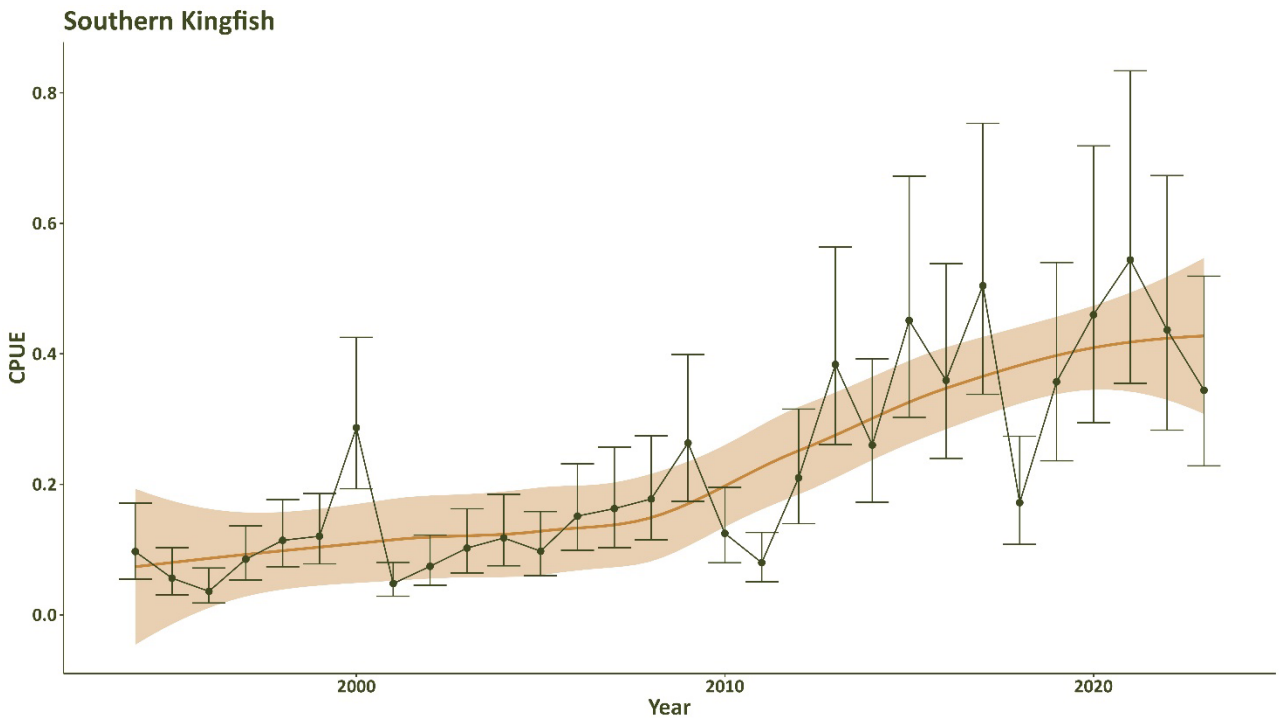

Figure 3. Southern Kingfish catch per unit effort in SCDNR's Inshore Fisheries trammel net survey by year from 1990 to 2023.

POPULATION SIZE AND DISTRIBUTION

The southern kingfish is found from Cape Cod to northern Argentina. The southern range of the northern king fish extends to northern Mexico in the Gulf; the two other species extend to southern Brazil. In waters of the United States, kingfish are relatively common from Chesapeake Bay, Virginia to southern Florida and throughout the Gulf of Mexico (Chao 2002). In South Carolina, southern kingfishes are commonly encountered in near-shore, ocean waters along the coast, and in higher salinity bays and estuaries like Calibogue Sound. Large southern kingfish are over 35 cm (13.8 in.) in total length; however, most individuals are smaller.

The population status of kingfishes along the Southeastern coast is unknown. The Southeast Area Monitoring and Assessment Program (SEAMAP) within the South Carolina Department of Natural Resources (SCDNR) is responsible for monitoring coastal waters. Cruises are undertaken during spring, summer, and fall from Cape Hatteras, North Carolina south to Cape Canaveral, Florida. These surveys provide estimates of relative abundance for a variety of species. Relative abundance is the average catch of a given species for all trawls made during a survey cruise. SEAMAP catch per tow values (CPUE) for South Carolina waters varies between years.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Southern kingfish prefer near-shore, shallow coastal waters with a muddy-sand bottom as well as high salinity bays and estuaries along the coast. Kingfish can also be found in areas that have sufficient benthic infauna. These animals that live in the sediment, such as polychaetes (sea worms), mollusks (clams and snails), and crustaceans (amphipods, sea-lice) represent an important food source to kingfish. Southern kingfish appear to move south in the winter to areas with warmer water temperatures. They return to South Carolina's waters in the spring as temperatures moderate (Wenner and Sedberry 1989).

CHALLENGES

Kingfish are consistently found in penaeid shrimp fishery by-catch along the Southeastern coast (unpub. data); this incidental catch can result in death for many kingfish juveniles. The mesh of a shrimp trawl is able to retain all but the very smallest kingfish juveniles. Any fishes that reside in the same area as the targeted shrimp will be caught by nets during shrimp trawls. Since the nets are pulled for a relatively long time (one or more hours), most fish caught by the net are dead by the time the catch reaches the boat (pers. obs.). Deckhands remove shrimp from the catch, then cull the remaining by-catch of fish and crab. Fish large enough for consumption are retained and the remainder is discarded over the side. Larger southern kingfish are placed in boxes, iced, and brought to the dock for sale (pers. obs.). Kingfishes are prized for their mild and firm flesh and can bring a fair price. In some kingfish habitat, shrimp fishing is not conducted, either because of rough bottom or an absence of shrimp. These areas provide a refuge for kingfish from the shrimp trawl nets (unpub. data).

Poor water quality from increased nutrient runoff and sewage discharges can cause oxygen depletion in kingfish habitat. Dredging offshore sandbars could eliminate some habitat as well as stir up sediments. Elimination of sandbars impacts the benthic infauna that forms the diet of the southern kingfish. During dredging activities, sediments and sediment-bound chemical toxicants become suspended in the water column. Turbidity that accompanies dredging activities may impact the respiratory lamellae in the gills of the fishes, resulting in affects similar to terrestrial animals breathing dust.

CONSERVATION ACCOMPLISHMENTS

Regulations require that shrimp nets be equipped with TEDs (turtle excluder devices) and BRDs (by-catch reduction devices). TEDs prevent large kingfish and marine turtles from being trapped in the nets and drowned. BRDs allow many fish to escape the nets that would otherwise be included in the catch. By-catch reduction devices have mitigated some of the by-catch mortality for kingfishes and other species. However, with increased fuel prices combined with soft markets due to competition from farm-raised, imported shrimp, the use of BRDs in the penaeid shrimp fishery has declined over the years—a pattern that may continue.

CONSERVATION RECOMMENDATIONS

- Continue to monitor southern kingfish distribution, relative abundance, maturity and age composition in the SEAMAP survey and through recreational fisher surveys.
- Develop ways to obtain better data from the recreational and commercial fisheries.
- Develop a management plan for kingfish in South Carolina.
- Work with municipalities to encourage the use of Best Management Practices (BMP) to reduce nutrient and sewage runoff.
- Identify key offshore habitat (sandbars) and work with the appropriate agency to deter dredging in these areas.
- Partner with federal agencies and NGOs to establish incentive programs that promote continued use of BRDs in the shrimp trawl industry.

MEASURE OF SUCCESS

The ability to estimate population trends for each species of kingfish is one measure of success. Stable population trends for all three species of kingfish, as documented during annual surveys, would represent another measure of success.

Atlantic Spanish Mackerel

Scomberomorus maculatus

Source: SAFMC

Contributors:
Pearse Webster (SCDNR) & Jordan Neely (SCDNR)

Revised 2025:
Elizabeth Bullard (SCDNR) & Tracey Smart (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Atlantic Spanish mackerel, *Scomberomorus maculatus* (Mitchell 1815), is a smaller member of the Scombridae family which includes a variety of mackerel, tuna, wahoo, and bonito, and the order Scombriformes (Page et al. 2023). This is a migratory species with two distinct populations, one of which is found off the Atlantic coast of the United States and another throughout the Gulf of Mexico (GOM). The Spanish mackerel is one of the three species in the Scomberomorini tribe (in addition to King mackerel and wahoo) that is frequently encountered off the coast of South Carolina (SC; Collette and Nauen 1983).

Spanish mackerel have laterally compressed, elongate, fusiform bodies. Along the dorsal surface is a forward dorsal fin, which fades from black to translucent, that is narrowly separated from a second dorsal fin with green coloration and a concave shape to the trailing edge. These fins are followed by 7 to 10 small finlets (Collette 2002). The lateral line of the Spanish mackerel begins to slope slightly downwards below the second dorsal fin. With the lateral line apparent at most sizes, it is a key feature to distinguish the species from smaller king mackerel which have a lateral line that drops abruptly below the second dorsal fin (Collette 2002). Spanish mackerel are gonochoristic, females reach sexual maturity by age two, and both sexes can live as long as 12 years, reach maximum lengths of 12 to 15 inches, and may weigh several pounds (Powell 1975; Schmidt et al. 1993).

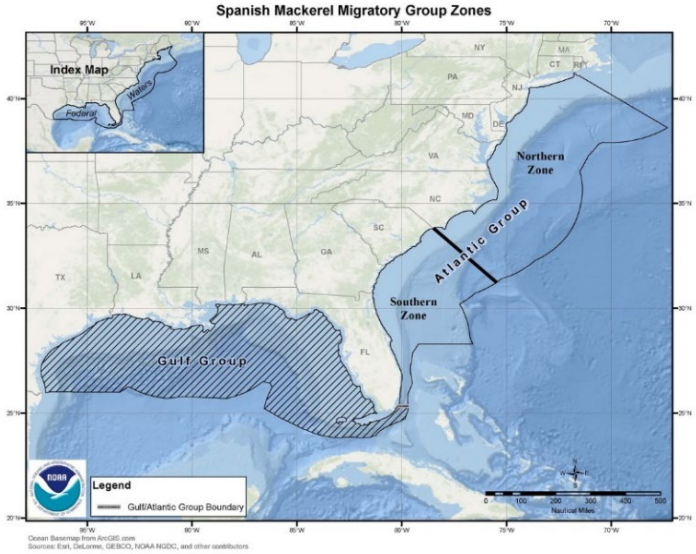

Figure 1: Map of Spanish mackerel distribution through migratory group zones management areas (noaa.gov)

Status

The International Union for the Conservation of Nature (IUCN) lists

Spanish mackerel as a species of Least Concern. While Spanish mackerel experienced low biomass and increased fishing pressure during the 1980s and 1990s, cooperative management by the Atlantic States Marine Fisheries Commission (ASMFC) and the South Atlantic Fishery Management Council (SAFMC) helped to rebuild stocks. In 2022, an operational assessment with data through 2020 through the SouthEast Data, Assessment and Review (SEDAR) process found the Atlantic Spanish mackerel stock was not overfished nor experiencing overfishing.

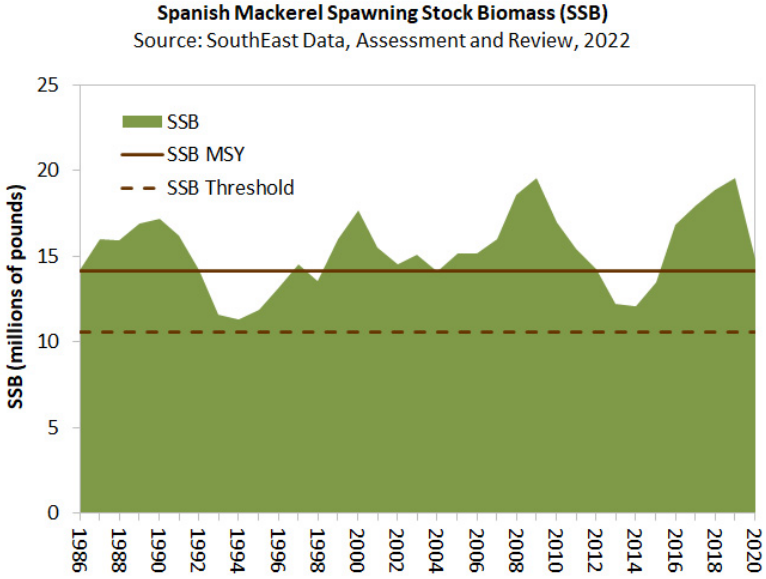

Figure2: Spawning stock biomass of Atlantic Spanish mackerel from 1986 to 2020 (SEDAR 78).

POPULATION SIZE AND DISTRIBUTION

Spanish mackerel ranges along the US Atlantic coast, around the Florida peninsula, and throughout the Gulf of Mexico predominantly in continental shelf waters (Figure 1; Collette 2002). For management purposes, this species is split into two separate stocks at the Florida Keys into an Atlantic and a Gulf of Mexico stock. There is little direct evidence of mixing between the two migratory groups around the Florida peninsula, however it is not known how closely these management units come to representing actual genetically defined stocks.

It was shown through SEDAR 78 that spawning stock biomass (SSB) had been increasing in recent years, but current fishing pressures are causing a decrease that

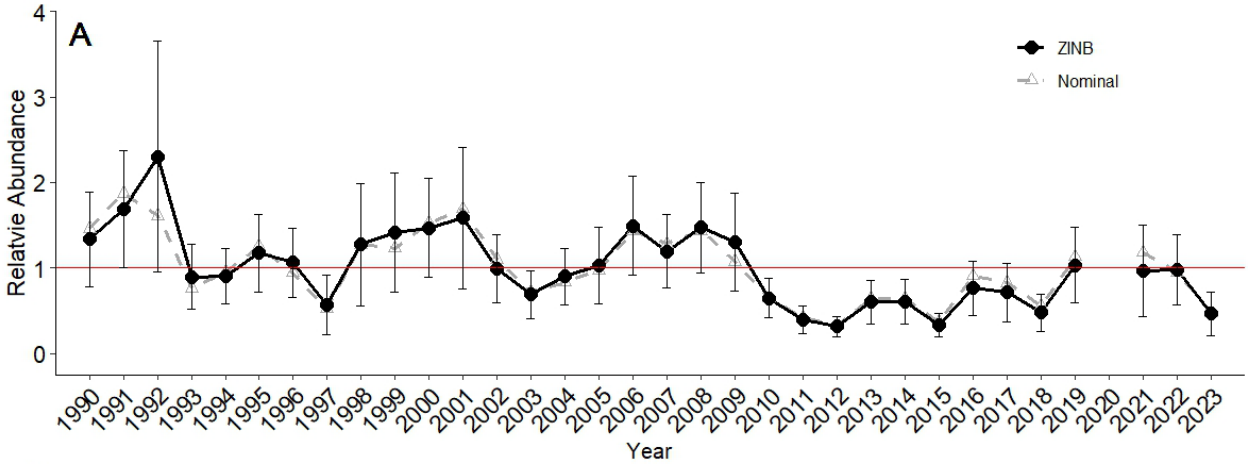

Figure 3: Nominal and ZINB standardized relative abundance of Spanish mackerel normalized to the time series mean of the SEAMAP-SA Coastal Trawl Survey. Error bars are representative of standard error.

could lead to decreased population numbers (Figure 2). The Coastal Trawl Survey (CTS) for the South Carolina Department of Natural Resources (SCDNR) has seen yearly variability in Spanish mackerel catches, with a general decrease in relative abundance per trawl sustained over the last 10 years (Figure 3).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Spanish mackerel is primarily a piscivorous pelagic occupant of coastal shelf waters. It is an opportunistic feeder encountered in a variety of habitats ranging from areas of structure (e.g., reefs, jetties) to grassy beds to open water in temperatures ranging from 65-80˚F (Earll 1883), with some occurrence observed outside of this range as well. All life stages from egg to adult appear to occur in near-shore ocean waters off South Carolina (Berrien and Finan 1977). Occasionally, individuals have been observed in estuarine waters as well.

CHALLENGES

The most recent Atlantic assessment showed recent fishing mortality was above the maximum fishing mortality threshold (MFMT), leading to a potential for the stock to be considered experiencing overfishing if current fishing rates continue (ASFMC; SEDAR 2022). Currently, no fishery-independent survey exists in the Atlantic for adult Spanish mackerel, leading to the assessment relying on landings data streams and a juvenile fishery-independent survey (SEAMAP-SA Coastal Trawl Survey). Spanish mackerel exhibit reduced movement and mixing compared to other migratory pelagics, which raises concerns about localized depletion from fishing pressures (Schrandt et al. 2015). More research is needed to determine movement patterns of adult fish to understand connectivity within the stock. Additionally, few studies have investigated spawning of Atlantic Spanish mackerel. This adds to the uncertainty of fish stock projections on a long-term basis (SEDAR 2022). Secondary challenges arise relating to bycatch of Spanish mackerel by the commercial shrimp trawl industry. Current bycatch numbers are thought to be inaccurate and underestimated (SEDAR 2012; SEDAR 2022).

CONSERVATION ACCOMPLISHMENTS

The original fishery management plan (FMP), effective in 1983, set a maximum sustainable yield (MSY) and size limit for the harvest of Spanish mackerel within the U.S. Exclusive Economic Zone (EEZ). Further expansion of Spanish mackerel management was implemented throughout the 1990s and 2000s as the stock was maintained through a variety of commercial trip limits, recreational bag limits, size limits, seasonal fishing restrictions, gear restrictions, and extensive monitoring of landings (SEDAR 2022). To date, these management efforts have supported a stock that is not overfished or undergoing overfishing.

CONSERVATION RECOMMENDATIONS

- Further investigation of migratory patterns, through tagging, otolith micro-chemistry, or genetics, to better define Atlantic and Gulf stocks and set biologically meaningful management boundaries.
- Expand research and monitoring of adults via fishery-independent surveys.
- Assess migratory spawning migrations and behavior to better determine stock projections, recruitment, and spatial scale of Spanish mackerel at all life stages.
- Investigate new methods to determine point estimates for natural mortality which can better inform stock assessments.
- Increase observer coverage of the shrimp trawl fishery along the SE Atlantic coast, quantifying bycatch estimates and discard mortality.

MEASURE OF SUCCESS

The SEAMAP-SA Coastal Trawl Survey program monitors the relative abundance, population demographics, and reproductive state of primarily juvenile Atlantic Spanish mackerel. Studying these metrics can help to detect when changes in these parameters occur relative to fishing pressures or current management efforts and can serve as early indicators of issues within the stock. Utilizing sufficient fishery-independent data can help to generate stock estimates with more confidence. Increases in recruitment, abundance, size- and age-composition, and spawning stock biomass (SSB) would indicate positive trends in the population. Ideally, stock structure would improve to a point that calculations of maximum sustainable yield (*MSY*) result in total allowable catch (*TAC*) levels that can accommodate demand for commercial and recreational harvest.

Speckled Hind

Epinephelus drummondhayi

Contributors:
Stephen Long (SCDNR)

DESCRIPTION

Speckled hind, a once abundant subtropical-tropical, deep-water grouper of economic importance, is found along the mid-continental shelf to shelf-edge at areas of vertical relief, including wrecks, from North Carolina to the Gulf of Mexico and Bermuda, and potentially the Caribbean (Farmer and Karnauskas 2013, Ross 1988). Presently, encounters with speckled hind are low in comparison to other Snapper-Grouper species in the southeastern U.S. Atlantic, and a rarity with juveniles (Bubley et al 2023).

Taxonomy and Basic Description

Speckled hind, colloquially known as *Kitty Mitchell* grouper, is found in the order Perciformes and family Epinephelidae (Page et al. 2023), with a maximum total length (TL) and weight of 1,096 mm and approximately 29 kg, respectively (Matheson and Huntsman 2011, SAFMC 2024). Speckled hind larvae (<20 mm TL) are reported as morphologically indistinguishable from related western Atlantic groupers (e.g. *E. morio*), while juveniles (20 to ~340 mm TL) exhibit a distinctly yellow pigmentation with white spots before transitioning to a red-brown coloration, also with white spots, by 2 years of age. (Johnson and Keener 1984, Ross 1988). Adult speckled hind have a deep body, with 11 spines and up to 16 soft rays on the dorsal fin, an anal fin with 3 spines and 9 soft rays, pectoral fins with 18 rays, and a caudal fin with no fork (Carpenter 2002). Speckled hind are protogynous hermaphrodites, starting life as female and transitioning to male as early as 3 years of age, shortly after maturity at 2 to 13 years (~360 to 730 mm TL; Brule et al 2000, Ziskin 2008, Ziskin et al 2011). Spawning in the Southeast U.S. (SEUS) Atlantic has been noted from May to October, although some observations have occurred outside this range (Ziskin et al 2011). A regional life history study found a maximum age of 35 years, while an age-validation of samples from adjacent waters indicate under-ageing and estimate true longevity at 45 to 80 years (Andrews et al 2013, Ziskin et al 2011).

Status

Speckled hind in the SEUS Atlantic (i.e. NC, SC, GA, and FL East) have not undergone a formal stock assessment, and no Southeast Data, Assessment, and Review (SEDAR) assessment is scheduled. The Gulf of Mexico (GOM) assumes a separate stock structure, due to a lack of information on population mixing with the Atlantic, but available genetic studies have not revealed a distinction (SEDAR 2016). A SEDAR

evaluation of GOM speckled hind in 2016 was inconclusive, due to issues with available data.

POPULATION SIZE AND DISTRIBUTION

Speckled hind occur from Cape Hatteras to the Florida Keys, Bermuda, and in the Gulf of Mexico, and possibly the Caribbean at depths of 25-183 m (Ross 1988). They are strongly associated with continuous hardbottom, distributed along the mid-continental shelf to the shelf edge, with probability of presence in the SEUS increasing with latitude (Farmer and Karnauskas 2013). This agrees with Southeast Reef Fish Survey (SERFS) video observations (Figure 1; Bacheler et al 2016). An estimate of absolute Speckled Hind population size off South Carolina is not available. Commercial landings for Speckled Hind off the SEUS peaked in 1986 (NOAA Fisheries 2024). Commercial and recreational landings of Speckled Hind throughout the southeast have been in a general decline since, and prior, resulting in strict regulation and eventual closure (NOAA Fisheries 2024).

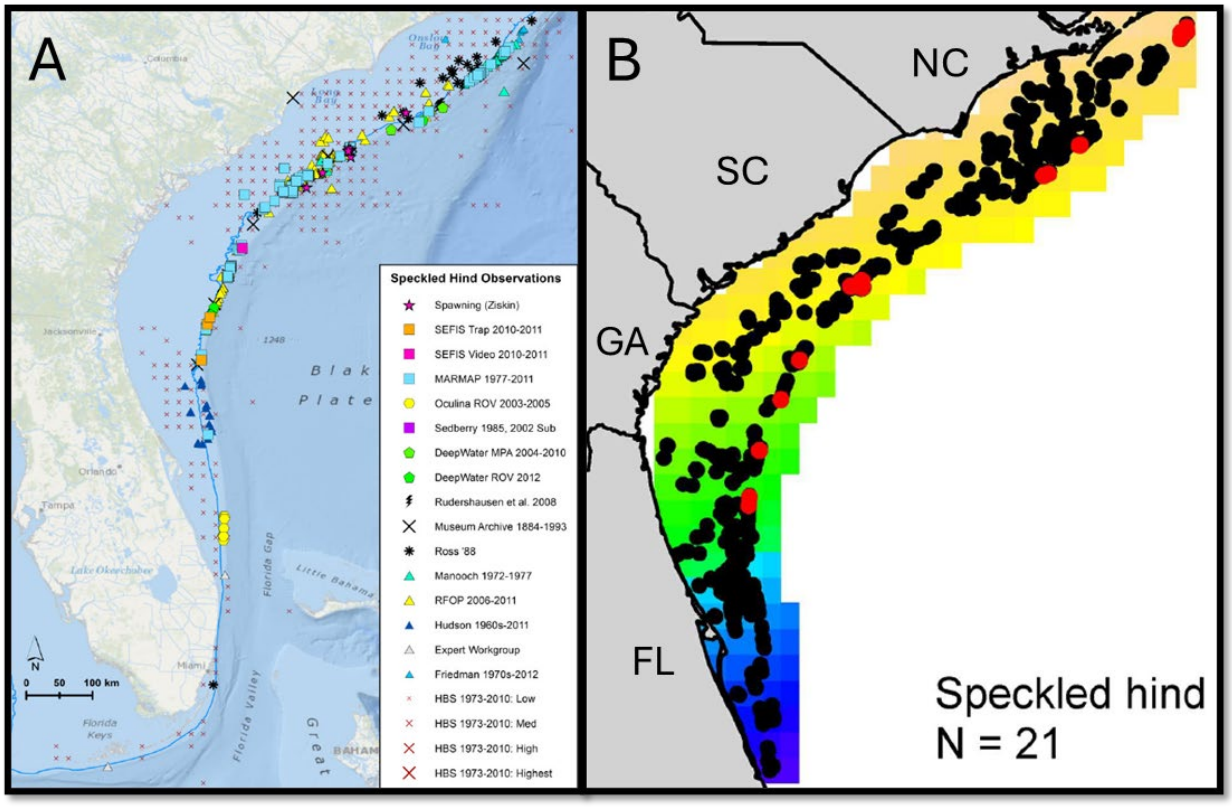

Figure 1: Modified figures from Farmer and Karnauskas (2013) displaying comprehensive reporting of Speckled Hind in SEUS Atlantic waters to 2011, and Bacheler et al (2016) showing the presence and absence of the Speckled Hind on videos. (A) Reliability of specific data sources (i.e. HBS) is noted as questionable. (B) Red indicates presence and gray points indicate absence from the Southeast Reef Fish Survey, 2011–2014. The "N" shows the number of videos samples in which the species was present.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Juveniles are concentrated in shallower depths (i.e. ~30-60 m), while mature adults are concentrated deeper (i.e. ~60-120 m), in temperatures of 60-85°F (SAFMC 2024, Ziskin et al 2011). Speckled hind occupy natural and artificial reef including wrecks, hard bottom, live bottom, and generally habitats that provide bathymetric relief (e.g. steep cliffs, rocky ledges; Ziskin et al 2011).

CHALLENGES

Speckled hind in the SEUS Atlantic has not undergone a formal stock assessment, but is considered overexploited (Ziskin et al 2011). Slower growing, long-lived species are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. Because they are sequential hermaphrodites, there is also disproportionate targeting of the larger sex (males) which can skew population demographics. As a deepwater species (≥30 m), they are highly susceptible to post-release mortality (e.g. barotrauma). Although harvest is prohibited, bycatch of speckled hind is difficult to reduce as there is potential for mortality even when they are not targeted in this multi-species fishery. Since harvest closure, fishery-dependent data is minimal, sporadic, and/or confidential (NOAA Fisheries 2024). Overall gear encounters by the fishery-independent SERFS is relatively low, with catches not significant enough to create an index of relative abundance (Bubley et al 2023). As a data-limited species, life history information (e.g. peak spawning) and distribution knowledge is incomplete and current stock status difficult to assess.

CONSERVATION ACCOMPLISHMENTS

Speckled hind in the SEUS Atlantic are managed by the South Atlantic Fishery Management Council (SAFMC). After various regulation increases to commercial and recreational harvest, beginning in 1992, a complete prohibition of harvest was enacted in 2011. In addition, the SAFMC established Marine Protected Areas (MPA) throughout the region in 2009. Although effectiveness is yet to be determined, these spatial reserves are closed to bottom fishing year-round, protecting known habitat of speckled hind, and providing a valuable data source and potential tool for rebuilding the stock. To mitigate bycatch release mortality of Snapper-Grouper species in the SEUS Atlantic, NOAA National Marine Fisheries Service (NMFS) has implemented various gear requirements onboard all vessels (e.g. non-offset circle hooks), including descending devices as recent as 2020 (NOAA NMFS 2020).

CONSERVATION RECOMMENDATIONS

- Initiate a formal stock assessment of speckled hind, specific to SEUS Atlantic.

- Assess and alter MPAs, as needed, for maximum effectiveness.
- Continue to monitor via fishery-dependent and -independent surveys.
- Continue pursuit of non-lethal methods of determining abundance estimates.
- Conduct discard mortality studies in conjunction with ongoing surveys.
- Assess/address data gaps for speckled hind (e.g. oceanographic variables, spawning locations/patterns).
- Initiate an age-validation study of SEUS speckled hind.
- Perform high-resolution mapping, where not present, of assumed preferred habitat.

MEASURE OF SUCCESS

The SCDNR Marine Resources, Monitoring, Assessment, and Prediction (MARMAP) Program historically monitored the economically important Snapper and Grouper fisheries off the SEUS Atlantic. MARMAP, along with the Southeast Area Monitoring and Assessment Program – South Atlantic (SEAMAP-SA), and the Southeast Fishery Independent Survey (SEFIS), collectively known as SERFS, use a variety of survey platforms, designs, and methods to collect data on the relative abundance, population demographics, and reproductive state of these fish. With the information collected, the program can observe long-term trends and provide data needed by decision-makers for management regulations. An increase in relative abundance would suggest an increase in the numbers of speckled hind.

Spinner Shark

Carcharhinus brevipinna

Contributor:
Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The spinner shark, *Carcharhinus brevipinna* is a member of the family Carcharhinidae and reside in the genus *Carcharhinus* (32 species). The spinner is a placentally viviparous shark (bears live young with a maternal connection). Spinners are moderate sized sharks reaching maximum reported total lengths (TL) of 242 cm (Castro 2011). Spinner sharks are frequently confused with blacktip sharks, both species are recognizable by a prominent "Z" line along their sides; however, spinner sharks can be differentiated by their pointy snout, less robust body, shorter dorsal fin, and a black tipped anal fin. They have moderate life histories with males maturing at 4.5 years old (127 cm fork length, FL), and females maturing at 6.6 years old at around 142 cm FL (Palmrose unpublished). Once mature, spinner sharks reproduce every other year (biennial) and produce an average of 5 pups (Palmrose unpublished). The maximum observed age for the spinner shark is 23.5 years old (Vinyard unpublished).

Status

The spinner shark is classified as a large coastal shark (LCS) and is managed as a complex by the National Marine Fisheries Service (NMFS). Status determination for LCS is hampered by a lack of species specific data. The large coastal shark complex was last assessed in 2006, and the results of that assessment prompted a 50% reduction in available commercial quota. Spinner sharks have never had a species-specific stock assessment due to a lack of critical data including life history, catch, and fishery-independent data. The International Union for Conservation of Nature (IUCN) Red List considers spinner sharks as "Vulnerable" (Rigby et al. 2020). In South Carolina spinner shark catches vary from year to year as some years they appear in greater frequency then other, that said, abundance trends suggest a moderate increase in spinner sharks over the time-series (Figure 1).

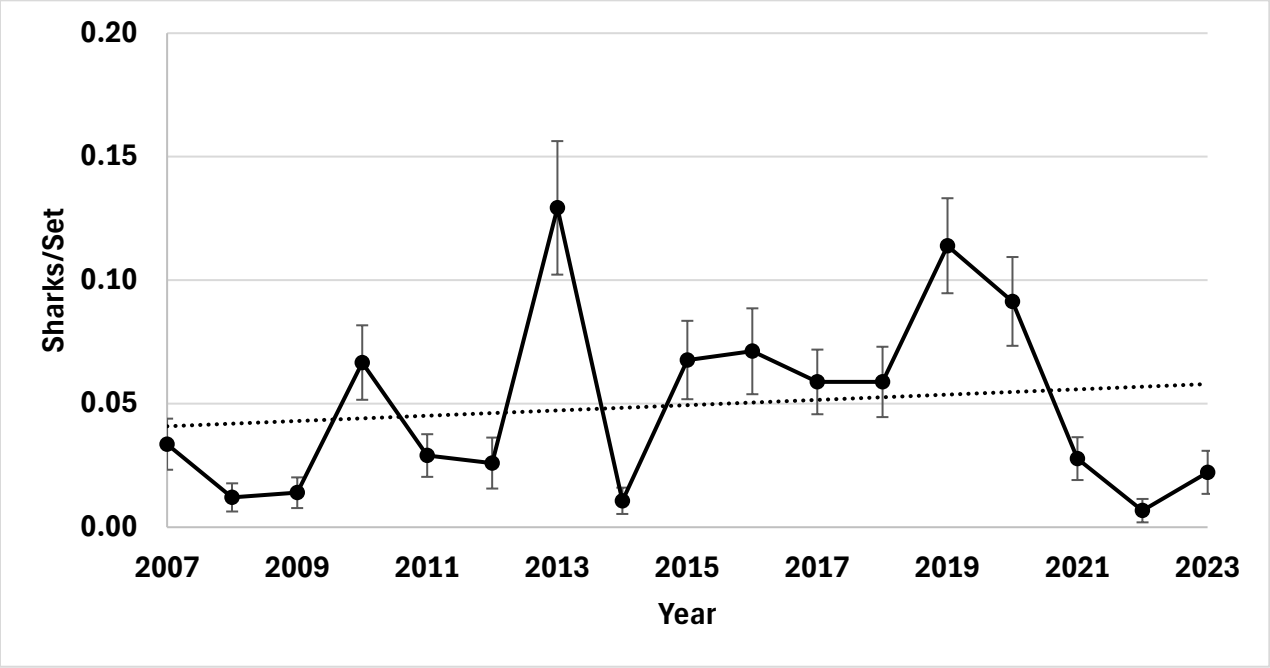

Figure 1. Catch per unit effort (sharks per set) of spinner sharks from 2007 to 2023 in the South Carolina Coastal Longline Survey. Standard error is denoted by error bars.

POPULATION SIZE AND DISTRIBUTION

Spinner sharks have a circumtropical distribution with the exception of the eastern Pacific Ocean (Castro 2011); however, records are spotty as they are often confused with blacktip sharks. In the US Atlantic Ocean, they are found from the mouth of the Chesapeake Bay (Virginia), south through the Gulf of Mexico. In South Carolina waters, they are primarily found as young of the year, with juveniles and adults occurring further offshore. Young of the year have been documented to be in estuarine waters. They are most abundant in late fall when other shark species have migrated out of SC waters.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In South Carolina, spinner sharks are commonly found over sandy and muddy bottoms in estuarine and coastal waters. They are known to actively feed on schooling fish and can often be found mixed in with larger schools of blacktip sharks. While young of year sharks are infrequently captured, the extent of their use of South Carolina waters is unclear, as some years young of year spinner sharks are not encountered at all in South Carolina, whereas in other years they can be abundant. It appears there may be plasticity to their use of estuarine habitat. Larger juvenile and adult spinner sharks are primarily found in nearshore coastal waters. Little is known about habitat requirements for spinner sharks, but they seem to prefer high salinity waters (>32 ppt) (Ulrich et al. 2007).

CHALLENGES

Large coastal sharks, including spinner sharks, were generally shown to be in decline in US Atlantic waters; however, in recent years, the majority of populations have been increasing (Peterson et al. 2017). Recent efforts have focused on gathering critical life history data including age and growth, reproduction, and stock structure (multiple publications expected in 2025). These data should allow for a species-specific assessment has for spinner sharks. That said, difficulties in separating catches of spinner sharks and blacktips sharks may hamper assessing the stock status of the spinner shark. The life history of these species (slow growing, late maturity, and few offspring) means they are highly susceptible to overfishing. Spinner sharks are harvested both commercially and recreationally and are bycatch in a variety of fisheries; therefore, it is imperative that the stock status of spinner sharks is assessed.

CONSERVATION ACCOMPLISHMENTS

There are no conservation accomplishments specific to this species at this time.

CONSERVATION RECOMMENDATIONS

- Continue to monitor the stock status of spinner sharks within SC waters through fishery-independent methods, primarily COASTSPAN, and the Coastal Longline Survey.
- Increase monitoring of spinner sharks within coastal waters to determine habitat utilization.
- Increase collection of species specific-data to allow for future species-specific stock assessments.
- Continue genomic studies of spinner sharks including using close-kin mark recapture studies to estimate population size.
- Conduct studies using electronic monitoring tags (i.e. PSATs, acoustic tags, and SPOT tags to understand spinner shark migratory behavior and essential habitat.
- Improve the public's understanding of the importance of sharks in the ecosystem through outreach activities such as school programs, providing story opportunities for media, and educational brochures.
- Continue to educate the public on the importance of species identification of sharks to ensure undersized and prohibited sharks are not landed.
- The primary action at the state level via law enforcement partnering is to ensure adequate compliance with regulatory actions implemented through the federal management plan and subsequent amendments.

MEASURE OF SUCCESS

One of the most important measures of success will be determining species-specific stock statuses for spinner sharks in US waters. Regional management efforts to maintain healthy, sustainable populations of spinner sharks will require active participation from South Carolina due to its importance as habitat for the species. Expanding our knowledge on the life history and importance of SC waters for spinner sharks as well as the drivers of their movements and essential fish habitat for the species is of high importance. Maintaining ongoing monitoring programs to continue indices of abundance and trends over time is critical to the success of stock assessments.

DESCRIPTION

Taxonomy and Basic Description

Spot is a common member of the family Sciaenidae that was first described by Lacepede (1802). Johnson (1978) provided the following description of morphology: the body of the Spot is deep and compressed laterally; the back is strongly elevated; the head is obtuse and short with the small mouth positioned ventrally. Spot are bluish-gray above and somewhat golden below. They have 12 to 15 oblique dark streaks that may become indistinct in larger specimens. A single large black spot is located above the gill cover. Their average size is 8 inches, 0.5 pounds, and maximum age is approximately 5 years.

Status

Spot provide important recreational and commercial fisheries in the South Atlantic, although year-to-year fluctuations in landings are common. This is because spot are short-lived and the catch in most years consists of a single year-class, the strength of which is variable (partly due to environmental conditions prevalent in the spawning and nursery areas). In 2017, the first coastwide benchmark stock assessment was completed for Spot. The assessment used a catch survey model to estimate population parameters (e.g., stock status, natural mortality, discard rates, and mortality) and biological reference points. However, due to conflicting trends in abundance and harvest, as well as other uncertainties, this assessment was not recommended to be used for management advice. Independent of stock assessments, each year a traffic light analysis (TLA) is performed to analyze trends in the fishery and implement state-specific management actions if necessary. However, recent TLA analyses have also shown conflicting trends in abundance and harvest of Spot. The 2020 TLA showed significant declines in harvest of Spot in the mid-Atlantic and South Atlantic and declines in adult abundance in the mid-Atlantic which triggered management actions be put in place for the entire region. Overall status could not be determined in the 2022 TLA due to limited data availability from fishery independent surveys and the TLA was not run in 2023 due to an ongoing stock assessment. An updated benchmark stock assessment for Atlantic Croaker will be completed in 2024. Based on a 2019 IUCN assessment, Spot is listed as a species of 'Least Concern'. However, this assessment dates from over a decade ago and is noted as 'needs updating'.

POPULATION SIZE AND DISTRIBUTION

Spot are commonly found within estuarine and coastal waters from Cape Cod to the Bay of Campeche in Mexico (Phillips et al. 1989). In South Carolina they are found in estuaries throughout the state's coastline. With adults inhabiting estuaries, tidal creeks, and shallow coastal waters; generally over muddy or sand-mud bottoms; also over oyster reefs and along beaches, and juveniles utilizing lower salinity tidal creeks; yearlings progress to deeper water of lower estuaries and inlets; most common over mud or detritus-laden bottoms and seagrass beds.

The Southeast Area Monitoring and Assessment Program – South Atlantic (SEAMAP-SA) Coastal Trawl Survey (CTS) is a fishery independent survey conducted by SCDNR. This shallow water trawl survey monitors status and trends of numerous coastal species within the coastal zone in Atlantic waters off the southeastern United States between Cape Canaveral, FL to Cape Hatteras, NC. The stratified annual mean catch per unit effort (CPUE) in kilograms per tow per hectare for all months for Spot from the CTS has been highly variable since 1989. The general trend has been increasing abundance since 2007 (Figure 1).

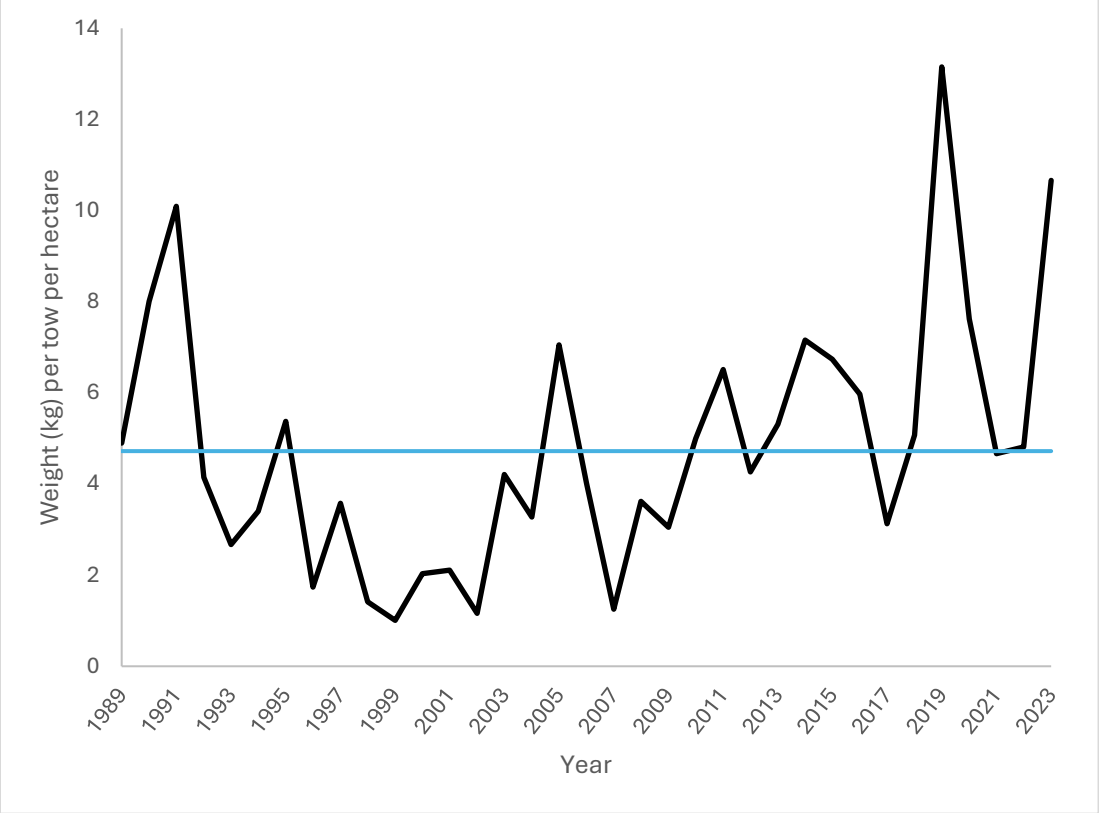

Figure 1. Stratified mean annual CPUE (kg/tow/hectare) for Spot from SEAMAP CTS from all months and strata. Blue line represents the long-term mean.

This species is commonly encountered in our fishery independent surveys; however, the population has decreased over the past few decades in the SCDNR Trammel Net Survey. (Figure 2), in which randomly selected sites along salt marsh edges amongst five estuaries along the South Carolina coast are sampled monthly. A similar trend is seen in the SCDNR Electrofishing survey over the past decade (Figure 3).

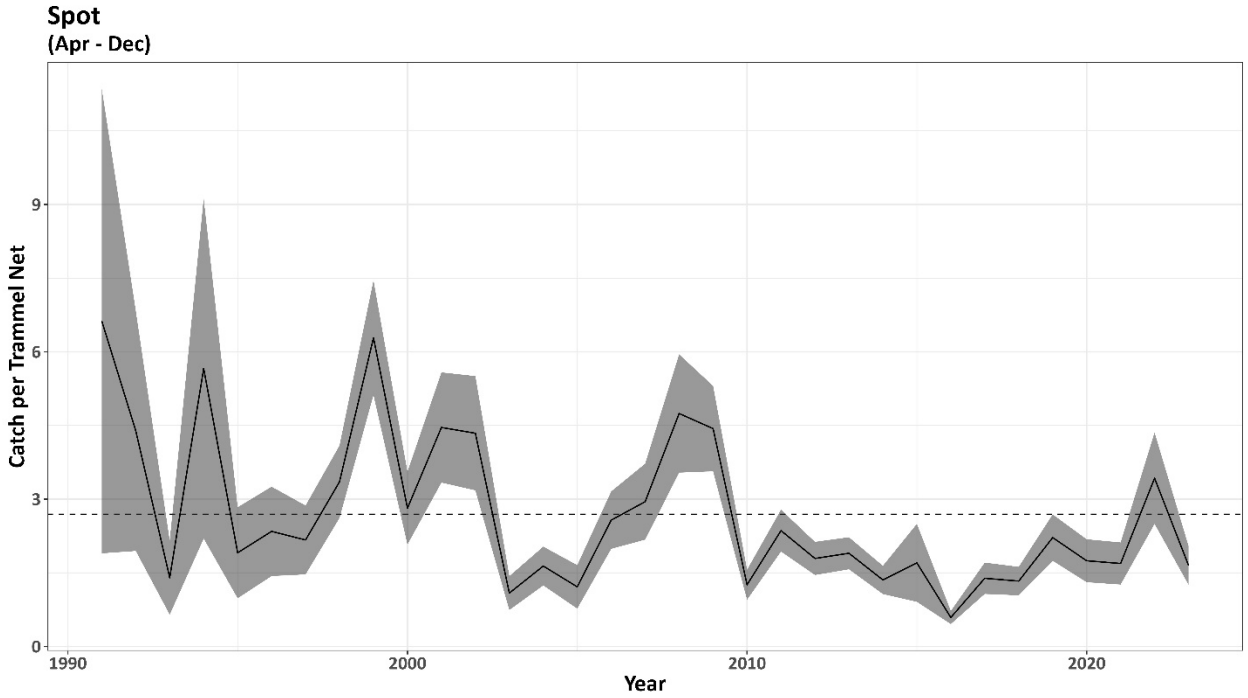

Figure 2. Trammel net index of Spot statewide normalized catch per unit effort (CPUE).

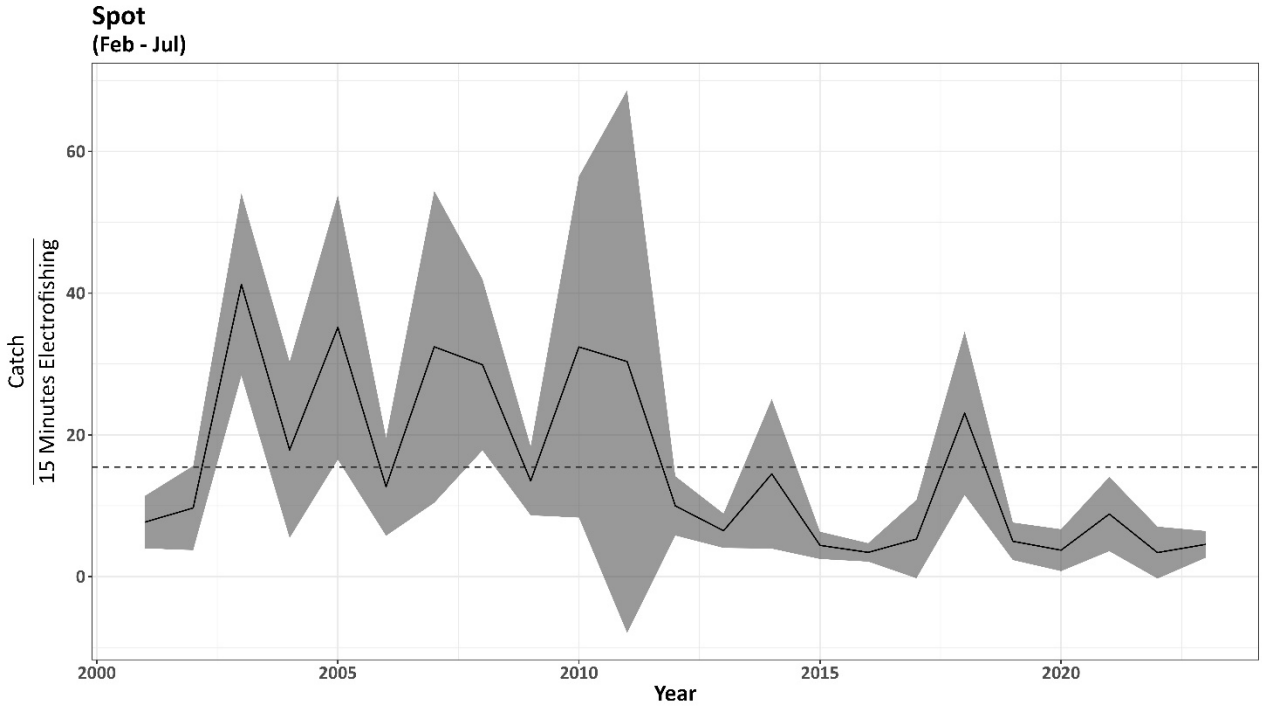

Figure 3. Electrofishing index of Spot statewide normalized catch per unit effort (CPUE).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Following entry to the estuary, Spot associate with shallow habitats, particularly tidal creeks. Due to its high productivity, this habitat provides ample prey for Spot, where they feed on locally available invertebrates including polychaete worms, amphipods, copepods, small mollusks and detritus. Adults gulp sediments and sort out invertebrate prey; juveniles graze on bottom-dwelling invertebrates. Larvae consume zooplankton.

The habitat is shallow and structurally complex, providing a physical refuge from predators. In addition, Spot are well adapted to live in the physiologically stressful, low dissolved oxygen/high carbon dioxide environment of small tidal creeks (Cochran 1994). Research in Rose Bay, North Carolina suggests that during their first summer, Spot grow and disperse from shallow edges of the bay to all depths (Currin 1984).

While offshore, Spot inhabit sandy or muddy bottoms in depths up to 60 m (197 ft.). Both sexes mature by 2 years of age; approx. size at maturity: 7 – 8 inches. Following spawning, larvae may take advantage of tidal mechanisms such as tidal bores and internal waves to migrate inshore (Williams 1993). Spot larvae are most dense in midwater and near the bottom during the day and migrate into surface waters at night. Nearshore, they are most dense on the bottom both day and night, possibly utilizing the salt wedge to enter the estuary.

Spot are strongly associated with the bottom as juveniles and adults and are seasonally dependent on the estuary. Along the east coast of the United States, spawning takes

place on the outer continental shelf from October through March. Peak spawning occurs during December and January off the North Carolina coast. As larvae mature, they are passively transported toward shore by currents (Warlen and Chester 1985). Near inlets, the larvae begin to metamorphose into juveniles (Phillips et al. 1989). In South Carolina, peak movement into the estuary occurs during late March (Williams 1993). Young-of-the-year Spot typically move first into the upper reaches of the estuary and then disperse to the lower reaches as they mature through their first season. In South Carolina, tidal creeks are important nursery habitats for post larval and juvenile spot (Cochran 1994). Young-of-the-year may remain in the estuary during their first winter, while older fish migrate offshore to spawn.

CHALLENGES

Conservation concerns: degradation and loss of estuarine habitat; pollution and compromised water quality; potential for significant recreational harvest; potential for significant commercial harvest and mortality as by-catch in southeast U.S. shrimp trawl fishery.

CONSERVATION ACCOMPLISHMENTS

Actions by the South Atlantic Fishery Management Council (SAFMC) led to the mandatory use of bycatch reduction devices (BRD) in shrimp trawl nets. Studies have shown that BRDs are effective at reducing mortality of fish such as spot. Also, since 1986 shrimp fishing in South Carolina is not allowed in the bays and sounds, thereby reducing exposure to trawls. Additionally, the South Carolina General Assembly closed most of the area in the State's sounds and bays to shrimp trawling in 1986, thus reducing fishing mortality and providing greater survival of juveniles. Another legislative action by South Carolina eliminated small mesh gill nets in the state's estuaries and significantly reduced the length of recreational gill nets to 30.5 m (100 ft.). Beginning in 2014, Spot are regulated in the recreational fishery by an aggregate bag limit along with other Sciaenids, Atlantic Croaker *(Micropogonias undulatus*) and Southern Kingfish (*Menticirrhus americanus*), where any combination of the three species can sum to 50 fish per person.

CONSERVATION RECOMMENDATIONS

- Continue fishery-independent surveys of Spot populations and identify factors affecting their abundance and recruitment.
- Investigate effects of chemical pollutants on spot populations and abundance.
- Continue to monitor long-term changes in Spot catch and effort statistics from the commercial and recreational fisheries to determine population trends.
- Protect water quality and important estuary habitat by working with municipalities to include best management practices (BMPs) in soil and water

conservation plans. Such plans should include installation of retention ponds, modified septic systems, and stream bank protection measures.

MEASURE OF SUCCESS

The measurement of success will be healthy estuarine habitat and a stable or increasing population trend for Spot. SCDNR has several fishery independent surveys that annually monitor trends in relative abundance, length frequency, size and age at maturity of estuarine finfishes including Spot, through monthly trammel netting, electrofishing, and the coastal trawl survey and can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, size, size and age at maturity would indicate positive trends in the population.

Spotted Eagle Ray

Aetobatus narinari

Contributors:
James Kilfoil (SCDNR) & Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The spotted eagle ray (*Aetobatus narinari*), members of the order Myliobatiformes and family Aetobatidae (Page et al. 2023), sometimes referred to as the whitespotted eagle ray, are a distinctive marine ray speices widely distributed across the Atlantic Ocean in tropical to warm-temperate waters (Sellas et al. 2015). Characterized by its broad, round, flat snout reminiscent of a duck's bill, the species also has large spiracles located just behind its eyes and pointed pectoral fins. Its body displays a unique pattern of white spots across its back, which is typically black, dark gray, or blue, while its underside is white.

They can reach a maximum size of approximately 230 cm disc width (DW). Males mature at 127–129 cm DW, while females mature at 134.9 cm DW (Tagliafico et al. 2012; Last et al. 2016). Spotted eagle rays have a single row of broad, flat teeth in each jaw, forming upper and lower plates for crushing shelled prey. The skin of this species is smooth and lacks significant denticles or thorns. Spotted eagle rays can weigh up to 507 pounds and achieve a length of up to 8.2 ft (2.5 m).

The species primarily inhabits the neritic zone, which extends from the low-tide mark to the edge of the continental shelf, in tropical to warm-temperate waters (Dulvy et al. 2021; H. Asmus & R. Asmus 2011). They are commonly found in lagoons and estuaries and are closely associated with coral reef ecosystems (Dulvy et al. 2021). Spotted eagle rays are benthopelagic, residing over the continental shelf from the surface to depths of 60 m. Their preferred habitat, often considered "Hard Bottom" habitat, includes mixed communities of algae, sponges, octocorals, and stony corals, occurring in subtidal, intertidal, and supratidal zones.

Spotted eagle rays are matrotrophic viviparous, with females producing litters of 1–5 pups, averaging three, after a 12-month gestation period (Tagliafico et al. 2012; Last et al. 2016). Pups are born at a size of 18–36 cm DW. The species has a relatively low reproductive rate and a lifespan of 15 to 20 years (Boyd 2017). The inferred generation length is about 10 years, slightly shorter than the 12-year generation length of the larger *Aetobatus ocellatus* (Kyne et al. 2016).

Spotted eagle rays play a crucial role in the marine food web as both predators and prey. They primarily consume bivalve and gastropod mollusks, but their diet also includes cephalopods, crustaceans, and teleost fishes, helping to maintain the population balance of these species (Tagliafico et al. 2012; Flowers et al. 2021; Ajemian et al. 2012). Predators of spotted eagle rays include other teleosts, mammals, and other elasmobranchs (Flowers et al. 2021).

Status

The spotted eagle ray was assessed by the International Union for Conservation of Nature's (IUCN) Redlist in 2020 and was listed as Endangered globally with current population trends being in decline (Dulvy et al., 2021). The major justifications were overall suspected declines of 50-79% over the last 30 years due to fishing levels (both actual and potential; Dulvy et al, 2021). Regionally, the IUCN list spotted eagle rays as Critically Endangered in the Eastern and Southeast Atlantic, Endangered in the Southwest Atlantic, Least Concern in US water and Caribbean Islands, Near Threatened in central and northern South America (Dulvy et al., 2021). In addition, the Defend Them All Foundation petitioned NOAA-NMFS to list the species under the Endangered Species Act in 2023. However, NOAA-NMFS did not find substantial scientific or commercial information indicating the petitioned action may be warranted.

The spotted eagle ray is often captured in both industrial and artisanal fisheries, primarily through the use of demersal trawls, shrimp trawls, demersal set gillnets, and beach seine nets. Its swimming behavior makes it highly vulnerable to a variety of fishing gear throughout the water column, particularly to inshore gillnets, which are extensively used across its range. This species is frequently targeted in artisanal gillnet fisheries and caught as bycatch in industrial shrimp trawls. The rays are typically retained and sold fresh for local consumption (Dulvy et al., 2021).

POPULATION SIZE AND DISTRIBUTION

The spotted eagle ray was initially limited to the Western Central and Southwest Atlantic (Sales et al., 2019) but has since expanded to the eastern Atlantic (Fricke et al., 2020). This species primarily inhabits shallow nearshore waters such as estuaries, lagoons, and bays, but can also be found in coral reef ecosystems up to 200 ft deep (Dulvy et al., 2021; Desgarnier et al., 2022). The ray's range in the Western Central and Southwest Atlantic extends from Cape Hatteras, North Carolina, USA, to Rio de Janeiro, Brazil, including the Gulf of Mexico, the Bahamas, and the Caribbean Islands (Last et al., 2016; Sales et al., 2019). In the Eastern Central and Southeast Atlantic, its range is believed to extend from Mauritania south to Angola, and possibly South Africa (Sales et al., 2019; Fricke et al., 2020).

This species is native to and resident in numerous countries, including Angola, Anguilla, Antigua and Barbuda, Aruba, the Bahamas, Barbados, Belize, Benin, Bermuda, Bonaire,

Sint Eustatius and Saba, Brazil, Cameroon, the Cayman Islands, Colombia, the Republic of Congo, the Democratic Republic of the Congo, Costa Rica, Cuba, Curacao, Côte d'Ivoire, Dominica, the Dominican Republic, El Salvador, Equatorial Guinea, French Guiana, Gabon, Gambia, Ghana, Grenada, Guadeloupe, Guatemala, Guinea, Guinea-Bissau, Guyana, Haiti, Honduras, Jamaica, Liberia, Martinique, Mauritania, Mexico, Montserrat, Nicaragua, Nigeria, Panama, Puerto Rico, Saint Barthelemy, Saint Kitts and Nevis, Saint Lucia, Saint Martin (French part), Saint Vincent and the Grenadines, Sao Tome and Principe, Senegal, Sierra Leone, Sint Maarten (Dutch part), South Africa, Suriname, Togo, Trinidad and Tobago, Turks and Caicos Islands, the United States (Alabama, Florida, Georgia, Hawaiian Islands, Louisiana, Mississippi, North Carolina, South Carolina, Texas), Venezuela, and the Virgin Islands (both British and U.S.; Dulvy et al., 2021).

In Belize, population trend data collected via baited remote underwater videos (BRUVs) from 2009 to 2018 showed an annual increase in abundance at a rate of 7.5% (G. Clementi and D. Chapman, unpublished data, 2019). Conversely, in Mexico, data from 2000 to 2014 indicated an annual decline of 0.95% (J.C. Perez Jimenez, unpublished data, 2019). When these datasets are combined, they suggest an overall annual increase of 1.32% over 30 years, placing the population primarily in the Least Concern category with a 72% probability (Sherley et al., 2020; Winker et al., 2019).

In the Western Central Atlantic, artisanal fisheries targeting spotted eagle rays are known in Mexico (Cuevas-Zimbron et al., 2011), Cuba (Cuba NPOA-Sharks, 2015) and Venezuela (Tagliafico et al., 2012). Declining annual catch rates have been observed in these fisheries. For example, fisher interviews in the southern Gulf of Mexico report a decline from 30-40 rays per trip in the 1990s to about 10-15 rays per trip more recently (Cuevas-Zimbron et al., 2011; J.C. Perez Jimenez, unpublished data, 2019). In Venezuela, unmanaged artisanal gillnet fisheries continue to target this species, contributing to population declines reported since the early 1970s (Gines et al., 1972, cited in Tagliafico et al., 2012). Data from the Guianas is sparse, but similar reductions are suspected due to the level of artisanal and commercial fishing pressure. While populations may be stable in U.S. waters and the Caribbean Islands, declines are suspected in central and northern South America, suggesting a Near Threatened status in these regions (Dulvy et al., 2021).

In the Southwest Atlantic, intense and unmanaged commercial and artisanal fisheries have led to significant declines in this and other species. For instance, in Pernambuco, Brazil, gillnet landings have decreased by about 80% since 1995 (F.M. Santana, personal communication, 2018 cited in Dulvy et al., 2021). Monitoring in São Paulo between 1996 and 2002 recorded only five individuals, with fishers reporting further declines (S. Montealegre-Quijano, personal communication, 2018 cited in Dulvy et al., 2021). It is suspected that the population in the Atlantic South American range has

decreased by 50-79% over the past three generations due to exploitation by widespread artisanal and some commercial fisheries, which lack adequate management (Dulvy et al., 2021).

In the Eastern Central and Southeast Atlantic, the largest reported elasmobranch fisheries in Africa are in Nigeria, Senegal, and Ghana, but actual landings are likely higher due to underreporting (Dulvy et al. 2021). From 1970 to 2015, the average elasmobranch catch per unit effort (CPUE) in West Africa decreased by 71%, while the average catch increased by over 250% (Pauly et al., 2020). In Mauritania, shark, ray, and skate landings increased by 246% from 1992 to 2015. In Senegal, reconstructed landings showed a decline of at least 30% over 15 years from 2001 to 2016. Guinea-Bissau experienced a 22% decline from 2012 to 2016, while Cameroon saw a 96% decline from 2007 to 2016 (Pauly et al., 2020). These declines in landings are indicative of population reductions, as fishing effort increased during the periods of declining landings (Dulvy et al., 2021).

There have been few records of the spotted eagle ray in the Eastern Central and Southeast Atlantic over the past decade. In the Republic of Congo, only a single specimen was caught in a pilot project, despite regular catches of similar species (P. Doherty, unpublished data, 2020). In Cameroon and Angola, landing site surveys have recorded very few instances of this species (A. Tamo, unpublished data, 2020; A.-L. Soares, unpublished data, 2020). The lack of recent sightings suggests that the species may have largely disappeared from West Africa, with an estimated population reduction of over 80% in the past three generations (Dulvy et al., 2021).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The spotted eagle ray is a benthopelagic species found over the continental shelf, ranging from the surface down to 60 m (Last et al., 2016). It commonly inhabits lagoons and estuaries and is often associated with coral reef ecosystems (Ajemian et al., 2012; Bassos-Hull et al., 2014).

Spotted eagle rays prey mainly on bivalves, crabs, whelks, and other benthic infauna. They also feed on mollusks, such as the queen conch (Dulvy et al., 2021), and crustaceans, particularly malacostracans (Richards et al., 2009), as well as echinoderms, polychaete worms (Schluessel et al., 2010), hermit crabs (Schluessel et al., 2010), shrimp, octopuses, and some small fish.

The spotted eagle ray's specialized chevron-shaped tooth structure helps it to crush the hard shells of mollusks (Froese and Pauly, 2024). The jaws of these rays have developed calcified struts to support them and prevent dents from hard prey (Summers, 2001). These rays exhibit a unique behavior of digging with their snouts in the sand of the ocean floor. While doing this, a cloud of sand surrounds the ray, and sand spews from its gills.

CHALLENGES

Spotted eagle rays inhabit coastal inshore waters where fishing pressure is significant, particularly in regions such as the Gulf of Mexico, Caribbean Sea, and Eastern Central and Southeast Atlantic Ocean along the African coast. These rays often enter estuarine waters, increasing their exposure to fishing activities. Their swimming behavior makes them vulnerable to various fishing gears throughout the water column, particularly inshore gillnet fisheries, which are prevalent across their range. They are commonly caught in both artisanal gillnet fisheries and industrial shrimp trawl fisheries (Dulvy et al., 2021).

In the Northwest and Western Central Atlantic, there is limited documentation of artisanal directed fisheries for spotted eagle rays, but they are known to exist in Mexico (Cuevas-Zimbrón et al., 2011), Cuba (Cuba NPOA-Sharks, 2015) and Venezuela (Tagliafico et al., 2012). In Caribbean Colombia, widespread artisanal fisheries lack proper management, and there is a collapsed shallow-water shrimp trawl fishery. The ray is caught using gillnet, longline, and trawl gears (P. Mejía-Falla and A. Navia, unpublished data, 2018). Venezuela experiences intense commercial and artisanal fisheries, which also lack management and have shown peaks followed by declines, indicating sequential overfishing. This ray species is targeted in artisanal fisheries (Tagliafico et al., 2012), and declining annual catch rates have been observed in both Mexico and Venezuela (Cuevas-Zimbrón et al., 2011; Tagliafico et al., 2012).

In the Southwest Atlantic, intense artisanal fisheries operate along much of the coastal regions of South America. Many areas have largely unmanaged commercial trawl and longline fisheries. By 2000, groundfish fisheries on the Brazil-Guianas shelf were fully over-exploited. These fisheries are multi-gear, multi-species, and multinational, with vessels crossing national maritime borders (Booth et al., 2001). Despite some closures and total allowable catch limits, the number of operating vessels has decreased (Diop et al., 2015). In northwestern Brazil, high artisanal fisheries pressure led to 44% of target stocks being overfished by the end of the 2000s (Vasconcellos et al., 2011). The intense and unmanaged fishing has resulted in the disappearance of several elasmobranch species in the region, including Largetooth Sawfish (Pristis pristis), Smalltooth Sawfish (Pristis pectinata), Daggernose Shark (Isogomphodon oxyrhynchus), and Smalltail Shark (Carcharhinus porosus) (Charvet and Faria, 2014; Lessa et al., 2016; Reis-Filho et al., 2016; Santana et al., 2020). In northeastern and eastern Brazil, artisanal fisheries are intense, predominantly using gillnets, and fishers report overexploited stocks and depleted shark populations (Guebert-Bartholo et al., 2011; Reis-Filho et al., 2016). The southern Brazilian trawl fishery expanded rapidly in the 1990s and 2000s, with over 650 vessels fishing at depths of 20–1,000 meters (Port et al., 2016). Artisanal fisheries are intense, with 58% of targeted stocks overexploited and half having collapsed (Vasconcellos et al., 2011).

In the Eastern Central Atlantic, sharks and rays have been exploited by semi-industrial fisheries since the 1950s, but these fisheries have gradually collapsed. The demand for dried salted shark meat (for export to Ghana) and shark fins in the 1980s spurred the development of artisanal targeted shark fishing across the region (Diop and Dossa, 2011; CCLME, 2016; Seto et al., 2017; Moore et al., 2019). This has expanded into targeted shark and ray fisheries across many countries, increasing fishing pressure on this species (Walker et al., 2005; Diop and Dossa, 2011). The result has been population reductions of many shark and ray species, including the local extinction of sawfishes (family Pristidae) from West African coastal waters and several species of wedgefishes from their northern range in Mauritania and Senegal (Walker et al., 2005; Kyne et al., 2020). Sharks and rays continue to be targeted in many countries, with artisanal fishers using drift gillnets and demersal set gillnets with large mesh sizes (M. Diop, I. Seidu, A. Tamo, and A.B. Williams, unpublished data, 2020).

Overall, fishing effort and the number of fishers have increased in recent decades across most of this species' range. For instance, in West Africa, there has been a marked decline in the diversity and average body size of many important commercial coastal, demersal, and pelagic fishery species, with many stocks now overexploited (FAO, 2002; Srinivasan et al., 2012; Polidoro et al., 2016; CCLME, 2016). Trawl surveys conducted across the Gulf of Guinea from 1977 to 2000 showed a 50% decline in fish biomass (Brashares et al., 2004), and the total demersal biomass of inshore stocks is estimated to have declined by 75% since 1982 (Meissa and Gascuel, 2015). The primary cause of this decline has been overcapacity within both industrial and artisanal fisheries and destructive fishing practices (GCLME, 2006; CCLME, 2016). From 1950 to 2010, artisanal fishing effort increased tenfold, with an estimated 252,000 unregulated artisanal vessels and 3,300 industrial vessels (mainly distant water fleets from Europe and East Asia operating under 'access agreements') operating in the region by 2010 (Walker et al., 2005; Diop and Dossa, 2011; Belhabib et al., 2018).

Due to their diet primarily consisting of mollusks, Whitespotted Eagle Rays sometimes negatively interact with shellfish farming, with episodic and anecdotal reports of such interactions in the Northwest Atlantic (McEachran and Carvalho, 2002). Confirmed interactions often involve molluscan culture operations in the Indo-Pacific, such as those reported for conspecifics like A. narutobiei in Japan (Yamaguchi et al., 2005). While predator culling programs have not been implemented for Whitespotted Eagle Rays in the USA, similar programs have been considered for other myliobatid species, such as the Bat Ray (Myliobatis californicus) off California (Gray et al., 1997) and the Cownose Ray (Rhinoptera bonasus) in Chesapeake Bay and other areas in the USA (Grubbs et al., 2016).

The quality of neritic marine habitats that the Whitespotted Eagle Ray occupies has deteriorated and is anticipated to worsen due to pollution and coastal development

affecting Atlantic coastlines (Dulvy et al., 2021). This species is particularly susceptible to habitat alterations because it inhabits, breeds, and feeds in shallow coastal areas such as lagoons, estuaries, and coral reefs (Dulvy et al., 2021). In addition, these concerns are likely exacerbated by the effects of warming ocean temperatures, as temperature fluctuations can influence spotted eagle ray behavior and migration patterns (Osgood et al., 2021)

CONSERVATION ACCOMPLISHMENTS

Certain countries, such as Cuba, have initiated National Plans of Action (NPOAs) to conserve sharks and rays and manage their fisheries sustainably, comprehensive management plans are essential for the conservation of elasmobranch species such as the spotted eagle ray. These plans can be local, regional, national, or international, such as the FAO International Plan of Action for the Conservation and Management of Sharks (IPOA-Sharks).

In West Africa, several countries have adopted a Regional Plan of Action for the Conservation of Sharks (including Sub-Regional Fisheries Commission countries from Mauritania to Sierra Leone, and Cape Verde) or are working on National Plans of Action (e.g., Liberia) under the FAO IPOA-Sharks to conserve sharks and rays and manage their fisheries sustainably.

The Regional Marine Protected Areas Network in West Africa (RAMPAO), established in 2007 across six countries from Mauritania to Sierra Leone, aims to conserve critical habitats and protect threatened species. However, many of these protected areas suffer from a lack of capacity, funding, infrastructure, and governance, undermining effective enforcement and conservation (Polidoro et al., 2016). Other countries, such as Gabon, the Republic of the Congo, and Côte d'Ivoire, are expanding their marine protected areas, but they will need financial and technical support to ensure effective enforcement and to promote connectivity and protection of key life history stages (K. Metcalfe, unpublished data, 2020).

In Florida state waters, the spotted eagle ray is protected under the Florida Administrative Code. The species cannot be harvested, possessed, landed, purchased, sold, or exchanged in Florida. In Bermuda, a small recreational fishery was quickly curtailed when protection was enacted in 2010.

CONSERVATION RECOMMENDATIONS

- Expand legislative protections to other US States within species range
- Continue monitoring of elasmobranchs within coastal waters
- Increase collection of species-specific data to allow for future species-specific stock assessment

- Investigate fine-scale movement to determine habitat utilization and potential influence of future habitat loss/degradation and/or climate change
- Conduct studies to investigate post-release mortality rates from targeted fisheries and bycatch
- Investigate potential gear-modifications and time-area closures to reduce unwanted interactions with fisheries

MEASURE OF SUCCESS

- Gather enough information to effectively monitor population trends by region
- Decreased bycatch and unwanted interactions in fisheries
- Species-specific legislative protections

Spotted Seatrout

Cynoscion nebulosus

Contributors (2025):
Zoe A. Golden (SCDNR/College of Charleston) & Joseph C. Ballenger (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Spotted seatrout are medium sized member of the order Perciformes and family Sciaenidae (Page et al. 2023). Individuals are dark gray above with a bluish reflection and silvery below, with numerous dark spots scattered along the upper sides of the body and on the dorsal and caudal fins (Carpenter 2002; Lorio & Perret 1978). Dorsal fin meristics include 9-10 spines located in the anterior dorsal fin and one spine located in the second dorsal with 25-28 rays (Carpenter 2002). The soft part of the dorsal fins do not have scales, which distinguishes it from their congener weakfish (*C. regalis*; Carpenter 2002). Weakfish also possess a snout with 1 marginal pore, compared to two in spotted seatrout, and an anal fin with 2 weak spines and 11-13 soft rays (Carpenter 2002). Spotted seatrout possess two large canine-like teeth at the tip of the upper jaw, while the remainder of the teeth are small and increase with size posteriorly on the lower jaw (Carpenter 2002). Unlike some other members of the family Sciaenidae, they do not have barbels or pores located on the chin (Carpenter 2002).

Spotted seatrout are found throughout the estuaries and coastal waters of South Carolina. On the Atlantic coast, they can be found from Cape Cod, Massachusetts to the Florida Keys, but are most commonly found south of Chesapeake Bay. Spotted seatrout are also found along the Gulf coast from Florida to northern Mexico. Throughout much of their range, they are considered non-migratory and spend their entire life within 5-10 miles of their natal estuary (ASMFC 2024b). However, in the northernmost estuaries, they exhibit some migratory behavior (ASMFC 2024b).

Spotted seatrout mature at about one year of age, when males and females are approximately 10 and 11 inches total length (TL), respectively (ASFMC 2024). The sexes exhibit dimorphic growth, with females being significantly larger than males at all life stages and reach greater maximum ages. Spotted seatrout have been documented to live up to 18 years, but individuals over 5 years of age are rare. The oldest individuals caught by the Inshore Fisheries Research Section were 10 years of age (J. Ballenger, pers. comm.).

Spotted seatrout spawn in the evenings, like many other Sciaenids, from April to September in the lower reaches of estuaries and around inlets (Roumillat & Brouwer 2004). Spotted seatrout are group-synchronous spawners with indeterminate fecundity (Roumillat & Brouwer 2004). Male spotted seatrout have the capacity to produce drumming sounds by contracting the swim bladder; this sound plays an integral role in spawning events (Roumillat & Brouwer 2004). Spotted seatrout exhibit external fertilization with the number of eggs released by a female during a spawning event correlated with body size.

Status

A coastwide stock assessment has not been conducted due to the non-migratory nature of the species (ASFMC 2024). Instead, age-structured analyses of stocks have been conducted in North Carolina, South Carolina, Georgia, and Florida. South Carolina and Georgia have adopted the goal of 20 percent spawning potential ratio, while North Carolina and Florida have adopted a goal of 30 percent and 25 percent SPR, respectively (ASFMC 2024).

A stock assessment was conducted for spotted seatrout in Florida in 2016 with results indicating stocks in northeast and southeast Florida are above the biomass threshold, but below the biomass target and overfishing is likely not occurring (Addis et al., 2018). An assessment of spotted seatrout in Virginia and North Carolina was completed in 2022, with data from 1991-2019, suggesting spotted seatrout were experiencing overfishing but not overfished (NCDMF 2022). The model suggested a shift in population dynamics around the year 2004, with lower fishing mortality and higher spawning stock biomass and recruitment with greater variation predicted since 2004 (NCDMF 2022).

The South Carolina population of spotted seatrout supports large scale recreational fisheries, with annual removals (harvest plus dead discards) generally increasing from lows in the early 1980's of less than 0.5 million fish to highs in recent years at greater than 3 million fish, peaking in 2021 at 5.2 million fish (Figure 1). Since the late-2000s, in most years greater than 50% of annual recreational removals is the result of dead discards (Figure 2), assuming 30% of catch-and-release spotted seatrout suffer post-release mortality as reported in Nelson et al. (2021). The South Carolina

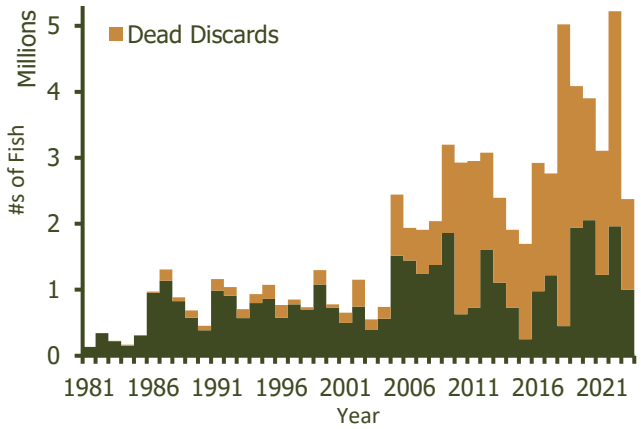

Figure 1: Recreational harvest (green) and dead discards (gold) of spotted seatrout in South Carolina (Source: NMFS, Office of Fisheries Statistics, pers. comm.). Dead discards calculated by applying a 30% post-release mortality rate to dead discards as estimated in Nelson et al. (2021).

Figure 2: Percent of annual removals represented by direct harvest (green) and dead discards (gold) for the South Carolian spotted seatrout fishery (Source: NMFS, Office of Fisheries Statistics, pers. comm.). Dead discards calculated by applying a 30% post-release mortality rate to dead discards as estimated in Nelson et al. (2021).

Department of Natural Resources (SCDNR) included several state-specific assessments into a report in 2001, though these were not peer reviewed. The initial assessment covering 1986-1992 indicated female SPR was just above the 20% goal in the terminal year leading to a minimum size limit increase and a creel limit reduction (Zhao and Wenner 1995). While an assessment has not been conducted recently, the coastwide increase in recreational harvest is concerning.

POPULATION SIZE AND DISTRIBUTION

The SCDNR Inshore Fisheries trammel net survey routinely captures spotted seatrout, with spotted seatrout being the second most encountered species in the survey. The trammel net survey conducts a monthly survey of coastal South Carolina salt-marsh edge habitats, with the survey encountering spotted seatrout year-round, though more frequently during the latter half of the year (Figure 3) as individuals born in the spring recruit to the gear as they grow to larger sizes. Throughout the time series of the survey, we see a cyclical pattern of spotted seatrout relative abundance with particularly high relative abundances in 1999-2000, 2006-2009, and 2020 (Figure 4). In contrast, particularly low abundances occurred in 1991-1996, 2001-2005, 2010-2011 and 2018. Note these generally followed marine cold spells during winters producing estuarine water temperatures known to lead to spotted seatrout mortality, with documented events during the winters of 1989-1990, 1993-1994, 2000-2001, 2010-2011, and 2017-2018 (J. Ballenger, pers. comm.). Spotted seatrout begin recruiting to the survey once 10” (254 mm) TL, with the largest individual encountered in the survey being greater than 27” (685 mm) TL (Figure 5).

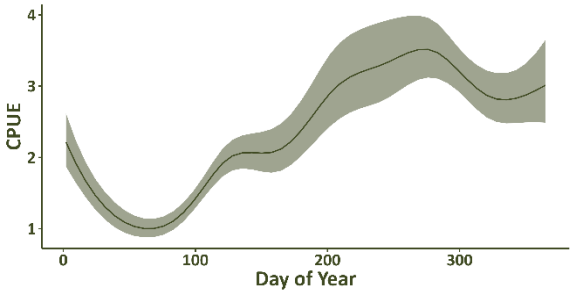

Figure 3: Predicted catch per trammel net of spotted seatrout as a function of day of year based on standardized relative abundance index.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Submerged aquatic vegetation, salt marsh, and oyster reefs, especially where submerged aquatic vegetation is not available, are fish habitats of concern for spotted seatrout (ASMFC 2024a). Seagrass beds provide important habitat for both juvenile and

adult spotted seatrout, but are in decline along much of the Atlantic coast (Orth et al. 2006; Waycott et al. 2009; Adams et al. 2019; Morris et al. 2022), though never present due to estuarine turbidity in South Carolina. In South Carolina, saltmarsh and oyster reef habitats provide fish habitat of concern for juvenile and adult spotted seatrout (ASMFC 2024a). Spotted seatrout prefer depths less than 10 ft and temperatures 60-80°F (15°-27° C). In South Carolina, and other areas, spotted seatrout are vulnerable to mortality in winter when water temperature decreases rapidly. Anweiler et al. (2014) found temperatures below 41°F (5° C) are cause for concern for this species, though the

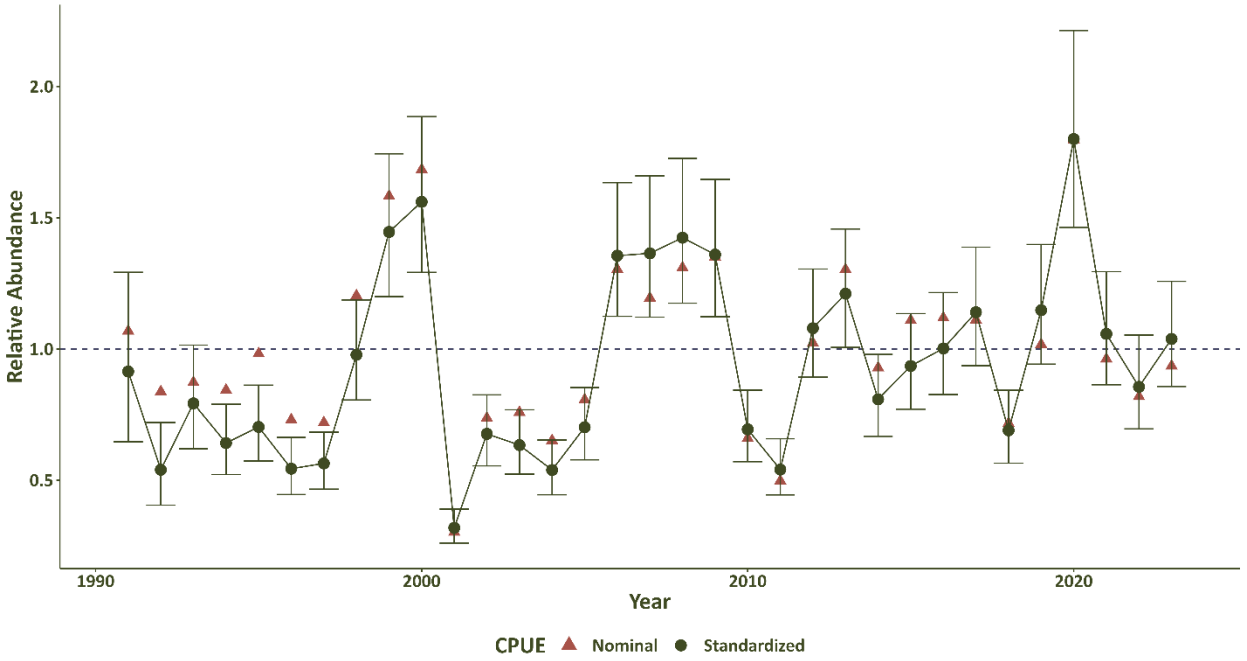

Figure 4: Spotted seatrout standardized catch per unit effort in SCDNR's Inshore Fisheries trammel net survey by year from 1991 to 2023. Shown is the standardized index of abundance (green line and circles) with a 95% CI (error bars) as well as nominal catch per trammel net (red triangles). Both the standardized and nominal indices are normalized to average catches from 2010-2023 (dashed line), such that if annual estimates are greater than 1, catch was above the 2010-2023 average and vice versa if below.

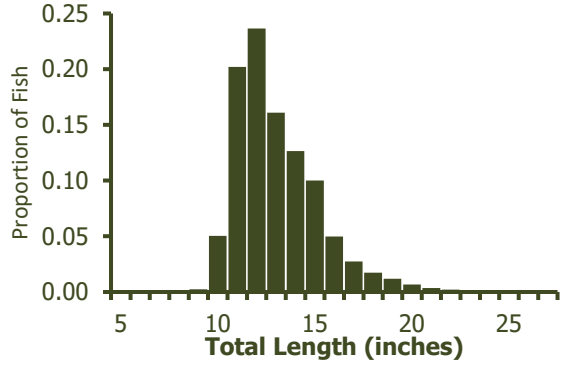

Figure 3: Length frequency distribution of spotted seatrout encountered by the SCDNR trammel net survey.

duration of cold temperatures and the spatial distribution of temperature conditions will determine the severity of a winter mortality event.

CHALLENGES

Spotted seatrout along coastal South Carolina face a number of challenges, including increased fishing pressure, changing and increasingly stressful environmental conditions, loss and degradation of habitats critical to juvenile and adult spotted seatrout due to coastal development, and other anthropogenic stressors such as contaminants and pollutants. To date these challenges have not apparently led to long-term declines in abundance, but additional study is warranted to predict changes in population demographics and abundance under future conditions. Further, major data gaps still exist, including the size composition of recreationally released fish, and hence the sizes and ages subject to post-release mortality and fishery selectivity, and the impact (lethal and sublethal) of catch-and-release fishing on spotted seatrout. Emerging challenges facing spotted seatrout, and many other estuarine species, include the impact of warming estuarine waters and

marine heat waves during critical life history stages, phenological changes in weather patterns and food web dynamics, and increased variability in the climate. Finally, the impact of contaminants of emerging concern, such as per- and polyfuoroalkyl substances and microplastics among others, on the productivity of the population still needs investigation.

CONSERVATION ACCOMPLISHMENTS

The South Atlantic Board approved the Omnibus Amendment for spotted seatrout in 2011, which included recommended efforts to protect the spawning stock (ASMFC 2024b). The Omnibus Amendment also required a coastwide minimum size limits of 12" TL for spotted seatrout. A report on fish habitat of concern designations for fish and shellfish species was released in 2024 1that included habitat information for spotted seatrout (ASMFC 2024a), drawing attention to habitats warranting protection. In South Carolina, there is currently a minimum size of 14" total length and a bag limit of 10 fish per angler per day (SCDNR 2007).

SCDNR's Inshore Fisheries group monitors the health of spotted seatrout populations through two long-term monthly fish surveys. These surveys collect critical long-term data sets on the relative abundance, population demographics, and reproductive status of spotted seatrout throughout coastal South Carolina. Further, Anweiler et al. (2014) investigated the minimum thermal tolerances of spotted seatrout during the winter, providing valuable information on impacts marine cold spells may have on the relative abundance of spotted seatrout. Since publication, when marine cold spells have occurred (e.g., winter of 2017-2018) information in Anweiler et al. (2014) has been used by managers to predict the impact on South Carolina spotted seatrout populations.

CONSERVATION RECOMMENDATIONS

To aid conservation of this important estuarine species, we propose the following research recommendations:

- Development of methods to estimate recreational discard length- and age-compositions and better characterize post-release mortality across size, age, and environmental conditions. In addition to direct post-release mortality, investigate the potential for sublethal effects of catch-and-release fishing on individuals.
- Expand biostatistical sampling to collect more otolith ages to provide robust age-length data for development of seasonal growth models necessary to support development of seasonal assessment models.
- Better characterize the reproductive potential of the population through investigations of batch fecundity, lengths- and ages-at-maturity, sex ratios, spawning seasons, and spawning frequencies. Investigate how these values change with size and/or age.

- Investigate the appropriateness of reference points used for spotted seatrout management.
- Identify impacts of water quality, environment, ecosystem, and habitat changes on spotted seatrout stock dynamics and incorporate into our assessment of population dynamics.
- Determine the level of contaminants (organics, pesticides, heavy metals, per- and polyfluoroalkyl substances) found in spotted seatrout as well as the sediments/waters in the areas in which they are caught. Relate that to the potential effects of bioaccumulation.
- Protect water quality in marine ecosystems by encouraging municipalities to use Best Management Practices (BMPs) to reduce runoff from highways, agricultural fields, and housing developments.
- Plan development based on sound terrestrial and estuarine ecology that takes into consideration all factors affecting the long-term health of the estuary ecosystem.
- Identify the origin of non-point source pollution and specific point source pollution and develop a plan of action to mitigate any negative effects to the affected aquatic systems.
- Improve BMPs in areas already impacted by non-point source pollution.
- Identify important or essential habitat types for different life stages of black drum and partner with other regulatory agencies to reduce impacts of development on these fish habitats.

MEASURE OF SUCCESS

The fishery-independent programs conducted by the SCDNR Inshore Fisheries research group annually monitors the relative abundance, population demographics (size- and age-compositions) and reproductive potential of estuarine finfish, such as spotted seatrout. These surveys can detect changes in those parameters, providing critical data for the assessment of stock status and early detection of change (positive or negative) in abundance or population demographics. Currently, the abundance of spotted seatrout throughout coastal South Carolina has remained stable, if cyclical, since the early-1990s

Further, work identifying abiotic and biotic drivers of population fluctuations, in particular concerning recruitment, remain critical for projecting the response of red drum to future climate change, climate variability, and emerging contaminants of concern. By learning more about this species and protecting the habitat upon which it depends, we can ensure this important recreational game fish remains abundant. In addition, by monitoring spotted seatrout populations in response to environmental

contaminants, South Carolina will be better able to detect problems and work to correct them more quickly.

DESCRIPTION

Taxonomy and Basic Description

The striped mullet is in the order Mugiliformes, family Mugilidae. There are 9 species of mullet found in the western central Atlantic, the most common being the striped mullet (*Mugil cephalus* Linnaeus, 1758). There are two species of mullet found in South Carolina territorial waters: the striped (*M. cephalus*) and white mullet (*M. curema*). The remaining species within this family are found mostly in the Caribbean and Central/South America.

Striped mullet are dark above (blue to green with some brown) and silvery on the sides. Conspicuous stripes on the sides are formed from dark spots at the base of scales. Dorsal and anal fins are unscaled. The second dorsal fin begins directly above the point where the anal fin begins. The anal fin has 3 spines and 8 soft rays; juveniles have 2 spines and 9 soft rays (Robins et al. 1986). Maximum recorded size for this species from the eastern Atlantic is 1,500 mm (59 in.) total length (TL) (Harrison 2002); however, the most common sizes in South Carolina range from 250 to 350 mm (10 to 14 in.) TL (McDonough et al. 2003).

Striped mullet spawn offshore, and their offshore migrations in large schools have been well documented historically in South Carolina (Ravenel 1887; Jacot 1920; Anderson 1958; Arnold and Thompson 1958). Striped mullet are considered isochronal spawning fishes; they have synchronous gamete development, and individuals spawn all of their reproductive material at once or in batches over a very short period of time (days as opposed to weeks) (Greeley et al. 1987; Render et al. 1987). Collins and Stender (1989) concluded that striped mullet spawn in and around the edge of the Continental Shelf off the coasts of North Carolina, South Carolina, Georgia and the east coast of Florida. These areas make up a larger area often referred to as the South Atlantic Bight. There is a protracted spawning season from October to April, with most spawning occurring from December through February (McDonough and Wenner 2003; McDonough et al. 2003). Most striped mullet in South Carolina recruit to estuarine nursery grounds from January through May and range in size from 18 to 30 mm (0.5 to 0.7 in.) TL (Anderson 1958; McDonough and Wenner 2003). Females mature at 3 years of age and at a size from 300 to 400 mm (12 to 16 in.) TL (Thomson 1963; Greeley et

al. 1987; McDonough unpub. data). Male striped mullet begin to mature at 2 years of age and approximately 250 mm (10 in.) TL (Stenger 1959; McDonough et al., 2005). Juvenile striped mullet are omnivorous and feed on zooplankton and phytoplankton. Adults are herbivorous and feed primarily on diatoms and algae siphoned from soft bottom mud, except in areas of submergent vegetation where they often feed on attached algae (Collins, unpub. data).

Status

The striped mullet is not listed as either an endangered or threatened species in any state in the Southeastern United States. Striped mullet are a commercially important fish throughout the world for both fisheries and aquaculture purposes. In the Southeastern United States, there are significant commercial fisheries for striped mullet in North Carolina and Florida, and in all of the Gulf Coast states (a wholesale landings value of over $20 million for 2012 to 2022). Recreational harvest and discard data by state obtained from a Marine Recreational Information Program Query (NMFS. pers. comm.).

Striped mullet are also one of the most important forage fishes in the estuaries of the Southeast and represent a significant food source to upper level piscivores (Wenner et al. 1990). Because striped mullet are ubiquitous throughout the estuaries of South Carolina and provide an important food resource for many recreationally important finfish species, the species is an excellent candidate as an indicator species for the relative health of finfish in South Carolina's estuaries.

Based on the 2018 IUCN assessment, the striped mullet is listed as a species of "Least Concern" with a global population status of "stable" (Camara et al. 2018).

POPULATION SIZE AND DISTRIBUTION

The striped mullet is distributed worldwide between latitudes 51^{o} N and 42^{o} S, although it is less abundant in the tropics (Thompson 1963; Rossi et al. 1998; Harrison 2002). Striped mullet are euryhaline; they are able to tolerate the entire range of salinities from freshwater to oceanic water. As such, they can be found year-round throughout the full range of estuarine salinities as well as freshwater in South Carolina (Jacot 1920; Anderson 1958). In many river basins, striped mullet have been documented hundreds of miles from marine habitats with their only apparent limitation being physical barriers such as dams (Gunter 1938; Johnson and McClendon 1969).

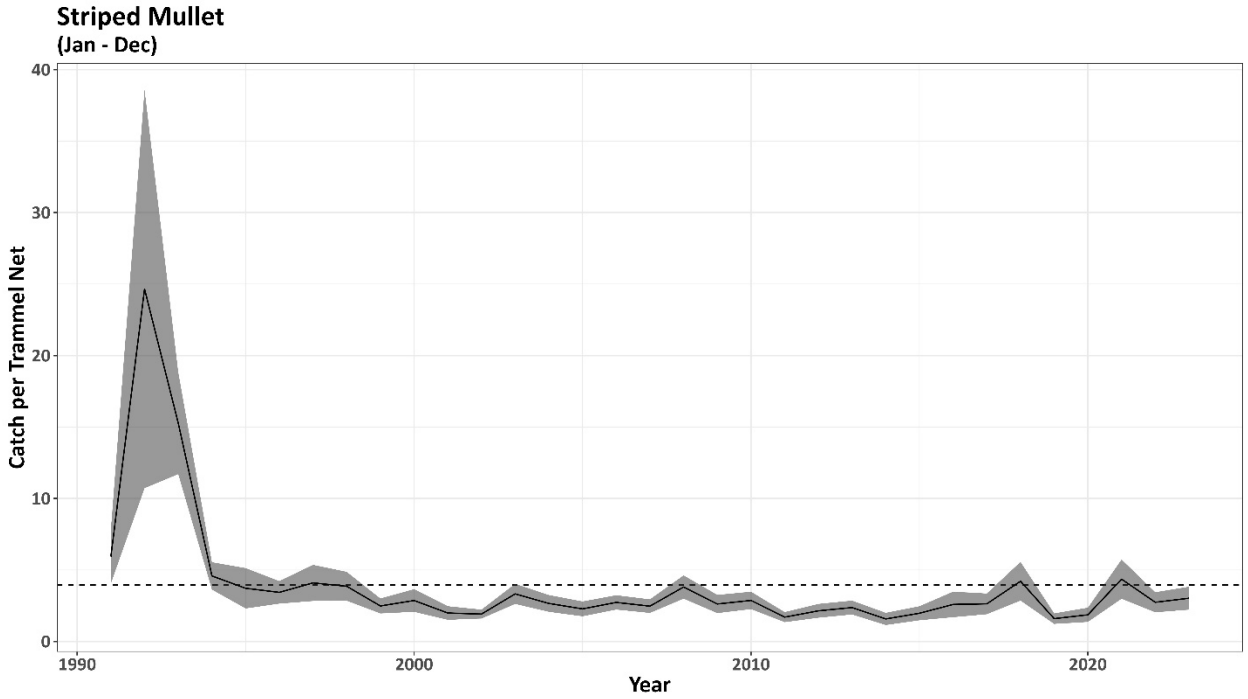

Figure 1. SCDNR Trammel net index of the CPUE of striped mullet statewide

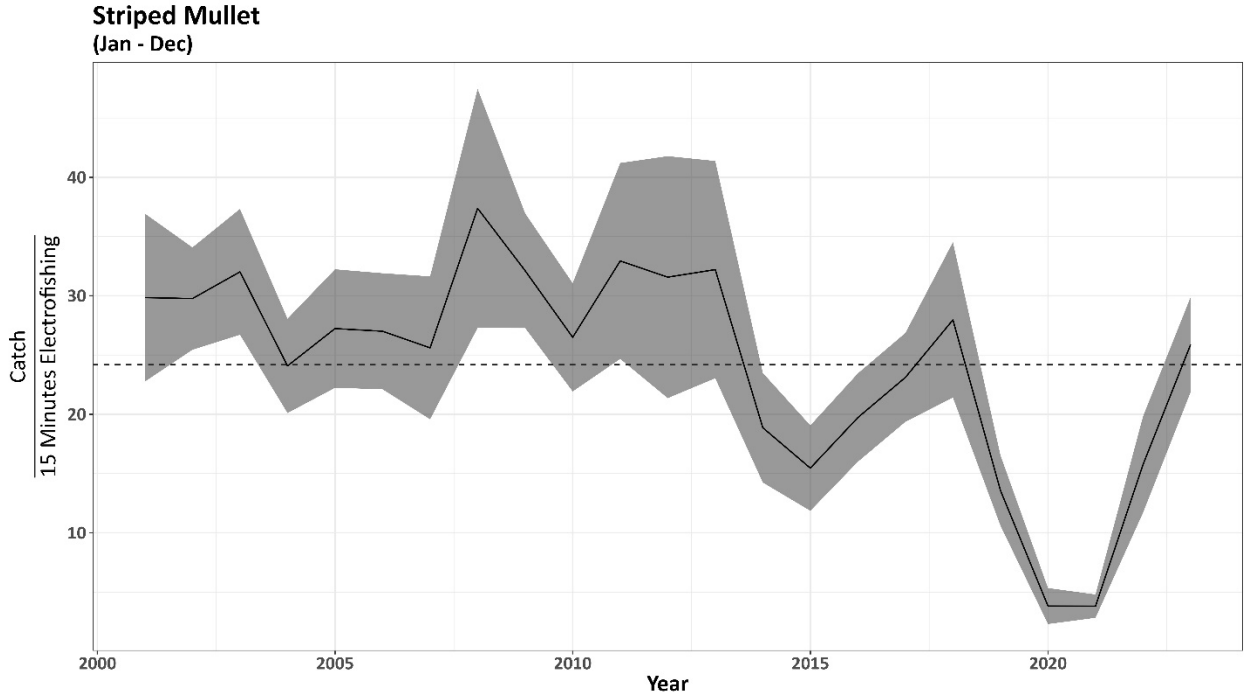

Figure 2. SCDNR Electrofishing survey CPUE of striped mullet statewide

SCDNR Inshore Fisheries (IF) group monitors relative abundance, length frequency, size and age at maturity of estuarine finfishes through monthly trammel netting,

electrofishing, and longline surveys and can detect changes in those parameters that result from management efforts.

Striped mullet are found in most habitats throughout South Carolina estuaries including mud flats, oyster bars, salt marshes, submerged aquatic vegetation beds, reservoirs, and tidal freshwater and riverine environments. Striped mullet in South Carolina prefer salinities less than 18 parts per thousand (ppt), but are commonly found throughout the entire estuarine salinity range (McDonough and Wenner 2003; McDonough et al. 2003). Juveniles less than 40 mm (1.5 inches) TL prefer salinities greater than 18.0 ppt, while juveniles and adults greater than this size can be found throughout the entire estuarine salinity range (McDonough and Wenner 2003). Larger striped mullet (greater than 350 mm or 14 in. TL) are frequently found in low salinity brackish water (less than 5.0 ppt) and freshwater, but this is more likely due to capture methods rather than the actual distribution of larger striped mullet. Striped mullet may stratify by depth according to size with the larger individuals moving into deeper water habitats, particularly in winter (Whitfield and Blaber 1978; Chubb et al. 1981). However, during the spawning migration—particularly in November and December—larger, reproductively developing striped mullet are seen in greater numbers closer to the mouth of most estuaries in high salinity habitats (McDonough et al. 2003; McDonough et al. 2005).

CHALLENGES

Striped mullet feed primarily on soft mud and other detritus, and therefore may be adversely affected by contaminants (organics, pesticides, and heavy metals) that settle out from the water column or become bound to sediment since their feeding strategy offers a vector for these contaminants to enter the food chain. While these types of contaminants are not currently considered a direct threat to striped mullet as a species, they could pose a threat in highly contaminated areas where bioaccumulation up the food chain may have an effect on gamefish, birds, and human health through direct consumption.

CONSERVATION ACCOMPLISHMENTS

South Carolina currently has no significant commercial striped mullet fishery, primarily due to gear restrictions and a lack of interest by commercial fishermen. Long term commercial catch statistics show a significant decrease in the commercial landings of striped mullet in South Carolina since 1982. Although limited inshore net bans were instituted in the 1950s, these regulations primarily targeted the trawl fishery, and the use of seines, gill nets, and stop nets accounted for most of the commercial catch up until the complete inshore net ban in 1986.

CONSERVATION RECOMMENDATIONS

- Determine seasonal movement and distribution of striped mullet in tidal freshwater systems by initiating a tagging project.
- Determine the level of contaminants (organics, pesticides, and heavy metals) found in striped mullet as well as the sediments in the areas in which they are caught. Relate that to the potential effects of bioaccumulation in predators.
- Protect water quality in marine ecosystems by encouraging municipalities to use Best Management Practices (BMPs) to reduce runoff from highways, agricultural fields, and housing developments.
- Plan development based on sound terrestrial and estuarine ecology that takes into consideration all factors that will affect the long-term health of the estuary ecosystem.
- Identify the origin of non-point source pollution and specific point source pollution and develop a plan of action to mitigate any negative effects to the affected aquatic systems.
- Improve BMPs in areas already impacted by non-point source pollution.
- Identify important or essential habitat types for different life stages of striped mullet and partner with other regulatory agencies (e.g. DHEC) to reduce impacts of development on these fish habitats.
- Partner with other state agencies in order to improve resource management at the whole estuary or drainage basin level using a more holistic ecological approach. Such restructuring should provide for greater regulatory authority in implementing migratory fish management plans.

MEASURE OF SUCCESS

Increases in recruitment, abundance, size, size and age at maturity would indicate positive trends in the population. In addition, by monitoring striped mullet populations in response to environmental contaminants, South Carolina will be better able to detect problems and work to correct them more quickly.

DESCRIPTION

Adult tarpon, 53 inches fork length (Photo D. Hammond)

The Atlantic tarpon (*Megalops atlanticus*) is recognized throughout its range as a very highly prized recreational species due in part to its fight strength and tendency to breach the water's surface while hooked. It is not utilized for food in the United States. While this species is reserved for recreational fishermen, only a small segment of the state's saltwater fishermen actually target this species. Little research has been done on this species on the east coast of the US north of Florida. State law bans the commercial harvest of this species in state waters.

Taxonomy and Basic Description

Tarpon belong to the family Megalopidae, which is represented by only one species in the eastern and southern United States. Members of this family are noted for their silvery herring appearance with large scales and a compressed, moderately deep body. Tarpon pass through an eel-like leptocephalus stage as young.

The sides of the fish are flat, virtually vertical in profile. The sides and belly are silvery and covered by very large scales; there are 40 to 48 scales present along the lateral line. The mouth is superior in position with the lower mandible extending far beyond the upper jaw. The fins are composed completely of soft rays. The dorsal fin has a high anterior lobe with a sharp downward slope posterior ending with the last ray greatly elongated into a heavy filament. The fin contains 13 to 16 soft rays. The caudal fin is deeply forked with the lobes equal in length. The anal fin is inserted behind the dorsal fin base and has a high anterior lobe; the remainder of the fin is long and low, ending in an elongated ray that is shorter than that in the dorsal fin. The anal fin has 22 to 25

soft rays. The pelvic fins are positioned in front of the origin of the dorsal fin and contain 13 to 14 soft rays (Whitehead and Vergara 1978).

Tarpon usually appear dark blue to greenish-black on the back. However, this color may be muted on individuals inhabiting inland waters. The sides and belly are bright silver in color. The dorsal and caudal fins have charcoal tipped margins.

Tarpon are reported to reach sizes of 250 cm (98 in.) (Whitehead and Vergara 1978) and weights of 161 kg (355 lbs.) (Claro 1994). Crabtree et al. (1995) reported that females grow more quickly than males and may live longer. Males are reported to reach 43 years of age while females can reach ages of at least 55 years (Crabtree et al. 1995). Sexual maturity for tarpon taken in Florida is reached by 117 cm (70 in.) in males and 128 cm (50 in.) in females (Crabtree et al 1997). By 10 years of age, all females were found to be sexually mature (Crabtree et al. 1997).

Tarpon are a schooling fish. They are usually found in small groups of 12 or fewer individuals but will form large schools comprised of over 100 fish.

Status

Tarpon are apex predators in South Carolina's coastal and estuarine waters. As such, they represent an excellent indicator of the condition of coastal waters for this trophic level.

Tarpon are considered one of the premier recreational species in the Western North Atlantic and support economically important fisheries in areas where they occur in high abundance. No stock assessment has been conducted on tarpon to determine whether the stock is being over-fished. With no regional or national fishery management plan in place for tarpon, management of this species rests with each coastal state.

Tarpon are infrequently caught in SCDNR's inshore fisheries' trammel net and electrofishing surveys. From 2013-2018, there were 26 tarpon caught in the trammel net survey (42nd most abundant species in this survey) and 30 tarpon captured in the electrofishing survey (53rd most abundant species; SCDNR 2018). However, currently there is virtually no data beyond creel occurrence for the species in South Carolina State waters. Subsequently, their population status is unknown.

POPULATION SIZE AND DISTRIBUTION

Tarpon inhabit a large range of warm temperate to tropical waters on both sides of the Atlantic Ocean (Whitehead and Vergara 1978). In the Western Atlantic, the fish are primarily found in warmer coastal waters with the largest populations found in the Gulf of Mexico off of Florida and in the West Indies (Smith 1997). However, they have been noted from Nova Scotia south to Argentina and eastward to Bermuda. Tarpon are also noted to enter freshwater (Boseman 1960).

Tarpon found in state waters are presumed to have migrated from points south, probably Florida. This is supported by a recovery of a tagged tarpon released in August 1996 at Hilton Head Island, South Carolina and recovered in June 1997 at Tavernier Key, Florida (R. Wiggers, SCDNR, pers. comm.). They have been captured from the three-mile state territorial limit in coastal waters westward into the estuaries and rivers along the entire coast of South Carolina (D. Hammond, pers. obs.). Tarpon will enter the estuaries at all ocean inlets in South Carolina. These fish follow tidal flow moving offshore as much as three miles from the inlets and bays during the ebb tide, and move inland as much as seven to ten miles on the flooding tide (D. Hammond, pers. obs.). They will occasionally stray up freshwater rivers; one specimen was captured approximately one mile below the Pinopolis Dam at Moncks Corner on the Cooper River (D. Hammond, pers. obs.). Recreational anglers have tagged tarpon for the Marine Game Fish Tagging Program from April to December. Tarpon begin to appear in state waters as early as April; peak abundance occurs in late summer (Hammond 1988; Elmo et al. 2021). They usually depart coastal waters in late October through early November, presumably due to declining water temperature (Mace et al. 2017).

The majority of current research on tarpon in South Carolina focuses on the larval and juvenile stages, and no work has been done to assess the population size of tarpon along the southeastern coast of the United States or in South Carolina. Subsequently, no information is presently available on the health of the east coast population.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Tarpon occur from near shore ocean waters to estuaries and up into freshwater rivers (Boseman 1960). They are primarily found in coastal waters, bays and estuaries, within tropical, subtropical and temperate climates (45° N to 30° S). Although a marine fish, tarpon can tolerate euryhaline environments and often enter river mouths and bays and travel upstream into fresh water (Boseman 1960). In addition, tarpon can also tolerate oxygen-poor environments due to a modified air bladder that allows them to inhale atmospheric oxygen (Bone et al. 1995; Geiger et al. 2000).

Spawning in Puerto Rico occurs in nearshore waters with tarpon leptocephali larvae arriving in the estuaries in their second stage of metamorphosis (Zerbi et al. 2001). Florida tarpon were reported to spawn from April through July (Crabtree et al. 1997). A similar spawning scenario may occur in South Carolina. Juvenile tarpon are common members of the ichthyofauna found in brackish water impoundments in the early fall (D. Hammond, pers. obs.; Mace et al. 2017). However, tarpon are not present in these impoundments in the spring, presumably due to escapement and/or die-off related to low water temperatures. Tarpon probably enter these impoundments during their annual flooding in late spring as leptocephali larvae. They become trapped in these bodies of water when the floodgate connections to the estuaries are closed.

CHALLENGES

Catch and release fishing by recreational anglers may be a source of adult tarpon mortality. However, Edwards (1998) found a high survival rate, 26 of 27 fish studied, for recreationally caught and released fish in Florida. This would indicate a small latent mortality for the recreational catch and release fishery. Recent studies estimate tarpon post-release mortality to be at least 5%, though researchers also recognize that the maximum realistic mortality rate could be 13-18% based on shark predation and tagging data (Guindon 2011; Horowitz et al. 2023).

Habitat and water quality are recognized as especially important in the early life stage of marine fish found in estuaries. Any degradation to the estuarine ecosystems could impact the survival, growth, and later life of juvenile tarpon that utilize these estuaries as a nursery ground. The impact that many pollutants have on marine fish life cycles are just now being discovered. Thomas (1990) found that four known mammalian reproductive toxins also altered the reproductive endocrine function in female Atlantic croaker, *Micropogonias undulatus,* impairing reproduction. These toxins could have a similar impact on tarpon.

Industrial and municipal sewage discharge along with runoff from agriculture, golf courses and suburban developments negatively affect tarpon and other estuarine fishes. Because of its prevalence in estuaries, tarpon are considered an indicator of the overall health of this ecosystem.

CONSERVATION ACCOMPLISHMENTS

The tarpon was declared a game fish in South Carolina by state law in 1991. This law banned the sale of tarpon and limited recreational anglers to a possession limit of one fish per person per day.

CONSERVATION RECOMMENDATIONS

- Identify the origin(s) of adult tarpon found in South Carolina and determine length of residence in state waters.
- Information on the temporal/spatial incursion of larval tarpon into South Carolina estuaries is needed to aid in defining spawning activity and larval recruitment.
- Determine essential habitat and water quality needed by tarpon at their various life stages and identify the corresponding areas found in South Carolina.
- Identify primary food sources at the various stages in their life.
- Educate fishermen to employ circle hooks and careful handling practices when releasing this fish. This can be accomplished, in part, by partnering with fishing clubs and conservation groups to push for stronger conservation ethics among their members. Community avocation and awareness will therefore help guide and direct the future of this fishery.

MEASURE OF SUCCESS

Because there are currently no known estimates of population size or trends, it is impossible to identify a measurement of success. However, once monitoring establishes baseline data, the measurement of success will be a stable tarpon population year to year.

Vermilion Snapper

Rhomboplites aurorubens

Contributors:
Brandon Reding (SCDNR) & Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Vermilion snapper, Rhomboplites aurorubens, is a small member of the order Perciformes and family Lutjanidae (Page et al. 2023) reaching a maximum length and weight of approximately 24 inches (600 mm) and 6 pounds (2.8 kg), respectively (Grimes, 1978; Schmidtke, 2024). The species has a streamlined body with a vermilion/red coloration dorsally and a silvery-white coloration ventrally. Narrow, yellow-gold streaks occur below the lateral line, either horizontal or diagonal. The moderately forked caudal fin appears red with a subtle black margin, while the dorsal fin appears red with a yellow margin. Individuals have a short snout, a slightly projecting lower jaw, and lack canine teeth (Allen, 1985; NOAA Fisheries, 2024; Schmidtke, 2024).

Vermilion snapper are gonochoristic, meaning sexes are separate, and indeterminate spawners with a spawning frequency of around 35 times per year, increasing with age (Bagley et al., 1999; Cuellar et al., 1996; SEDAR, 2018). The spawning season begins in April and continues through September, with a peak between June and August in the southeast U.S. Atlantic Ocean (SEUSA). Sexual maturity occurs early in this species with 0.85 years as the estimated age at 50% maturity for females, and 100% of individuals are mature by age 2. Males and females have not been shown to exhibit sexual dimorphism, however, 68% of individuals within the SEUSA stock of vermilion snapper are female (SEDAR, 2018; Zhao et al., 1997). The current oldest observed age for the stock is 19 years (SEDAR, 2018).

Status

The last stock assessment, conducted in 2018 through SEDAR 55, determined the stock is not experiencing overfishing and is not overfished using fishery data through 2016 (SEDAR, 2018). However, the IUCN Red List currently lists the species as vulnerable.

POPULATION SIZE AND DISTRIBUTION

Vermilion snapper occur from North Carolina and Bermuda, throughout the Caribbean Sea and Gulf of Mexico to southeastern Brazil (Grimes & Huntsman, 1980; Potts et al., 1997). In U.S. waters, the species has traditionally been managed as two separate and distinct stocks – South Atlantic and Gulf of Mexico (GOM). This species represents a significant component of the fishery-independent catches obtained using chevron traps by the Southeast Reef Fish Survey (SERFS: joint program between SCDNR and NOAA),

spanning from Cape Hatteras, NC, to Cape Canaveral, FL (i.e., SEUSA). High densities of vermilion snapper can be found in the waters off the states of South Carolina and southern North Carolina, but remain prevalent across the entire range of the survey, spanning various depths (Figure 1).

The most recent estimate of population size for the South Atlantic stock was ~16.8 million as of 2017. The SERFS chevron trap index indicates that the stock is above the long-term average value after approximately ten years of relatively low population levels (Figure 2).

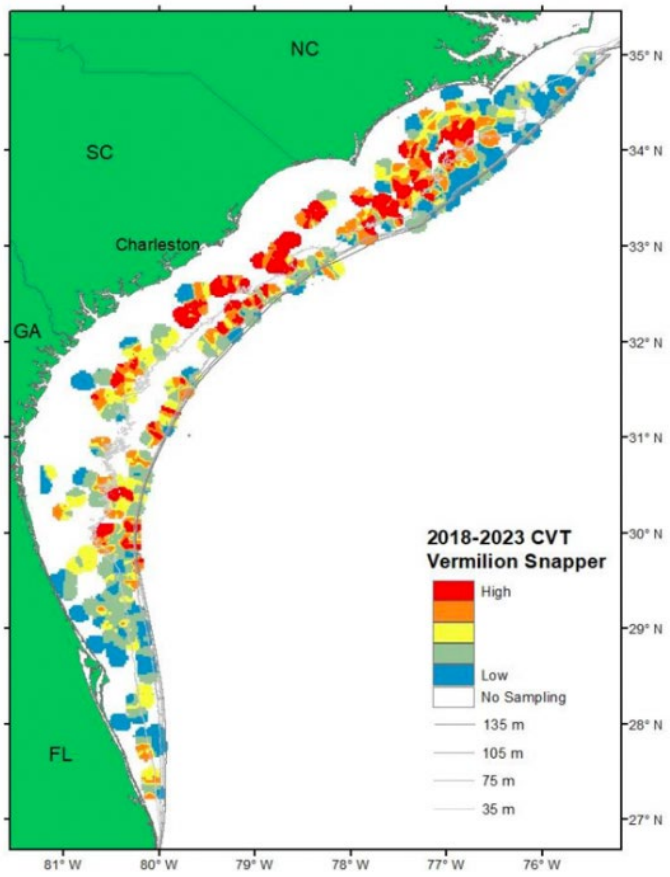

Figure 1: Density of vermilion snapper catches from SERFS Chevron Trap survey: 2018 – 2019 and 2021 – 2023.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

This schooling species is associated with high and low relief live bottom habitat encompassing sponge/coral, rocky outcrops, and rocky ledges (Davis et al., 2015; Grimes et al., 1982). They can be found throughout the continental shelf and shelf break (26-56 m) and upper slope reef habitats (64-183 m; Cuellar et al., 1996; Grimes, 1978; Grimes et al., 1982). They will often utilize the upper water column and show patterns of diel vertical migration, with data suggesting individuals feed in the late afternoon and evening (Grimes, 1979; Grimes et al., 1982; SEDAR, 2018). Within these habitats vermilion snapper can often be found feeding on fishes, shrimps, crabs, polychaetes, other benthic invertebrates, cephalopods and planktonic

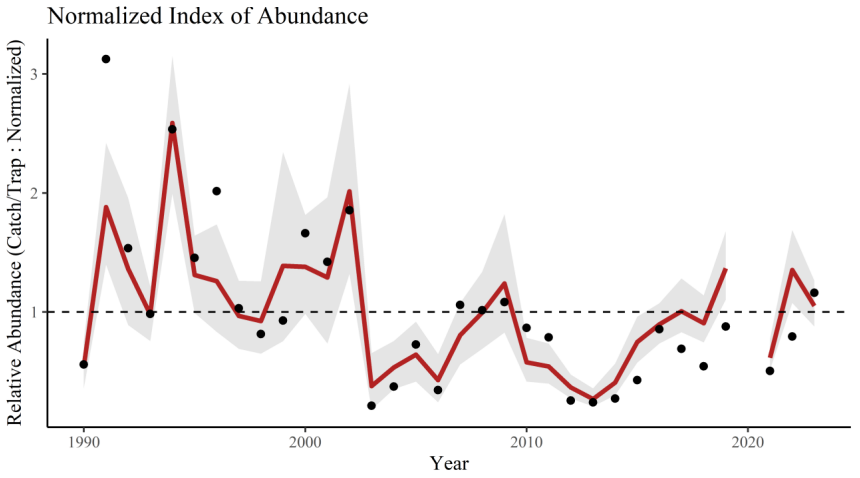

Figure 2: Chevron trap index of abundance and length compositions for vermilion snapper from the SERFS. Red line is the modeled value through time, gray shading represents the 95% confidence interval for the model, and black dots are nominal values.

organisms (Allen, 1985). Copepods are the primary prey for juvenile vermilion snapper, while adults shift their diet to predominantly consume fish (Grimes, 1979).

CHALLENGES

Among reef fish species in the SEUSA, vermilion snapper provide important economic contributions to both recreational and commercial fisheries (Bagley et al., 1999). As part of a multi-species fishery (snappers, groupers, etc.), the species is susceptible to elevated rates of discard mortality. Presently, the commercial discard mortality rate is estimated at 0.41 and the recreational rate at 0.38 (SEDAR, 2018). Given the depths vermilion snapper often inhabit, barotrauma poses a threat to individuals if proper descending practices are not carried out, potentially contributing to the rates of discard mortality. In addition, as fishing regulations become more restrictive for other snapper/grouper species, vermilion snapper could see an increase in fishing pressure and mortality.

Climate change has led to warming waters all around the world that could affect vermilion snapper species distribution. This trend has already been observed in other stocks, such as Black Sea Bass (*Centropristis striata*), in the SEUSA (ASMFC, 2024). Should South Atlantic waters continue to warm, we could see a potential shift northward of the SEUSA vermilion snapper stock. This may, in turn, affect other aspects of the species' life history such as growth rates and reproduction.

CONSERVATION ACCOMPLISHMENTS

The SEUSA stock of vermilion snapper is managed by the South Atlantic Fishery Management Council (SAFMC). The first benchmark assessment of vermilion snapper was completed in 2003 and found the stock was not overfished but experiencing overfishing (SEDAR, 2003). It was not until SEDAR 17 Update Assessment that the stock was no longer experiencing overfishing (SEDAR, 2012), which continues today. Throughout the species' assessment history, the stock has never been overfished. The minimum size limit for the stock has remained relatively constant throughout its history, with the current limit set at 12" total length for both the recreational and commercial fisheries. A bag limit of 5 individuals is set for the recreational fishery, while a trip limit of 1000 lbs gutted weight is set for the commercial fishery. Allowable gear for fishing this species includes vertical hook-and-line (hand line and bandit gear) and spearfishing gear without rebreathers. In federal waters north of 28°N latitude non-offset, non-stainless steel circle hooks are required. Fish must be landed with fins and head intact, and a descending device is required aboard all vessels and readily available for use (Schmidtke, 2024).

CONSERVATION RECOMMENDATIONS

- Continue monitoring via fishery-dependent and -independent sampling programs
- Investigate discrepancies between age compositions and indices of abundance

- Develop methods to standardize and combine SERFS chevron trap and video gears for creating indices of abundance
- Investigate the optimal level of spatial structure to model in an assessment of snapper-grouper species such as vermilion snapper.
- Investigate the genetic stock connectivity between the Gulf of Mexico and South Atlantic stocks

MEASURE OF SUCCESS

The SERFS program works to monitor various stock parameters for vermilion snapper, including relative abundance, population demographics and reproductive status. This program can detect changes in those parameters as a result of changes in fishing pressure and/or management efforts. SERFS can then inform fishery managers and scientists of these changes to take the appropriate action. Increases in abundance, size- and/or age-compositions, and spawning stock biomass would indicate positive trends in the population.

Wahoo
Acanthocybium solandri

NOAA

Contributors:
Amy Dukes, Elizabeth Gooding, and Sydney Bates (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Wahoo are part of the family Scombridae, in the order Scombriformes, connecting them to Spanish mackerels (Page et al. 2023). They share an elongate body form that is cylindrical enabling them to be one of the fastest fish in the ocean. Wahoo have distinct coloration with dark blue, iridescent vertical streaks along the body sides. Beyond these bands, the base color of the wahoo begins dorsally as metallic blue and fades to a silvery ventral side. With a streamlined body, they have an infamously prolonged snout and serrated, razor-sharp teeth (SCDNR Sea Science). Identifiable features of the wahoo include a first and second dorsal fin with spines ranging between 23 and 27 and rays between 12 and 16. In addition to the dorsal fins, there are eight to nine finlets present posterior to these fins (Zischke 2012).

It is hard to measure the ages of individual wahoo, because the scales, otoliths, and vertebrae do not provide an accurate record of age. Instead, scientists use their growth rate to estimate age. Research in North Carolina has shown maturity is typically reached in one year of life. At this age, male wahoo are 860 mm total length (TL), while females are often slightly larger at 1010 mm TL (Hogarth 1976). In these age estimations, it is also found that wahoo live five to six years.

Wahoo are gonochoristic; each fish develops as either male or female. When both sexes reach sexual maturity, the fish can reproduce via spawning. Females release buoyant eggs and males release sperm into the water column to disperse. The sperm will fertilize the egg, form larvae, and continue to develop (Triay-Portella 2023).

Wahoo have great importance toward commercial and recreational fisheries. They are a targeted species due to their size and high-quality meat, as well as an incidentally caught species (Zischke 2012). For this reason, fisheries management and conservation are critical to prevent the depletion of the resource and protect the populations. Understanding the life history of wahoo can allow for informed decisions for size and catch limits that can enable sustainable marine fisheries for future generations (SCDNR Sea Science).

Status

The four stocks of wahoo have not been assessed and the status of this species is unknown. Based on catch data, fishing pressures are not causing overfishing and catch limits are in place for the South Atlantic and Gulf of Mexico stocks (NOAA 2024).

POPULATION SIZE AND DISTRIBUTION

Wahoo remain in the tropical and subtropical waters of the Atlantic, Pacific, and Indian Ocean year-round. However, in the warmer months, this species is present at a higher distribution in northern waters of the Atlantic (Oxenford 2003).

Several studies have demonstrated differences in sex ratios. Values near 1:1 have been reported in most studies (Brown-Peterson *et al.,* 2000; Oxenford *et al.,* 2003; Jenkins and McBride, 2009). Meanwhile, research from Hogarth (1976) found a sex ratio of 3:1 with the higher abundance being female.

A recent risk assessment resulted in low vulnerability for northern Atlantic wahoo and high vulnerability for southern Atlantic wahoo. (Lucena-Frédou *et al.,* 2017a). Using length-based data, a stock assessment was conducted for these stocks and determined that the population was being overfished in the Northwest Atlantic. Results pertaining to the Northeast Atlantic also determined slight overfishing, however, the methods of these two assessments were different (Pons *et al*., 2019).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Wahoo are found in offshore waters of the Carolinas more prevalently in the warmer months. The distribution of wahoo has been reported as very wide. They are found worldwide and in a variety of ocean features. Because they are aggressive piscivores, habitat usage is possibly driven by competition for resources (Theisen 2012). They have been reported near objects floating on the water, including *Sargassum* or naturally occurring fish attracting devices. They are solitary apex predators with a diet that consists of 70% finfish species. Wahoo search for food sources in open water, primarily feeding on fast-swimming pelagic prey, including small tunas, flying fish, herring, squids, and several additional species. It has also been suggested this species forages below floating material due to occurrence of such within their diet (Oxenford 2003).

CHALLENGES

Wahoo have not been formally assessed which poses a challenge for management. Without having the best available information regarding this species, resources cannot be properly allocated to help support its conservation. In addition to lack of assessment, because wahoo are commercially and recreationally important, the species faces increased fishing pressure which can negatively impact the population status (NOAA 2024).

CONSERVATION ACCOMPLISHMENTS

Atlantic wahoo are managed through several organizations including NOAA Fisheries, the Caribbean Council, and the South Atlantic Fishery Management Council (SAFMC). Under the SAFMC Dolphin and Wahoo Fishery Management Plan, there are fishing regulations to help manage the Atlantic wahoo population. These regulations include different levels of permits (i.e., vessel, dealer, charter), annual and daily catch limits, and size limits (NOAA 2024).

CONSERVATION RECOMMENDATIONS

- Characterize stock status in Atlantic waters
- Determine potential shifts in distribution and driving factors
- Investigate migration patterns
- Expand research and monitoring in fishery-independent surveys
- Research early life stages and develop better understanding of complete life history
- Enforce restrictions to minimize overfishing

MEASURE OF SUCCESS

A successful species can be viewed by measuring a strong and healthy population size. The use of fishery independent and dependent data from recreational and commercial fishing effort and catch can aid in this determination (NOAA 2024). However, few studies prioritize wahoo for data collection. Without reliable research it is hard to measure the health of the Atlantic wahoo population. Wahoo have been identified as a critical species needing assessment and actions toward proper management. Wahoo have been categorized as high risk, but no assessments are available to provide data in this fishery (Pons et al. 2019).

Warsaw Grouper

Hyporthodus nigritus

Contributors:
Wiley Sinkus (SCDNR)

Illustration by Duane Raver, Jr.

DESCRIPTION

Taxonomy and Basic Description

The Warsaw grouper (*Hyporthodus nigritus*) is a large-bodied fish belonging to the Epinephelidae family within the order Perciformes (Page et al. 2023). It is characterized by a robust body, typically dark reddish brown to gray in coloration, juveniles may have a yellow caudal fin with irregular lighter spots and blotches (FAO 2002). Warsaw grouper are characterized by having 10 spines and 13-15 soft rays on their caudal fin, with the second spine being distinctly elongated and the interspinous membranes deeply incised (FAO 2002) Warsaw grouper diet consists of a variety of crabs, shrimp, lobster, and fishes. It is a long lived, slow growing species that reaches a maximum age of 59 with annulus formation occurring between April and May (Manooch and Mason 1987) and can reach lengths exceeding 6 feet and weights over 400 pounds (FAO 2002; Sanchez 2019). Reproductively, Warsaw groupers are slow-growing and late-maturing, with individuals reaching reproductive age around 7-9 years old. They exhibit protogynous hermaphroditism where females can transition into males as they mature. Spawning typically occurs in aggregations during specific seasons, but exact timing and locations can vary. The Warsaw grouper spawns during August, September, and October in the Gulf of Mexico (SAFMC 2010), and during April and May off Cuba (Naranjo 1956).

Status

Warsaw grouper are an important sport fish for bottom fishers due to their large size, but historically have contributed to less than 1% of commercial grouper landings on the southeast Atlantic Coast (FAO 2002). They were first identified as a species of concern by the NOAA National Marine Fisheries Service in 1997 and are also listed as near threatened across their range on the International Union for Conservation of Nature (IUCN) Red List which was last assessed in 2016 (IUCN 2018; NOAA 2009). In the United States, including South Carolina, regulations are in place to prohibit the possession of Warsaw groupers to aid in population recovery. Warsaw grouper was listed as having ongoing overfishing status up until 2021 due to concern about monitoring discards from incidental catch of Warsaw grouper when fisherman targeted co-occurring snapper-grouper species (Farmer 2014; SAFMC 2010). The current Warsaw grouper stock status, however, has been changed to an unknown overfishing status and an unknown overfished status due to a lack of data (Farmer 2014; NOAA 2023; SAFMC 2010).

POPULATION SIZE AND DISTRIBUTION

Warsaw groupers are distributed in the western Atlantic Ocean from North Carolina to the Florida Keys and throughout much of the Caribbean and Gulf of Mexico to the northern coast of South America, occurring along the continental shelf break in deep waters ranging from 180 to 1,000 feet (FAO 2002; Manooch and Mason 1987). Juveniles can occasionally occur on shallow water reefs and jetties (Heemstra and Randall 1993). Warsaw Grouper have been rarely encountered in any survey covering their reported habitat that SCDNR has been involved in, including the historic short bottom longlining survey conducted by SCDNR or the ongoing cooperative South Atlantic Deepwater Longline Survey (SADLS) conducted jointly by commercial fisherman, NOAA Fisheries and SCDNR (less than 75 individuals since 1978). Commercial catches peaked in 1973 at 34,0005 lbs. landed and steadily declined throughout the 1970's, 80's, and 90's, reaching a low of 1,393 lbs. in 1995 (Figure 1; Parker and Mays 1998). Due to data deficiencies, little is known about Warsaw grouper sex ratio or population demographics (size- and age-composition) in the region.

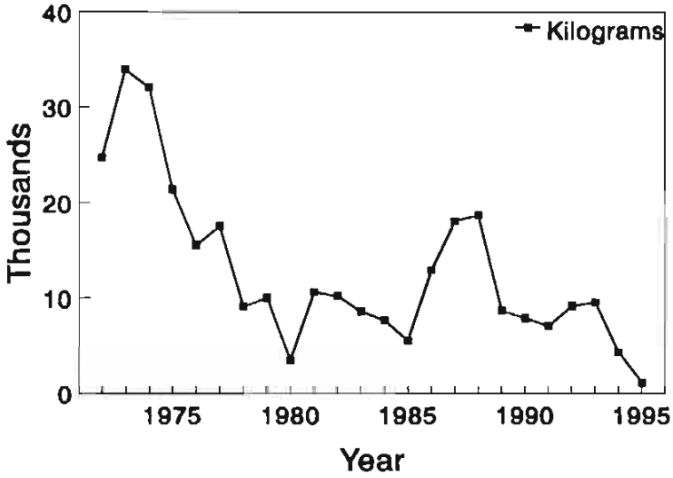

Figure 1: Warsaw Grouper commercial fishery catch (kg) from 1972-1995.

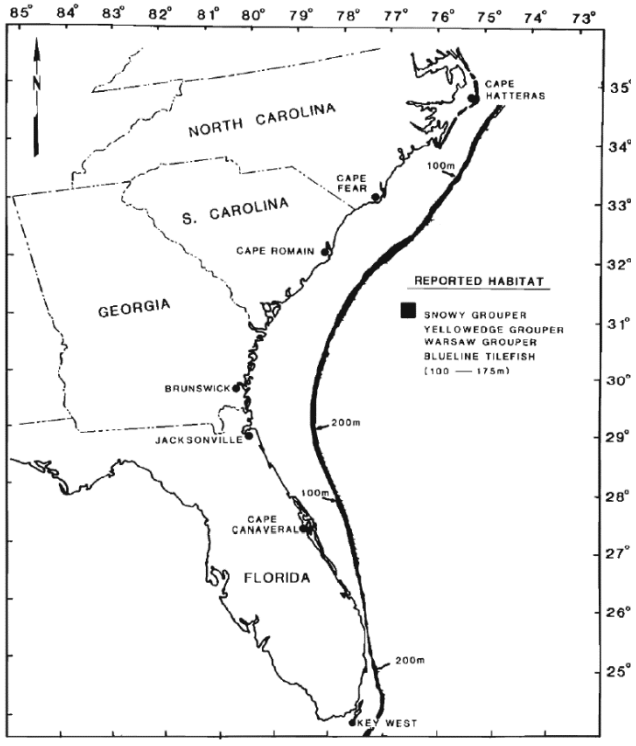

Figure 2: Reported habitat for deep water species in the Atlantic along the Southeastern US.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Warsaw grouper inhabit rough irregular bottom, notches, valleys, seamounts and drop-offs, occurring along the continental shelf break, in waters ranging from 180 to 1,000 feet. (FAO 2002) This habitat is characterized by steep cliffs, rocky ledges, and swift currents and is the same habitat where snowy grouper, yellowedge grouper and blueline tilefish are found (Figure 2; Manooch and Mason 1987; Parker and Mays 1998; Robins and Ray 1986).

CHALLENGES

Slower growing, long-lived species are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. Because Warsaw grouper are sequential hermaphrodites, there can be disproportionate targeting of the larger sex (males) which skews population demographics. As with many other reef fish species which have substantial overlap in habitat use, there is potential for mortality even when they are not targeted in this multi-species fishery which is further compounded in deepwater species (≥30 m), as they can be highly susceptible to post-release mortality (e.g. barotrauma). Deeper reef species, such as Warsaw grouper, may also be especially vulnerable because of their limited geographic ranges (Parker and Mays 1998). Small impacts to their preferred habitat due to climate change or anthropogenic effects could have large consequences. Data deficiencies due to low population size or lack of reporting discards of these fish makes it difficult to assess the health of the population leading to continued stringent restrictions.

CONSERVATION ACCOMPLISHMENTS

In 1994, a recreational and commercial bag limit of 1 Warsaw grouper per vessel per trip and no sale was put in place by the SAFMC to try to limit fishing mortality. In 2008, fishery-independent projects indicated they were conspicuously absent from historical areas of catch. Because the overfishing limit could not be determined, the incredibly small biomass and the high degree of uncertainty associated with these species, any catch was thought to result in overfishing of this stock and therefore the acceptable biological catch (ABC) and annual catch limits (ACL) were set to zero (SAFMC 2011). In 2011, SAFMC prohibited the harvest and possession of the remaining six deepwater species that co-occur with Warsaw grouper to reduce bycatch of Warsaw grouper in water deeper than 240-ft (40-fathoms) where release mortality is very high (SAFMC 2011). This act of prohibiting the harvest of deep-water species is thought to protect spawning aggregations of Warsaw grouper, as well (SAFMC 2011). Existing Marine Protected Areas (MPAs) in 2013 covered 10% of probable shelf-edge habitats for Warsaw Grouper, protecting 8% of Warsaw grouper stocks. Proposed additional MPAs could add 24% more probable shelf-edge habitat and protect an additional 20% of Warsaw grouper stocks (Farmer and Karnauskas 2013).

CONSERVATION RECOMMENDATIONS

- Harvest restrictions for Warsaw grouper are currently as strong as they can with an annual catch limit = 0, however increasing enforcement of these regulations could result in the quicker recover of this species.
- Increasing the size and quantity of MPAs in areas likely to be inhabited by Warsaw grouper would benefit the population.

- Increasing funding for research studying fisheries population dynamics in preferred habitats.
- Educating stakeholders on sustainable fishing practices and conservation needs.

MEASURE OF SUCCESS

The SADLS monitors relative abundance, population demographics and reproductive state of deep-water fishes and can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, size- and/or age-compositions would indicate positive trends in the population.

Weakfish

Cynoscion regalis

Contributors:
Erin Levesque (SCDNR)

Revised 2025:
Jimmy Kilfoil (SCDNR), Michelle Taliercio (SCDNR), Erin Levesque (SCDNR) & Joseph C. Ballenger (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Weakfish, *Cynoscion regalis* (Bloch and Schneider 1801), are members of the order Perciformes and the family Sciaenidae (drums; Page et al. 2023). Diagnostic characters include a rather large mouth with a pair of large canine teeth in the upper jaw, a silvery body with dark speckles along the dorsal surface, and yellowish pelvic and anal fins. In South Carolina, weakfish are found predominantly in estuaries as juveniles and in shallow coastal waters as adults. The species may be confused with the closely related spotted seatrout (*C. nebulosus*), silver seatrout (*C. nothus*), and sand seatrout (*C. arenarius*). Weakfish can be clearly differentiated by the presence of only one marginal pore on the snout, while the three other species have two pores. However, hybridization between species may sometimes occur (Tringali et al. 2011).

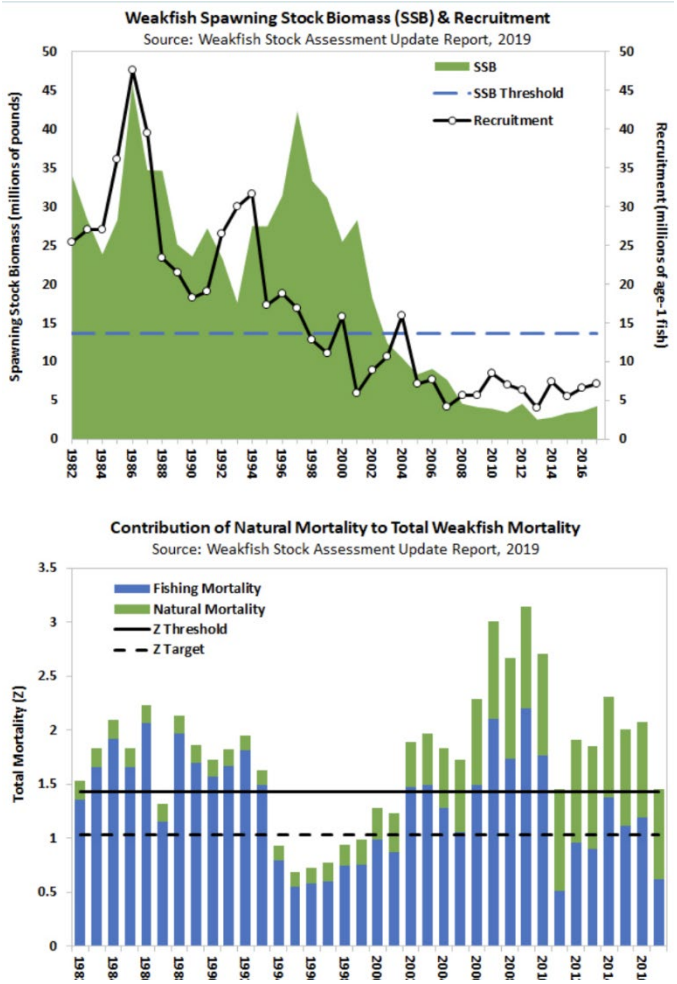

Figure 1: Top: Time series of weakfish spawning stock biomass (SSB; green area) and recruitment (black line). Also shown is the SSB threshold. Bottom: Time series of total mortality (Z) broken down by components: fishing mortality (blue bar) and natural mortality (green bar). Also shown is the Z target (dashed line) and threshold (solid line; Source: ASMFC 2019).

Status

Currently, the weakfish population is managed as a unit stock along the east coast of the United States and managed by the Atlantic States Marine Fisheries Commission (ASMFC). The

most recent assessment, finalized in 2019, concluded weakfish were depleted and total mortality exceeded threshold levels in the terminal year (2017; ASMFC 2019). Coastwide estimates of recruitment, spawning stock biomass, and total abundance remained low in recent years with moderately high, though not near time-series highs, fishing mortality (Figure 1). Natural mortality remained high in the terminal year, averaging 0.92 in the most recent 10 years, compared to 0.16 over the first 10 years of the time series (Figure 1). Therefore, even though harvest has been at low levels in recent years (Figure 2), the weakfish population has been experiencing very high levels of total mortality, preventing the stock from recovering. In support of assessment findings, the 2019 IUCN assessment lists weakfish as "Endangered" under criteria A2b and noted a decreasing population trend as measured by the number of mature individuals (Barbieri & Barbieri 2020).

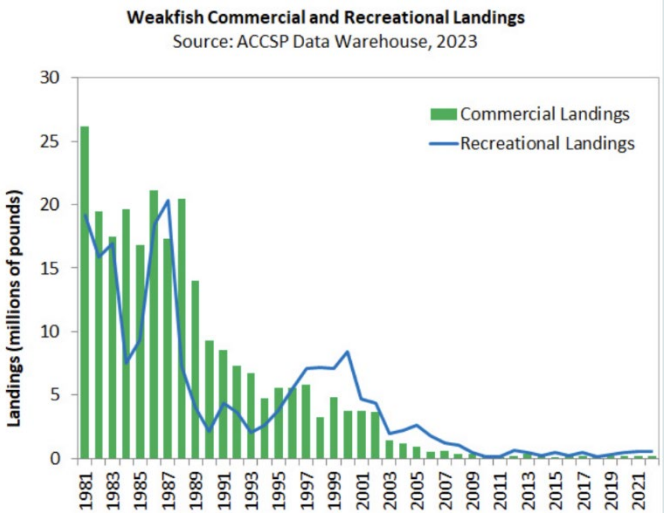

Figure 2: Time series of coastwide weakfish commercial and recreational landings (Source: ASMFC 2024)

POPULATION SIZE AND DISTRIBUTION

Weakfish are found along the Atlantic Coast from southern New England to Florida, occuring in highest numbers in the mid-Atlantic area (New York to North Carolina; Wilk 1979). Historically, weakfish were one of the most important components of a mixed-stock fishgery on the Alantic coast since the 1800s (ASMFC 2024). However, landings in the weakfish fishery have generally declined sinc ethe late-1980s as weakfish biomass began to decline, natural mortality rates increased, and fisheries management regulations were put into place (ASMFC 2019). Commercial landings have dramatically declined since the early 1980s, dropping from over 19 million pounds landed in 1982, still below the peak in 1980 at 36 million pounds, to 190,176 pounds in 2022 (Figure 2; ASMFC 2024). The majority of landings occurred in New York, North Carolina, and Virginia. Commercial fishermen have been known to discard weakfish, especially in the mixed species trawl fishery, and the discard mortality is assumed to be 100%. Discards peaked in the 1990s but have since declined as the result of management measures and a decline in stock abundance.

Coastwide, recreational catches followed similar trends to that of commercial landings (Figure 2; ASMFC 2024). After harvests above 10 million pounds in the early-1980s, landings decreased to two million pounds by 1989, and hovered between one and two million pounds through the early 1990s. Harvest then increased to over four million

pounds by the late 1990s, before exhibiting a decline like that in the commercial fishery. Recreational harvest has been dominated by New York, North Carolina, and South Carolina (ASMFC 2024). Recreational landings in 2023 were 468,618 fish (46,264 pounds) and recreational releases were estimated at 2.87 million fish. Recreational harvest in South Carolina in 2023 was 176,118 fish (215,795 pounds; 37.6% of the Atlantic catch by fish number and 33.4% by pound), the most of any individual state, followed by Florida and North Carolina (NMFS, Office of Fisheries Statistics, pers. comm.).

Several SCDNR fishery-independent surveys encounter weakfish in low to moderate numbers, including the estuarine trawl and the SEAMAP-SA coastal trawl surveys. The SCDNR estuarine trawl survey primarily encounters age-0 weakfish, providing an index of annual recruitment along coastal South Carolina. This index suggests a general increasing trend in weakfish recruitment in South Carolina estuaries since the early-2010s, though there is high uncertainty in this trend (Figure 3). Unfortunately this index was not available for consideration during the benchmark assessment (ASMFC 2016) due to its short time series, but may be included in future regional assessments. In the regional SEAMAP-SA coastal trawl survey, weakfish abundance has gradually increased over time, generally above the long-term average since 2003 (Figure 4). This survey also encounters smaller, younger weakfish (primarily age-0 and age-1), though in different habitats than surveyed by the estuarine trawl survey.

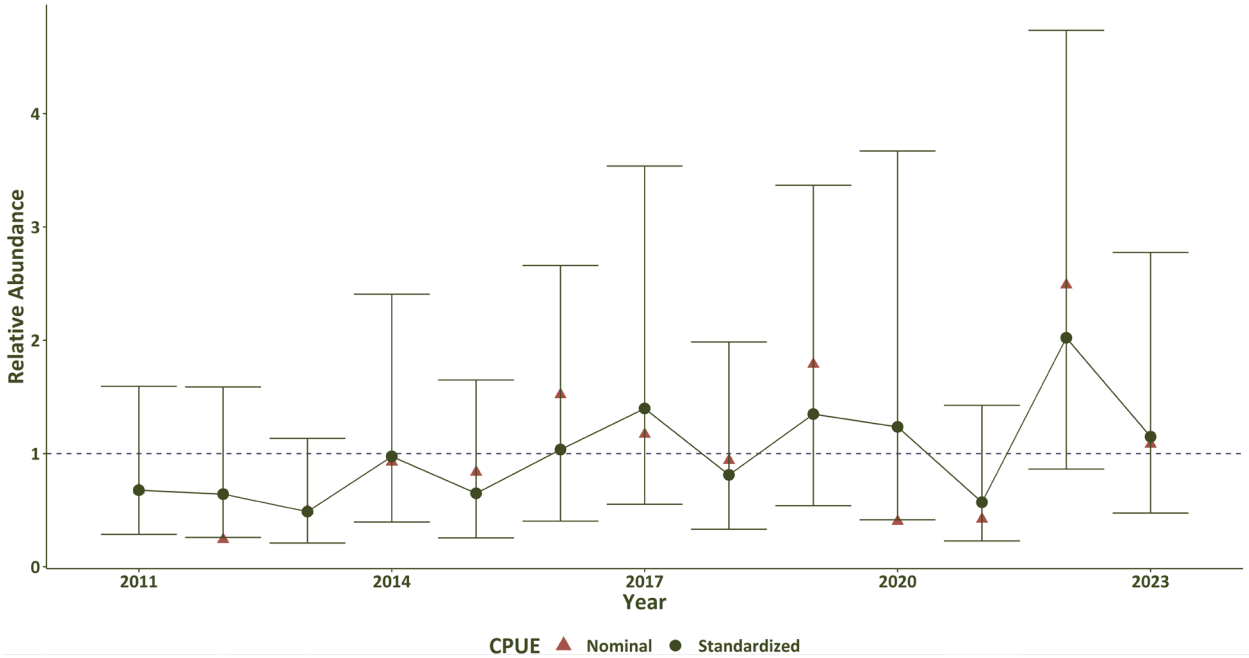

Figure 3: Annual relative abundance of weakfish in South Carolina estuaries based on SCDNR estuarine trawl survey catches. Nominal and standardized abundance shown, with the dashed line representing the time-series mean. (Source: Joseph Ballenger, SCDNR, unpublished data)

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

During warmer months of the year, weakfish adults live in nearshore coastal waters and inside bays and estuaries. In the winter, they aggregate and move farther offshore and possibly south to warmer, more stable water temperatures (Bigelow and Schroeder 1953; Mercer 1985; Wilk 1979). In South Carolina, the recreational fishery for weakfish begins in the late fall and continues through winter and early spring, taking advantage of the large schools that form offshore, often associated with live-bottom.

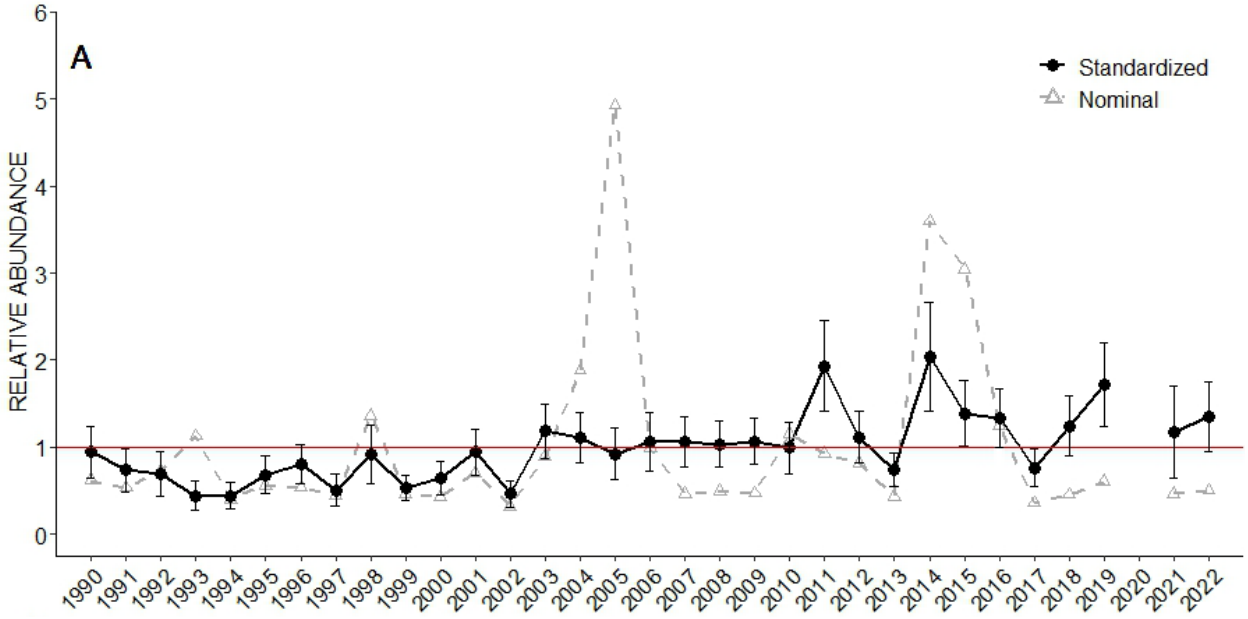

Figure 4: Annual relative abundance of weakfish as observed in the regional SEAMAP-SA coastal trawl survey. Nominal (gray line + triangles) and delta-GLM standardized (black line + circles) CPUE normalized to the time series mean (red line) are provided. Error bars represent the annual standard error estimate for the standardized index.

Weakfish have a protracted spawning season from spring through late summer. Males attract females with sounds produced by vibrating their swim bladder using adjacent musculature. Larval and juvenile weakfish make their way from nearshore spawning grounds to shallower, lower salinity nursery habitats inside of estuaries. Weakfish mature at approximately one-year old, the first spring/summer after they are spawned (Lowerre-Barbieri et al. 1996).

Diet of juvenile weakfish consists mostly of shrimp and anchovies and shifts in adults to larger fish including clupeids, sciaenids, carangids, and other locally abundant fishes that inhabit the mid-water column where weakfish tend to feed (Merriner 1975; Wilk 1979; Bowman et al. 2000).

CHALLENGES

Recreational harvests of weakfish have been in a precipitous decline along the entire Atlantic Coast. The South Carolina harvest typically makes up a very small proportion of the entire harvest and has declined at a slower rate than areas further north. As a

result, however, the South Carolina weakfish fishery now comprises a larger portion of the total Atlantic Coast harvest. As such, South Carolina now is one of the top three recreational harvesters of weakfish along the Atlantic coast (ASMFC 2024), suggesting the state is contributing to the continue moderate to high exploitation rates of the speices (Figure 1).

Since weakfish use waters off the coast of South Carolina as winter habitat, any dredging activity that adversely affects water quality or live bottom habitat where weakfish aggregate could negatively impact adults. Dredging activity that increases suspended sediment and reduces oxygen levels in shallow estuarine habitats could aso impact the survival of larval and juvenile stages.

South Carolina is also near the southern extent of the native weakfish range, suggesting the thermal conditions of South Carolina estuaries and coastal waters were historically near upper limits. As such climate change, whethe represented by increses in annual mean temperatures or, perhaps more likely, a higher frequency and intensity of marine heatwaves could have a negative impact on weakfish along our coast. Such an impact would affect weakfish natural mortality rates, either on certain sizes and ages or across all ages, which is already acknowledged as a primary factor restricting their range wide recovery. Further, even without changes to the thermal profile of our estuarine and marine waters, climate change may impact the phenology of events along coastal South Carolina, leading to poorer recruitment. Such impacts have already been observed for southern flounder (Erickson et al. 2021) and red drum (Goldberg et al. 2021) in our region.

CONSERVATION ACCOMPLISHMENTS

Regionally, weakfish are currently managed under Amendment 4 to the Interstate Fishery Management Plan and its subsequent addenda (Addendum I-IV), with the most recent addendum requiring states to implement a one fish recreational creel limit, 100 pound commercial trip limit, 100 pound commercial bycatch limit during closes seasons, and 100 undersized fish per trip allowance for the finfish trawl fishery (ASMFC 2024). The Addendum's measures are intended to reduce the level of harvest withou creating a large amount of discards and to poise the stock for recovery should natural mortality decrease in the future. The State of South Carolina lost its *de minimis* management status for weakfish in 2009 because its combined recreational and commercial catch exceeded 1% of the total Atlantic Coast catch. Therefore, the State is now subject to the ASMFC Weakfish Management Plan regulations of 1 fish per angler per day with a 12 inch total length limit (reduced from 10 fish per angler per day prior to 2010).

CONSERVATION RECOMMENDATIONS

The recent update assessment (ASMFC 2019) supported the research recommendations from the benchmark assessment, identifying seven high priority research avenues:

- Increase observer coverage to identify the magnitude of discards for all commercial gear types from both directed and non-directed fisheries.
- Evaluate predation of weakfish with a more advanced multispecies model.
- Develop a bioenergetics model that encompasses a broader range of ages than Hartman and Brandt (1995) and use it to evaluate diet and growth data.
- Analyze the spawner-recruit relationship and examine the effects of the relationship between adult stock size and environmental factors on year class strength.
- Develop a coastwide tagging program to identify stocks and determine migration, stock mixing, and characteristics of stocks in overwintering grounds. Determine the relationship between migratory aspects and the observed trend in weight at age.
- Monitor weakfish diets over a broad regional and spatial scale.
- Continue to investigate the geographical extent of weakfish hybridization.

Beyond these assessment recommendation, we identify these additional conservation priorities:

- Collect catch and effort data including size and age composition of the catch (harvested and released).
- Derive alternative estimates of discard mortality rates and the magnitude of discards; in particular, quantify trawl by-catch and refine estimates of mortality for below minimum size fish.
- Identify stocks and determine coastal movements and the extent of stock mixing, including characterization of stocks in over-wintering grounds.
- Develop latitudinal/seasonal/geo-specific age length keys for the Atlantic Coast. Increase sample sizes to consider gear specific keys.
- Compile data on larval and juvenile distribution from existing databases in order to obtain preliminary indications of spawning and nursery habitat location and extent.
- Conduct hydrophonic studies to delineate weakfish spawning habitat locations and environmental preferences (temperature, depth, substrate, etc.) and enable quantification of spawning habitat.
- Investigate the lethal and sub-lethal effects of marine heatwaves on weakfish, in particular focusing on impacts to recruitment.

MEASURE OF SUCCESS

Currently, SCDNR fishery-independent programs monitors the relative abundance, population demographics and reproductive status of estuarine and nearshore demersal species through a variety of long-term monitoring programs, including the estuarine and coastal trawl surveys. These programs can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, and population

demographics would indicate positive trends in the population. Furthermore, investigations of discard mortality, migration habits, identification of predators and competitors in South Carolina, and juvenile recruitment will greatly benefit the future success of the species.

White Grunt

Haemulon plumierii

Contributors:
Wiley Sinkus (SCDNR) & Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The White grunt, *Haemulon plumierii*, is a demersal marine reef fish belonging to the order Perciformes and family Haemulidae, commonly known as grunts (Page et al. 2023). They are found in temperate and tropical waters of the western Atlantic from Virginia to Brazil, including Bermuda, the Caribbean and the Gulf of Mexico (Böhlke and Chaplin 1993; FAO 2002). White grunt are characterized by a silver-gray body, with numerous blue and yellow horizontal stripes on the head and anterior portion of the body. The fins are typically brown-grey with the dorsal fin having 12 spines and 15 to 17 soft rays, and the anal fin having 3 spines and 8-9 soft rays. Its underbelly is white when out of the water or can take on a dark hue when underwater. White grunt have large mouths with bright orange lips, typical of the Haemulidae family. The lining of the body cavity, or peritoneum, is black (FAO 2002). White grunt have a maximum age of 27 in the South Atlantic, a maximum size of 20 inches, a maximum weight of 5.6 lbs., and on average reach sexual maturity by 2 – 3 years of age and at about 6 inches total length (SCDNR 2009; White et al. 2006). White grunt are a gonochoristic species, having separate males and females within the population.

Status

White grunt are managed in the snapper-grouper species complex by the South Atlantic Fisheries Management Council (SAFMC); however, no stock assessment has been performed on this species. While they may not be a commercially important species, only using 26% of the 2023 commercial annual catch limit (landings of all grunts: 58,707 pounds), they are a commonly caught hook and line recreational game fish (NOAA 2024). There is no minimum size limit for white grunt and recreational fisheries have a 10 fish bag limit that is part of the 20 fish aggregate limit for "All Other Snapper-Grouper Complex Species". According to the IUCN, White Grunt is a species of least concern throughout the range.

POPULATION SIZE AND DISTRIBUTION

White Grunt are encountered in chevron traps by the Southeastern Reef Fish Survey (SERFS) conducted jointly between NOAA and SCDNR from mid-April through mid-October surveying from Cape Hatteras, NC to Port St. Lucie, FL. White Grunt have a disjunct distribution off the Southeastern United States, as it typically occurs

infrequently off Georgia and northeast Florida (Potts and Manooch 2001). The genetic differentiation, along with regional growth studies, warrant the management of White Grunt as three separate stocks in the Atlantic Ocean bordering the continental USA: the Carolinas, southeast Florida and Florida Keys, and the eastern Gulf of Mexico, with at least one other separate stock in the Caribbean Sea (O'Donnell et al., 2019). In SERFS, the spatial distribution of White Grunt catch is centered mainly in the shallower waters off the northern portion of the region, with highest abundances off North Carolina in recent years (Vecchio et al. 2024; Figure 1).

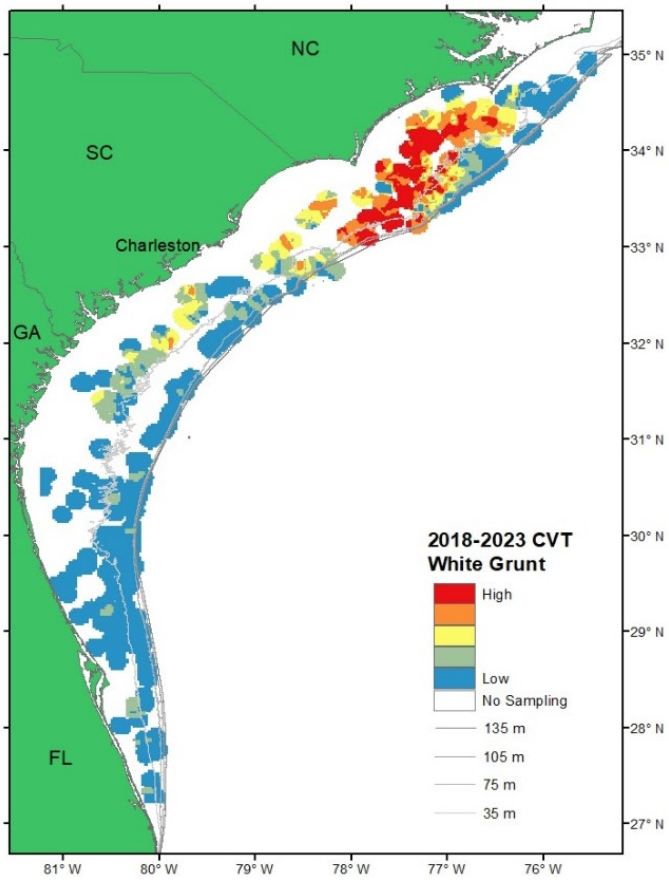

Figure 1: Distribution map of white grunt catch from chevron-video traps (CVT) from 2018-2023 (excluding 2020).

Relative abundance has fluctuated above and below the time series mean over the past two decades. In recent years both the nominal and the standardized index for white grunt decreased falling below the time series mean (Figure 2; Vecchio et al. 2024). The survey samples nearly the entire size range, however juvenile life stages are difficult to survey due to the traps mesh size not typically capturing fish below 150 mm TL. The sex ratio is significantly different from 1:1, favoring females (Padgett al. 1997). No sexual dimorphism occurs in body shape or color, however males attain larger sizes than females (Billings and Munro 1974). White grunt spawn from May to September with peak spawning occurring inshore of the shelf edge in 24.7–26.2°C waters during the waxing half-moon from May to June (Farmer et al., 2017).

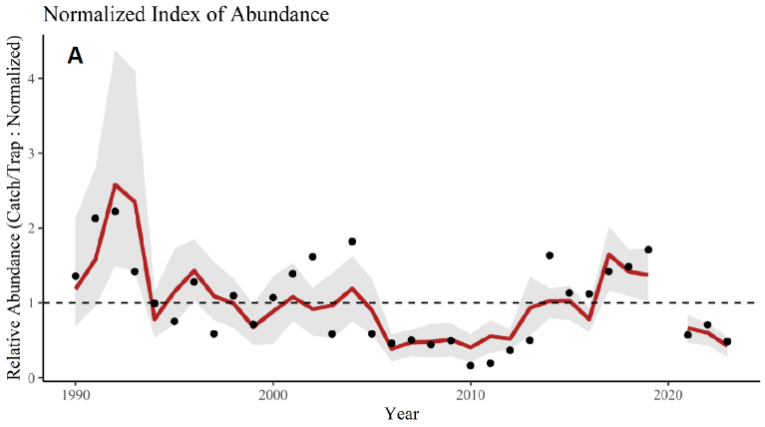

Figure 2: Chevron trap index of abundance and length compositions for white grunt. Chevron trap normalized nominal and ZINB standardized abundance with 95% Confidence Intervals.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

This species inhabits nearshore sponge-coral live-bottom habitats or offshore rocky outcrop habitats on the continental shelf along the southeastern coast of the United States and the Gulf of Mexico (Powles and Barans 1980; Darcy 1983) in depths ranging from 18-55 m (Huntsman 1976). They have a widespread diet that includes amphipods, bivalves, bony fishes, bryozoans, crabs, decapods, echinoderms, gastropods, isopods, ostracods, plants, shrimp, sponges, stomatopods, tunicates and worms (Babrowicz 2015).

CHALLENGES

While white grunt are not currently considered threatened, there are several challenges that could impact the population. White grunt are a target species for recreational and commercial fisheries in some regions, but currently has not been formally assessed. As harvest of other, more popular, reef fish species become increasingly restricted, white grunt may see increased fishing mortality. The mean annual South Atlantic recreational discards and landings data for White Grunt from 2014-2016 shows the private sector having a high discard ratio which could result in high discard mortality for this species (SAFMC 2019). High fishing mortality could lead to population declines if not managed sustainably. Degradation of coastal ecosystems, such as coral reefs and seagrass beds can reduce their food availability and suitable spawning grounds. Rising sea temperatures associated with climate change could negatively impact their populations by altering their distribution, growth rates, and reproduction.

CONSERVATION ACCOMPLISHMENTS

Snapper Grouper Regulatory Amendment 26 by SAMFC set the first bag limit for white grunt when it specified that no more than 10 fish of any one species can be retained in the 20-fish aggregate (SAMFC 2019). Outreach programs by SCDNR and SAMFC educate anglers, divers, and the public about responsible fishing practices and the importance of marine conservation. Fishers targeting white grunt and other reef fish are required to have a descending device on board and required to use non-stainless steel, non-offset circle hooks north of 28°N to reduce discard mortality due to barotrauma and excessive handling (SAFMC 2010; SAFMC 2020). White grunt must be landed with the heads and fins intact to facilitate enforcement of regulations. The establishment of artificial reefs and Marine Protected Areas may have benefited white grunt populations as they have increased suitable habitat and protected a section of the population against harvest.

CONSERVATION RECOMMENDATIONS

- Performing a formal stock assessment in the Southeastern US Atlantic waters would greatly benefit the species, allowing for a better understanding of the

stock status, fishing pressure, and best future direction for the sustainable management of this species.
- Continue to monitor populations via fishery-independent sampling programs such as SERFS.
- Initiate studies of the early life history, juvenile habitat preference, and spawning locations for White Grunt, including environmental drivers.

MEASURE OF SUCCESS

SERFS annually monitors relative abundance, population demographics, and reproductive status of reef fishes and can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, size- and/or age-compositions would indicate positive trends in the population.

White Mullet

Mugil curema

Contributors 2025:
Michelle Taliercio and Jimmy Kilfoil (SCDNR)

Photo courtesy of the Florida Museum

DESCRIPTION

Taxonomy and Basic Description

Bluish green or olive dorsally, flanks silvery and abdomen off-white; yellowish blotch between eye and upper edge of opercle (Harrison, I.J. 2008). Dorsal fins translucid with numerous, fine, black speckles on and between rays, second dorsal fin sometimes slightly darker than first. Caudal fin yellowish at base, with fine black speckles on and between rays and blackish distal margin. Anal and pelvic fins are paler than dorsal fins and may be yellowish. Pectoral fin speckled with fine black spots, but paler than dorsal fins. Dark spot dorsally at origin of pectoral fin. Maximum size is around 910 mm total length (TL) for western Central Atlantic specimens, eastern Central Atlantic specimens may reach 350 mm TL and commonly reach 250 mm TL.

Status

POPULATION SIZE AND DISTRIBUTION

White mullet is a widespread coastal pelagic fish with its distribution ranging from Massachusetts to southern Brazil. They can be found from the Western Atlantic from Nova Scotia, but uncommon north of Cape Cod (Harrison, 2008.) to Argentina. In the Eastern Atlantic, they can be found from the Senegal River outlet southward to Namibia, the Eastern Pacific, and in addition from the Gulf of California to Chile.

The white mullet possibly uses temperature or other signals associated with upwelling to synchronize its spawning with upwelling events. The variations in the timing of recruitment of white mullet in different geographical regions may be the result of variation in the timing of favorable conditions that enhance survival.

The most recent assessment by the International Union for Conservation of Nature (IUCN) conducted in 2019 found the white mullet to be of "Least Concern" status across their global range, with a population status of "unknown" (Castro et al. 2018).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

wis a widespread coastal pelagic fish, inhibiting sandy coasts and littoral pools but also occurs in muddy bottoms of brackish lagoons and estuaries. Sometimes penetrate rivers. May also be found on coral reefs. Juveniles are common in coastal waters and

are known to find their way to estuaries and coastal lagoons. Growth in juveniles is moderate (30-40 cm in 4 years). Adults form schools. Mullet feed on microscopic or filamentous algae and small juveniles of planktonic organisms. Reproduction occurs between March and August. It is considered a catadromous fish, with juvenile fish recruit to lagoons and estuaries following a period of spawning offshore. Spawn several million eggs provided with a notable yolk. Oviparous, eggs are pelagic and non-adhesive. An important foodfish, it is marketed fresh, smoked, and salted.

CHALLENGES

The periodicity of white mullet reproduction may be related to environmental variability that may signal periods of early growth and survival. Stability of the water column and suitable food in coastal lagoons, river deltas, and estuarine areas have been identified as important factors influencing the recruitment of juvenile Mugilidae (Yañez-Arancibia, 1976; Blaber and Blaber, 1980; Blaber, 1987; Vieira, 1991).

CONSERVATION ACCOMPLISHMENTS

White mullet have a very wide range and are important ecologically as food fish as well as recreationally to anglers as bait and food. South Carolina currently has no significant commercial mullet fishery, primarily due to gear restrictions and a lack of interest by commercial fishermen. Long term commercial catch statistics show a significant decrease in the commercial landings of mullet in South Carolina since 1982. White mullet are not considered at risk of significant population depletion by humans in South Carolina. If there ever were a concern regarding population size, regulations could be put in place to establish a recreational bag limit in a similar fashion to Florida's laws (FWC 2024).

CONSERVATION RECOMMENDATIONS

- Performing a formal stock assessment for white mullet in the Southeastern US coastal waters would allow for a better understanding of the stock status, fishing pressure, and the best future direction for the sustainable management of this species.
- Continue to monitor white mullet populations via fishery independent sampling programs such as our SCDNR trammeling, electrofishing, and trawl surveys.
- Initiate studies of the early life history, juvenile habitat preference, and spawning locations for white mullet.

MEASURE OF SUCCESS

Measurement of management success is difficult given the lack of population assessments for white mullet in SC. However, the SCDNR Inshore Fisheries group monitors relative abundance, length frequency, size and age at maturity of estuarine finfishes through monthly trammel netting, electrofishing, and longline surveys and can detect changes in those parameters that result from management efforts. Increases in recruitment, abundance, size, size and age at maturity would indicate positive trends in the population.

White Shark

Carcharodon carcharias

Contributors:
Claire Benson (SCDNR) & Bryan Frazier (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

White sharks are one of the largest sharks with a maximum size estimated at 600 cm total length (TL; Fergusson et al. 2009). Males mature at about 350-410 cm TL and females at about 450-500 cm TL (Castro 2011). Size at birth is between 109-165 cm TL (Fergusson et al. 2009). White sharks have viviparous, oophagous reproduction, meaning embryos hatch in uteri and are nourished through ingestion of unfertilized eggs until the female gives birth to a live pup (Sato et al., 2016).

The white shark is an apex predator preying on items including marine mammals and fishes, including other sharks and rays, and the occasional sea turtle. Few animals prey on white sharks. Killer whales (*Orcinus orca*) pose the main threat for an adult white shark. Larger shark species may also prey on juvenile white sharks.

White sharks are classically shaped with a triangular dorsal fin, pointed snout, lunate tail, and crescent shaped caudal fin. They are identifiable by a sudden color change on their flanks which transitions from greyish black on top to a pale, almost white, underside. They can often have a black spot on the underside of pectoral fins. This species appears to be intelligent and inquisitive and exhibits complex social behaviors (Compagno et al. 2005).

Status

White sharks are listed as globally vulnerable on the IUCN Red List. In 2002, the Convention on International Trade in Endangered Species (CITES) placed white sharks on its Appendix II list, which demands tighter regulations and requires permits to monitor trade in white shark products (Fergusson et al., 2009).

Stock status in U.S. waters is unknown and no stock assessments have been completed to date. White sharks are a prohibited species in U.S. waters and fisheries. They are occasionally caught by recreational and commercial fishermen but must be released immediately. In the Atlantic, the white shark is managed under the 2006 Consolidated Atlantic Highly Migratory Species (HMS) Fishery Management Plan. In the Pacific, it is managed by the Pacific Fishery Management Council under the West Coast HMS Fishery

Management Plan. There are complementary management measures protecting the white shark in state waters along both the east and west coasts. The white shark is further protected in some of NOAA's National Marine Sanctuaries.

POPULATION SIZE AND DISTRIBUTION

White sharks occur worldwide in temperate, subtropical and tropical waters, often migrating seasonally to follow their preferred temperature range (approximately 10-26° C). In the North Atlantic, they range from Nova Scotia down to the Gulf of Mexico and U.S. Caribbean. In the U.S. Pacific, they range from Alaska down to California and Hawaii.

Globally, white sharks range in the western Atlantic as far north as Newfoundland and as far south as Argentina. In the eastern Atlantic, they are found from France to South Africa, including the Mediterranean Sea. In the Indian Ocean they occur from the Red Sea, to South Africa, the Seychelles, Reunion and Mauritius. In the western Pacific, they range from Siberia to New Zealand and the Marshall Islands, and down to Panama and Chile in the Eastern Pacific. Young-of-the-year (YOY) and juvenile white sharks are thought to prefer shallow coastal waters (Weng et al., 2007) with waters off New York considered a nursery area (Curtis et al., 2018). Global population size estimates for this species are unknown. Regional estimates conducted to date have been considered unreliable.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

White sharks spend most of their time in the upper part of the water column in nearshore waters. However, they range from the surf line to the open ocean and from the surface to depths of over 1300 m (Compagno et al. 2005). White sharks commonly patrol small coastal archipelagos inhabited by pinnipeds, offshore reefs, banks and shoals, and rocky headlands where deepwater drop-offs come close to the shoreline. White sharks usually cruise in a purposeful manner, either just off the bottom or near the surface, but spend relatively little time at midwater depths

CHALLENGES

As with most sharks, white sharks are slow-growing, producing few young, and are therefore highly vulnerable to overfishing. Fortunately, the threat of habitat loss is not significant for white sharks. They are adaptable predators capable of shifting diet as conditions dictate and may simply move away from an area with little food.

The most significant challenge for effectively managing white shark populations stems from the lack of accurate data associated with fecundity, age, growth, and population numbers. Research indicates shark populations, including those of the white shark, will dwindle unless measures for their protection are implemented.

CONSERVATION ACCOMPLISHMENTS

No conservation accomplishments specific to this species are reported.

CONSERVATION RECOMMENDATIONS

- Determine stock size & status of white sharks in Atlantic waters
- Use techniques (e.g. Close-Kin Mark Recapture genomics techniques) to develop estimates of population size
- Determine usage of habitat from white sharks migrating near SC waters
- Generate life history information (age, growth and reproduction) using non-lethal techniques
- Determine driving forces of distribution & movements

MEASURE OF SUCCESS

An important measure moving forward would be to determine the stock status of the population residing in the western North Atlantic.

Wreckfish

Polyprion americanus

Contributors:
Julie Vecchio (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Wreckfish, *Polyprion americanus*, is a member of the order Acropomatiformes and family Polyprionidae (Page et al. 2023). The species can grow quite large with a maximum recorded total length (TL) of 210 cm and commonly recorded catches around 80 cm TL (Bauchot 1987). Adults are bluish-gray above and paler below with a silvery sheen. Fins are blackish-brown. Juveniles have black blotches on head and body (Heemstra 1986). The body is laterally compressed with a large head, large mouth, and a rough bony ridge across the upper operculum. The species is long-lived and late-maturing with aged fish up to 80 years and 50% maturity at 790 mm TL (Lytton et al. 2015, Wyanski & Meister 2002). The species is gonochoristic having separate males and females within the population (Wyanski & Meister 2002).

Status

The latest stock assessment for the U.S. South Atlantic region, completed in 2014, indicates the stock is not overfished nor is it undergoing overfishing (Rademeyer and Butterworth 2014). IUCN Red List status is data deficient. Because the species lives in relatively deep water and constrained habitats there exists a possibility of overexploitation, but data is limited so no world-wide determination can be made.

In 2022, the last year with commercial landings data available, 22,000 lbs of Wreckfish were reported as landed and sold in the U.S. South Atlantic region (NOAA Fisheries, 2024).

POPULATION SIZE AND DISTRIBUTION

Pelagic juveniles for this species are widely distributed throughout the north Atlantic Ocean, more commonly found in the eastern Atlantic Ocean. Adults are associated with high-relief hard-bottom environments in deep water. In the Atlantic Ocean off the Southeastern U.S., the Charleston Bump is a well-known habitat (Sedberry et al. 1999).

Repeated genetic analyses have indicated northern and southern hemisphere stocks are genetically distinct but that significant mixing occurs within hemispheres and ocean basins (Ball et al. 2000).

Wreckfish are not regularly encountered by any long-term survey efforts in the region. All life stages are difficult to survey due to their diverse ontogenetic habitat preferences as well as wide distribution with low density.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The species is known to spend their juvenile period in pelagic waters in the North Atlantic basin. Length of settlement to the benthos is 56-65 cm TL, occurring around 3-4 years of age (Michias et al. 2003). Post-settlement individuals are associated with the benthos and found in isolated areas of high relief in depths of at least 150 m (Sedberry et al. 1999).

CHALLENGES

Deepwater species are very difficult to monitor based on the logistical challenges associated with weather, gear, currents, and depth in capturing these individuals. The distinct habitat requirements of each major life-phase and the isolated nature of populations make the species especially challenging to monitor. In addition, slower growing, long-lived species are not as resilient to disturbances compared to others in their community. This leads to more opportunities for removal from the ecological system, whether natural or fisheries-related, before their first reproductive contribution to the fishery. This is exacerbated in deepwater species as they can be highly susceptible to post-release mortality (e.g. barotrauma).

CONSERVATION ACCOMPLISHMENTS

The commercial wreckfish fishery in the Southeastern U.S. is managed under an ITQ (Individual Transferable Quota) program for the region and is closed during the spawning season of January 15 to April 15 each year. The recreational fishery is allocated a small proportion (5%) of catch and is currently open during June and July with a 1 fish per vessel bag limit (SAFMC, 2024).

Despite challenges, the Wreckfish fishery off the Southeastern U.S. has been developed in a relatively responsible and conservation-minded way. The ITQ program has kept the commercial fishery relatively contained and modernization efforts have kept the monitoring of the species up-to-date. Due to distance from shore, the recreational fishery is also quite limited. Seafood Watch rates the fishery as sustainable within the region.

CONSERVATION RECOMMENDATIONS

- Increase fishery independent information to develop reliable indices of abundance

- Partner with commercial fishers for updated life history information, genetic analyses, and reproductive parameter assessments
- Complete research studies of pelagic juvenile movements, settlement requirements, and other factors associated with habitat needs

MEASURE OF SUCCESS

Because there is currently no fishery-independent measure of population size or trends, fishery catch is the only available measure of success. In recent years landings have fluctuated. Total landings have been considered confidential in seven of the past ten years due to the small size of the fleet. If a fishery-independent or hybrid fishery-independent/fishery-dependent survey can be initiated, a stock level will be able to be estimated, with a measure of success being a stable population and size distribution through time.

American Horseshoe Crab

Limulus polyphemus

Contributors: Elizabeth Wenner (SCDNR, (2005); Larry Delancey and Peter Kingsley-Smith (SCDNR, 2013); Daniel Sasson and Peter Kingsley-Smith (SCDNR, 2023)

DESCRIPTION

Taxonomy and Basic Description

Despite their name, horseshoe crabs are not true crabs. Horseshoe crabs are more closely related to spiders and scorpions than they are to other crabs; in fact, recent molecular analyses now place horseshoe crabs within the arachnid lineage (Ballesteros *et al.,* 2022). Unlike true crabs, horseshoe crabs lack antennae and jaws and have 6 pairs of appendages, including a pair of chelicerae. Chelicerae are appendages similar to those used by spiders and scorpions for grasping and crushing. Their carapace is divided into three sections: the anterior portion is the prosoma; the middle section is the opithosoma; and the "tail" is called the telson. Horseshoe crabs have two pairs of eyes located on the prosoma, one anterior set of simple eyes, and one set of lateral compound eyes similar to those of insects. In addition, they possess a series of photoreceptors on the opithosoma and telson (Shuster, 1982). Horseshoe crabs are the only living group that have book gills, which are related to the book lungs found in many arachnids. The American horseshoe crab, *Limulus polyphemus*, is the only member of the Arthropoda subclass Xiphosura found in the Atlantic Ocean.

Status

The American horseshoe crab, *Limulus polyphemus,* is not currently listed as threatened or endangered (although on December 21, 2023, NOAA's National Marine Fisheries Service received a petition from the Friends of Animals to list *Limulus polyphemus* as threatened or endangered under the Endangered Species Act of 1973). The status of the American horseshoe crab differs across populations. For instance, while population health is considered "good" in the southeastern United States, populations in the New York region are declining (ASMFC, 2019). Continued assessments of horseshoe crab populations are crucial as American horseshoe crabs are an important species, both commercially and ecologically. Ecologically, horseshoe crabs are an important component of coastal food webs and have been shown to be a controlling factor in benthic communities through their feeding activities.

POPULATION SIZE AND DISTRIBUTION

The range of the American horseshoe crab (hereafter simply horseshoe crabs for the purposes of this account) extends from northern Maine to the Yucatan Peninsula, but this species is particularly abundant in Delaware Bay, the center of its distribution, and in coastal areas between Virginia and New Jersey. Horseshoe crabs are thought to inhabit every major estuary along the Atlantic Coast. Across this range are multiple genetically distinct populations (King *et al.,* 2015).

In South Carolina, horseshoe crabs can be found in shallow estuarine areas and offshore habitats near the continental shelf and are relatively common in trawls in South Carolina. Trawl collections can be used to obtain a measure of relative abundance, although there is no current estimate of population size. Research has indicated that the horseshoe crab population in South Carolina is genetically diverse with little evidence of inbreeding (Cushman *et al.,* 2019).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Horseshoe crabs are long-lived, benthic animals. Like other arthropods, horseshoe crabs must molt in order to grow. As the horseshoe crab ages, more and more time passes between molts, with 16 to 19 molts occurring before a horseshoe crab becomes mature, stops growing, and switches energy expenditure to reproduction (Shuster & Sekiguchi, 2003). They obtain sexual maturity between 9 to 12 years of age and may live for another 10 years or more as adults, although there is no way to directly measure the age of a horseshoe crab.

Adult horseshoe crabs feed on a variety of bottom-dwelling organisms including marine worms, shellfish, and decaying animal matter. The larvae and juvenile stages are preyed upon by many species of fish and birds, while adult horseshoe crabs are known to be an important food item for the threatened loggerhead sea turtle, *Caretta caretta* (Keinath *et al.,* 1987). Horseshoe crab eggs are also the primary source of fat for at least 20 species of migratory shore birds (Harrington, 2001). There has been great concern about how the harvest of horseshoe crabs in the mid-Atlantic affects the red knot, *Calidris canutus*, an imperiled species of migratory shorebird (Piersma & Barker, 2000).

Early each spring in SC, as estuarine water temperature approaches 16°C (60.8°F), adult horseshoe crabs move inshore to seek suitable spawning habitat. Throughout the spring, females with males attached to their carapace follow flooding tides high onto the beaches and marshes where they excavate nests and deposit thousands of eggs. In South Carolina, mating and nesting activities coincide with high tides; spawning activity is especially abundant during night-time spring tides. During mating, the male grasps the carapace of the female and fertilizes her eggs externally as she deposits them in the nest cavity. Oftentimes, other unattached “satellite” males may also fertilize some of these eggs. Nests are excavated by the female and eggs are laid in clusters. Females nest several times per season, usually returning to deposit more eggs on subsequent high tides. After approximately 2 – 4 weeks, depending on temperature, moisture, and oxygen levels, larval horseshoe crabs emerge from the nest. Larval horseshoe crabs are semi-planktonic for about 3 weeks before their transition to a benthic existence. They then settle to the bottom and assume a benthic existence, typically spending their first 2 years in intertidal sand flat habitats near beaches where they were spawned. Adults return to deeper estuary bays and continental shelf waters after the breeding season (Thompson, 1999).

While beaches were often considered the primary spawning habitat for horseshoe crabs, recent work has found that horseshoe crabs also spawn with regularity in salt marshes (Kendrick *et al.,* 2021, Sasson *et al.,* in press); however, more work needs to be done to understand the extent and the ecological impacts of marsh spawning in South Carolina and other regions.

CHALLENGES

Horseshoe crabs are harvested for a number of uses. They are the primary bait used in the whelk and eel fisheries along the Atlantic coast (ASMFC, 1998). The ASMFC places yearly state harvest quotas on the collection of horseshoe crab for bait (ASMFC 2019) and, since 2013, those quotas have allowed for the harvesting of only males for Delaware Bay-origin horseshoe crabs (ASMFC 2012). Horseshoe crabs are also harvested for use in biomedicine. A clotting agent in horseshoe crab blood (or hemolymph), known as *Limulus* Amoebocyte Lysate (LAL), is used to detect microbial toxins in medical intravenous fluids, injectable drugs, and supplies (Rudloe, 1983). Biomedical companies purchase adult horseshoe crabs which are harvested by hand from spawning areas in SC or by trawlers in some other regions. The crabs are transported to the LAL production facility, bled, and then transported back to the general harvest vicinity and released alive. LAL is currently used as the standard (FDA required) test for microbial contamination in injectable pharmaceutical products in the United States (Walls & Berkson, 2000), although a synthetic version of LAL has been developed (Maloney *et al.,* 2018). Horseshoe crabs have also been used in eye research and the development of wound dressings and surgical sutures. [Note: The horseshoe crab is also discussed in the Intertidal Marine Invertebrates Guild.]

Resource managers are concerned that the health of horseshoe crab populations along the northeastern coast of the United States is impacted by overharvesting (Widener & Barlow, 1999; ASMFC, 2001). Fishery regulations are set by individual states and the Atlantic States Marine Fishery Commission (ASMFC) fishery management plan for the Atlantic Coast (ASMFC, 1998). In South Carolina, the harvest of horseshoe crabs is limited to the LAL industry, and a permit has been required since 1991. The ASMFC estimates that 15% of horseshoe crabs harvested for LAL production do not survive (ASMFC 2019). Dredging practices may also result in horseshoe crab mortality, but the impacts of dredging on horseshoe crabs have not been well studied (ASMFC, 2019). The main challenge to conservation in South Carolina is providing high quality habitat for juvenile and spawning horseshoe crabs.

COMMENTS ON ASIAN HORSESHOE CRAB IMPORTATION

In 2013, prompted by recent importations of Asian horseshoe crab as bait in northern states (*e.g.,* New York), the ASMFC passed a resolution intended to curtail this practice. Several concerns were listed, including the potential introduction of parasites and diseases into the native *Limulus* populations, potential toxic effects from one species if ingested, and threats to the populations in Asia which are thought to be in serious decline. In addition, South Carolina prohibits the importation of the giant Asian horseshoe crab, *Tachypleus gigas*, the Asian horseshoe crab *Tachypleus tridentatus*, and the mangrove horsehoe crab, *Carcinoscorpius rotundicata*, along with other marine and estuarine species not already found in the wild or native to South Carolina. (For more information, see South Carolina Codes of Laws Sections 50-5-45 and 50-16-20).

CONSERVATION ACCOMPLISHMENTS

A fishery management plan is now in place for horseshoe crabs through the ASMFC. States must comply with the goals of the plan and provide updates on their horseshoe crab status. In states that allow the harvest of horseshoe crabs for bait, restrictions have lowered the allowable harvest

from the high levels seen in the late 1990s. Crabs in the ACE Basin were once harvested for bait in small numbers; however, South Carolina prohibited this activity in 1991. Increased funding has led to the establishment of a long-term trawl survey (*e.g.,* the Virginia Tech Trawl Survey conducted in the Delaware bay) and standardized methodology for spawning and egg surveys. Basic research has increased in recent years, and public awareness has been heightened to support conservation measures.

CONSERVATION RECOMMENDATIONS

- Determine the long-term trends in horseshoe crab spawning stocks and investigate how these trends relate to environmental and other factors such as harvesting and LAL bleeding practices.
- Determine the relative importance of marsh spawning vs beach spawning in population recruitment.
- Determine the nutritional importance of horseshoe crab eggs and larvae for shorebirds and how this is influenced by habitat change.
- Quantify the impacts of dredging on horseshoe crabs
- Avoid beach renourishment activities during the horseshoe crab spawning season due to the importance of low energy beachfront as spawning and juvenile nursery habitat for horseshoe crabs.

MEASURES OF SUCCESS

Success will be reflected as stable population trends for horseshoe crabs in South Carolina.

Atlantic Brief Squid

Lolliguncula brevis Blainville 1823

Contributors: David Whitaker (SCDNR, 2005, retired) & Peter Kingsley-Smith (2013 & 2023, SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The brief squid, *Lolliguncula brevis* (Cephalopoda, Myopsida, Loliginidae) was first identified by Blainville (1823) from specimens collected in Brazil. This squid is relatively small, rarely exceeding 120 mm in mantle length. Having rounded fins, the body is less streamlined than most oceanic squids, such as the northern shortfin squid, *Illex illecebrosus*. Within the order Myopsida, the family Loliginidae contains over 40 species of squid that vary widely in their distribution (Jereb & Roper, 2010). Loliginid squid inhabit all shallow continental shelf habitats of the world, with the exception of the polar ocean regions (Jereb & Roper, 2010), and contribute significantly to coastal fisheries (Arkhipkin *et al.,* 2015). Loliginid squid lay large clutches of eggs that yield high numbers of paralarvae, facilitating life history studies that can begin with early life stages (*e.g.,* Jackson, 2004; Guarneros-Narváez *et al*., 2022). The sexes are separate in this species, with males and females in South Carolina reported to reach reproductive maturity at mantle lengths of 50.2 mm and 59.2 mm, respectively (Good *et al*., 2023). Through the utilization of statolith-based age assessments, Jackson *et al.* (1997) showed that brief squid in the northern Gulf of Mexico have an estimated life span of between 100 and 200 days, whereas Good (2022) deduced that this species collected in South Carolina reached 128.7 ± 3.38 days.

Status

As a common component of the nearshore and estuarine nektonic community of South Carolina, this species represents a considerable portion of the estuarine biomass and therefore likely occupies a critical role in the estuarine food web. That being said, there are no long-term fisheries independent surveys for this species that document trends in abundance and the species has not been the target of any rigorous assessments to determine its status in relation to fisheries pressure or conservation efforts.

POPULATION SIZE AND DISTRIBUTION

Brief squid inhabit protected shallow water habitats along the continental shelf of the Atlantic Ocean from Argentina to the Bay of Fundy (Voss, 1956; Jereb & Roper, 2010) and are common throughout the coastal waters of South Carolina, with all age classes, from small juveniles to adults, having been collected in trawl samples throughout the coastal zone. The presence of both small and large brief squid throughout the year in stations spanning a broad salinity range supports a pattern of overlapping cohorts, whereas the continual presence of immature brief squid suggests asynchronous recruitment dynamics (Good *et al*., 2023).

While precise information on spawning locations is lacking, egg strings have been found in trawl samples taken in Charleston Harbor (Whitaker, pers. obs.). Cephalopods typically attach egg strings to solid objects such as oyster shells, clam shells, or other bare, solid objects. Brief squid egg strings have been observed on shallow mud flats in South Carolina, presumably attached to molluscan shells (M. Maddox, SCDNR, pers. comm., 18 March 1980). Given the planktonic development of paralarvae in this species, it is assumed that there is a single population distributed along the South Carolina coast; however, this has not been specifically investigated and field observations suggest that there may be different temporal patterns of reproduction among estuaries along the coast (Kingsley-Smith, pers. observation).

In the study by Good *et al.* (2023), season and sampling station were significantly related to brief squid abundance, which was greater for all sexes (*i.e.*, indistinct individuals, males, and females) in spring, summer, and fall than in winter, and generally greater at higher salinity stations than more upstream, lower salinity stations. In this same study, excluding sexually indistinct squid, and across all seasons, significantly more male squid were collected than female squid. In addition, mean brief squid size tended to be larger in May than in several other months of the year, largely due to the lower abundance of small squid in that month. Furthermore, catches were numerically dominated by immature squid compared to mature squid and both temperature and salinity were significant predictors of the occurrence of brief squid.

Although the brief squid is relatively common in trawl and seine samples collected in South Carolina, there is no estimate of population size or trend. Additionally, the factors that may negatively affect brief squid populations and the principle aspects of its life history are still largely unknown.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The brief squid is one of the few cephalopod species that is able to osmoconform to salinities ranging from 17.0 ppt to 35.5 ppt (Hendrix *et al.,* 1981; Laughlin & Livingston, 1982; Mangum 1991, Bartol *et al*., 2002). The study by Laughlin & Livingston (1982) demonstrated that brief squid can even tolerate salinities as low as 8.5 ppt. This physiological adaptation allows brief squid to occupy an extended habitat range from marine environment to fluvial, tidal creeks (Voss, 1956), including estuaries that present abiotic stressors, such as rapid changes in salinity, temperature, nutrient flow, and dissolved oxygen (Islam *et al*., 2005). For example, brief squid tolerate waters with low dissolved oxygen by increasing their rates of oxygen uptake, and their paralarvae tolerate hypoxic waters of < 2 mg O_2 L^{-1} (Wells *et al.*, 1988; Vecchione, 1991).

No specific critical habitats have been established for the brief squid. Vecchione (1991) found catch rates of brief squid paralarvae (a planktonic form that is anatomically identical to the adult) to be higher in bottom samples compared to samples taken in the upper portion of the water column. Ogburn-Mathews & Allen (1993) found brief squid to be more abundant over mud bottoms versus sand bottoms within inlets. Bartol *et al.* (2002) noted that in Chesapeake Bay, brief squid were more common in central channels, at depths of 10 m to 15 m (33 to 49 ft.), than in deeper waters.

The Atlantic brief squid plays an important role in the food webs of estuarine ecosystems, such as North Inlet, SC where it can comprise up to 5.5% of the faunal biomass (Ogburn-Matthews & Allen, 1993). Furthermore, brief squid are important prey for many recreationally- and commercially-important species, such as the black sea bass (*Centropristis striata*, Sedberry 1988). In addition, the diets of endangered shark species that use estuaries as juvenile nurseries, specifically the scalloped hammerhead (*Sphyrna lewini*) and the Carolina hammerhead (*Sphyrna gilberti*), can comprise up to 16.6% brief squid (Bornatowski *et al.,* 2014). Brief squid are also the most abundant prey items in the guts of lactating female bottlenose dolphins, *Tursiops truncatus*, a species of high conservation concern (Pate & McFee, 2012). In turn, based on experimental trials, brief squid prey upon white shrimp (*P. setiferus,* Hanlon *et al.,* 1983), a commercially important species that supports an approximately $7M fishery annually in South Carolina (Liddel *et al*., 2017).

CHALLENGES

Shrimp trawlers occasionally catch brief squid (D. Whitaker, pers. obs.); however, they are not likely captured by this fishery in quantities that would be likely to threaten the sustainability of the species. The vast majority of squid utilized as bait and food in South Carolina are of the genus *Loligo* that are imported from California due to their larger size and preferred texture. Reported commercial landings of *L. brevis* in South Carolina average < 454 kg (< 1,000 lbs.) annually, most if not all of which is derived from by-catch from the shrimp trawl fishery. Brief squid have been part of the shrimp fishery bycatch for over 50 years and there appear to be no negative impacts upon the population due to trawling; however, population trends are not specifically monitored.

Brief squid probably rely on relatively clean water and appear to be linked to mud bottom habitats that are common in South Carolina. Hard structures for attachment of egg strings are important for the species, and oyster and clam shell are abundant on estuarine bottoms. Substantial alteration to intertidal and subtidal mud flats, particularly resulting in siltation covering shell and hard structure, could reduce optimal substrate for egg string attachment.

Reductions or alterations in river flow rates through out-of-basin transfers or diversions may negatively impact brief squid. Presuming brief squid are estuarine-dependent, adequate quantities of fresh water flowing into estuaries may be necessary to maintain viable populations, although the species is common in North Inlet, which is a small system with very little freshwater inflow. Pollutants associated with terrestrial runoff are likely to be problematic for brief squid populations.

CONSERVATION ACCOMPLISHMENTS

In the 1950s, South Carolina closed most of its estuarine waters to shrimp trawling. Additionally, the State's sounds and bays, which were periodically opened on a limited basis, were permanently closed to trawling in 1986. Shrimp trawling is known to produce bycatch of brief squid such that these closures may have contributed to some level of conservation of stocks. The State has also prohibited the use of small mesh gill nets and "stop nets" (nylon mesh nets used to

entrap fish) in most estuarine waters. It is presumed that these gear types could have contributed to the mortality of brief squid when they were in use.

CONSERVATION RECOMMENDATIONS

- Explore estuary-scale and regional geographic differences in life history patterns and apply genetic and molecular tools to investigate population structure (see Zaleski *et al*. (2012) and Sales *et al*. (2014) for discussion of cryptic sister species of brief squid).
- Examine long-term trends in brief squid population size, as well as the influence of natural environmental and anthropogenic factors, including physical factors such as depth and tidal currents (see Pinckney & Dustan 2006) on temporal and spatial patterns of life history.
- Improve our understanding of predator/prey relationships through the application of gut content analyses and diet studies, including the application of stable isotope analyses.
- Determine spawning locations, overwintering habitats, and recruitment mechanisms.
- Improve our understanding of recruitment dynamics in brief squid through statolith-based assessments.
- Conduct tag-recapture studies to determine the degrees to which migration and local environmental conditions influence these spatial patterns in brief squid size.
- Determine effects of pollutants on distribution, reproduction, growth, maturation, and longevity of brief squid.
- Examine regional water use plans to assure that adequate quantities of water are provided to coastal estuaries during the appropriate seasons.
- Work with municipalities and counties to include Best Management Practices (BMPs) in development plans throughout the Coastal Zone. Such plans should include installation of retention ponds, modified septic systems, and stream bank protection measures. Poorly designed, existing storm water systems should be retrofitted to updated designs.

MEASURES OF SUCCESS

Once threats and conservation actions are better identified by addressing the above-mentioned survey and research needs, a management plan for brief squid could be developed. This plan would represent a measure of success for this species. Furthermore, improved water quality will benefit many sensitive marine and estuarine species.

Atlantic Ghost Crab
Ocypode quadrata

DESCRIPTION

Taxonomy and Basic Description

In 1787, J.C. Fabricius formally described the Atlantic ghost crab from specimens collected in Jamaica, originally calling it *Cancer quadrata*. Following Linnaeus' development of the modern scientific method of naming organisms, the name '*Cancer*' was commonly applied to a variety of crustacean taxa, not just crabs, by taxonomists and carcinologists. *Ocypode quadrata*, also known for some time as *O. albicans* or the "fleet-footed one of white," was characterized by Phillips (1940) as "an occult, secretive alien from the ancient depths of the sea." Since the time he wrote that romanticized description, much has been learned about this conspicuous inhabitant of the ocean beach community.

A true crab, or brachyuran, the ghost crab belongs to the family Ocypodidae, which also includes the fiddler crabs. Worldwide, there are approximately 20 species of ghost crabs, but *O. quadrata* is the only one found on the East Coast of the United States. The species is a small, straw-colored or grayish-white crab, measuring about 5 cm across the carapace at maturity. *Ocypode quadrata* has the greatest terrestrial adaptation of any crab in South Carolina, returning only occasionally to the water to wet its gills. It can also moisten its gills by extracting water from damp sand, using fine hairs near the base of its walking legs to wick ground water up onto the gills through capillary action (Ruppert & Fox, 1988). Despite this semi-terrestrial existence, the ghost crab's link to the sea is a critical one that provides not only moisture for its gills, but also the necessary means for development of larvae that are hatched from eggs that the females release at the water's edge.

Status

The ghost crab is not presently included in federal lists of threatened or endangered species, and there is no present-day human exploitation of this species. Having few terrestrial predators or competitors, a flexible feeding behavior, and the ability to endure starvation for long periods, *Ocypode quadrata* is an ideal top carnivore in a simple, filter feeding-based food chain of the dune and fore-beach ecotone (Wolcott, 1978). As such, it may prove to be a useful indicator of the health of that environment.

POPULATION SIZE AND DISTRIBUTION

Williams (1984) reported a range for *Ocypode quadrata* that extends from Block Island, Rhode Island to Santa Catarina, Brazil, including the Gulf of Mexico, the Caribbean, and Fernando de Noronha, 322 km (200 mi.) off the Brazilian mainland. It is also found in Bermuda, and populations are known to exist as far north as Martha's Vineyard, Massachusetts (Luanne

Johnson, Edgartown, MA, pers. comm.). Although rarely seen in the winter, during the rest of the year *O. quadrata* is common or abundant on outer beaches and on more protected harbor beaches near coastal inlets along the coast of South Carolina (Fox & Ruppert, 1985). Rarely has the species been the target of quantitative study in South Carolina, and despite its abundance, nothing is known of trends in its population status here. Quantitative measures of the population size in South Carolina are non-existent, although estimates based on burrow counts or nocturnal transect counts could provide a good measure of abundance (Wolcott, 1978). Such efforts have not been undertaken across a wide geographic area within the State.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The ecology of ghost crabs was recently reviewed by Lucrezi & Schlacher (2014). While they have long been considered beach scavengers, a careful study of ghost crab behavior showed that on oceanfront beaches they are more likely to subsist on a diet of the common filter-feeding inhabitants of the swash zone, like the coquina clam, *Donax variabilis,* and the Atlantic sand crab, *Emerita talpoida* (Wolcott, 1978). There is evidence, however, that they may be effective scavengers of organic matter; on more protected beaches, their prey is believed to include eggs and nestlings of the loggerhead turtle, *Caretta caretta* (Dodd, 1988).

Ghost crabs are largely nocturnal in nature and it is rare to catch a glimpse of them during daylight hours. Most feeding activity occurs at night, which reduces predation by visual predators like shorebirds and gulls that might otherwise be capable of exerting considerable pressure on populations of this species. In the event that they do leave their burrows during daylight, their ability to change color to match the sand where they live lessens their chances of being seen on such a foray.

The burrows dug by ghost crabs may be up to 1.3 m deep (4 ft.). Their habits of periodically closing the burrow opening with sand during the hottest part of the day and of remaining within the burrow through the colder months provide sufficient protection from the climatic extremes that fully aquatic species rarely encounter. These burrows, which take different shapes beneath the sand, are found from near the high tide line to a distance as great as 400 m (0.25 mi.) from the ocean. A distributional gradient based on crab age is typical for this species, with younger crabs generally burrowing closer to the shore than older individuals (Williams, 1984).

CHALLENGES

Berry (1976) reported that because of their burrowing and scavenging habits, ghost crabs might be adversely affected by increased oil tanker traffic and the resultant increase in the amount of stranded oil on ocean beaches. Contact with the oil, although it appears not to be acutely toxic to the crabs, may cause a reduction in the breeding rate and increased mortality at molting.

The decline in undeveloped beachfront habitat may represent the greatest threat to the ghost crab. In South Carolina, coastal regions claim a significant portion of the State's tourism. For example, in 1996 these coastal areas accounted for 56% of the State's visitors (SCDNR and NOAA 2000). Spending time at the beach is a highly popular activity among tourists during their visit to the coast. Alterations to the upper intertidal zone caused by residential or commercial development of coastal areas and other beach construction may eliminate *Ocypode* from its natural habitat,

either by direct mortality or by displacement to less optimal habitat. Such development, undertaken to accommodate increased recreational uses of the beaches, has been cited as the cause of the elimination of the ghost crab *O. stimpsoni* from the coastal Chinese region of Rizhao (Gao & Xu, 2002).

In North Carolina, Peterson *et al.* (2000) found significant deleterious effects on ghost crab populations resulting from beach nourishment and bulldozing activities on eroding beaches. Although these short-term responses to erosion are considered to be preferable to "hardening" the shoreline by constructing of seawalls and groins, Peterson *et al.* (2000) demonstrated a clear impact, not only on ghost crabs but also on the abundance of their principal prey items. These erosion control measures are readily permitted and widely practiced on barrier islands in southeastern U.S. states (Leonard *et al.,* 1990; Peterson *et al.,* 2000); for that reason, erosion control measures present a potential but undefined threat to the well-being of ghost crab populations in South Carolina.

Even well-meaning conservation efforts targeting other species may present a threat to ghost crabs. Previous turtle protection efforts, for example, have included measures to destroy ghost crabs when its burrows were found in close proximity to loggerhead turtle nests (*Caretta caretta*), based upon widespread reports of predation. The true impact of such predation on the loggerhead population, however, has not been adequately assessed; there is recent evidence that this level of predation is insignificant (Thompson, 1995; Von Harten *et al.,* 2002).

CONSERVATION ACCOMPLISHMENTS

Mathews *et al.* (1980) previously recognized the importance of protecting the beach/dune ecosystem in South Carolina. Five of the top 14 areas in South Carolina identified by the U.S. Fish and Wildlife Service as needing preservation measures included barrier islands with pristine dune habitat.

Although not directed specifically at the conservation of ghost crabs, a 2004 judicial ruling will keep 30 ha (75 ac.) of oceanfront property in Georgetown County uninhabited, which will ensure the preservation of that critical habitat for the Atlantic ghost crab. The ruling serves to maintain the suitability of this pristine acreage as prime habitat for sea turtles and numerous species of shorebirds, as well as ghost crabs.

Acquisition and conservation easements on undeveloped uplands and coastal islands in the ACE Basin drainage area have previously resulted in the protection of roughly 56,656 to 64,750 ha (140,000 to 160,000 ac.) though conservation measures on public and private land (Mike McKenzie, ACE Basin Committee Chairman, pers. comm., 2004). The ACE Basin National Estuarine Research Reserve includes four barrier islands, assuring protection of significant ghost crab habitat on Otter, Pine, Edisto and Morgan Islands. Some additional protection is afforded by state ownership of 4 oceanfront parks (Hunting Island, Edisto Beach, Huntington Beach, and Myrtle Beach) that include substantial amounts of suitable ghost crab habitat, although beach maintenance efforts at some of them may have the negative impacts noted above.

Although numerous beach nourishment studies conducted in the past failed to include an assessment of impacts on ghost crabs, this oversight has recently been recognized; measures are

underway to include such evaluations at several sites in South Carolina in the near future (Pam Jutte, SCDNR, pers. comm., 2005). Peterson *et al.* (2000) recently conducted such a study of nourished and bulldozed beaches in North Carolina.

CONSERVATION RECOMMENDATIONS

- Assess impacts of beach nourishment projects on Atlantic ghost crab populations in South Carolina.
- Investigate the impact, if any, that ghost crab predation may have on loggerhead turtle populations.
- Establish estimates of population size and determine trends for ghost crabs in South Carolina by widespread and long-term monitoring of ghost crab abundance, incorporating both unaltered and developed areas along the entire coastline.
- Work with municipalities and private landowners to schedule beach renourishment activity so that it is completed prior to the warm season, when *Donax variabilis* and *Emerita talpoida* (two primary food sources for ghost crabs) return in large numbers to intertidal beaches.
- To mitigate impacts to ghost crabs associated with beach bulldozing practices, encourage municipalities and private landowners to implement dune stabilizing techniques such as planting grasses.
- Develop either a state or federal management plan for the Atlantic ghost crab.
- Continue SCDNR participation in Emergency Response training programs to ensure that the Department has the most current information on planning logistics and technology for dealing with coastal oil and hazardous material releases, as well as the most effective design of aftermath shoreline assessments.

MEASURES OF SUCCESS

If the burrow-counting census methods of Wolcott (1978) were used in conjunction with other periodic beach monitoring efforts (*e.g.* horseshoe crab surveys), a cost-effective program of data collection could be undertaken that would initially provide a baseline assessment of the ghost crab population size. Ultimately, this could be used to follow population trends, provide data necessary for determining what conservation measures, if any, are needed, and enable managers to make informed decisions on how useful this species might be as an indicator of the overall "health" of the dune and fore-beach ecotone. The measurement of success will be stable population trends for the Atlantic ghost crab and increased conservation of front beach habitat in South Carolina.

Atlantic Mud Crab

Panopeus herbstii (H. Milne Edwards, 1834)

Contributors: Amy E. Fowler (2013) and Peter Kingsley-Smith (2013, 2023)

DESCRIPTION

Taxonomy and Basic Description

The Atlantic mud crab or black-fingered mud crab, *Panopeus herbstii* (H. Milne Edwards, 1834), belongs to the super family Xanthidae (family Panopeidae) and is the largest of mud crab species, with the exception of the stone crab, *Menippe mercenaria* (Ruppert & Fox, 1988). *Panopeus herbstii* is a true crab, growing to a maximum carapace width of 6.4 cm (Ruppert & Fox, 1988) and is distinguished from other mud crab species by its robust black or dark brown fingers (top and bottom portion of the claw) that fade into a pale white along the interior portion of the base of the claw. The outsides of the claws are often mottled. The claws themselves are dissimilar in size, with the larger one having a curved upper finger and an enlarged white tooth at the base and the smaller one exhibiting a nearly straight lower finger (Williams, 1984). The brownish green, slightly granular carapace of *P. herbstii* is approximately ⅔ as long as it is wide and has five teeth on the anterolateral margins of which the first two are mostly fused (Williams, 1984). Ryan (1956) found a red spot to be present on the third maxilliped (feeding appendage) of males and some females (Williams, 1984).

Status

Panopeus herbstii is currently not included on any Federal lists of threatened or endangered species and there is no human exploitation of this species. As the dominant mud crab species in salt marshes along the Mid-Atlantic coast of the United States (Daiber, 1982; Williams, 1984), however, *P. herbstii* plays a key role in the food web structure of this ecosystem on a regional scale (Silliman *et al*., 2004) and may be a potential indicator of the heath of that particular ecosystem.

POPULATION SIZE AND DISTRIBUTION

Panopeus herbstii inhabits oyster reefs, mangrove swamps, and salt marshes along the Atlantic Coast of North America, from Massachusetts to Brazil and on Bermuda (Williams, 1984). While the maximum age of *P. herbstii* is unknown, it is thought to vary between populations along the latitudinal gradient and to be driven by differences in temperature and food availability. The population density of *P. herbstii* can vary over small spatial scales; in a survey of salt marshes from Delaware to North Carolina, densities ranged from 0 to 82 individuals m^{-2}, with individuals

positively associated with the height of the associated cord grass, *Spartina alterniflora,* and the availability of bivalve prey (Silliman *et al.,* 2004). Like other crustaceans, the timing of *P. herbstii* reproduction is seasonally dependent on water temperature and food availability and therefore can vary between populations along the coast (Williams, 1984). After hatching, the planktonic larva stays within the estuary (Dittel & Epifanio, 1982) and molts through four zoeal stages and a megalopa stage before metamorphosing into the juvenile stage (Williams, 1984).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The type localities for *Panopeus herbstii* are oyster beds and mangrove swamps from the intertidal zone to 22 meters in depth (Williams, 1984). Both adults and juveniles can be found on muddy bottoms or areas covered with shells and/or stones or in shallow burrows (4-10 cm) along the edges of the higher marsh (Williams, 1984; Dittel *et al.,* 1996). While little empirical work has been conducted on the temperature and salinity tolerances of this species, the broad latitudinal gradient that it encompasses suggests that it has the potential to withstand wide ranges of environmental conditions. Individuals have been kept in the laboratory at temperatures between 5°C and 30°C (Dame & Vernberg, 1978) and have been observed in brackish water estuaries above 10 ppt (Gosner, 1978; Rodriguez & Epifanio, 2000).

Primarily carnivorous, adult and juvenile *P. herbstii* have been documented to consume oysters, barnacles, clams, crustaceans, annelid worms, fish, and snails (McDermott, 1960; Castagna & Kraeuter. 1977; Whetstone & Eversole, 1981; Silliman & Bertness, 2002; Silliman *et al*., 2004; Tolley & Volety, 200; Whitefleet-Smith & Harding, 2014) and play an important role as prey items for a variety of birds, fish, and larger crustaceans (Grabowski, 2004). Silliman *et al.* (2004) showed that predation by *P. herbstii* on the marsh periwinkle (*Littoraria irrorata*) population had a positive effect on salt marsh vegetation growth. The megalopae of *P. herbstii* prey upon other zooplankton (Harvey & Epifanio, 1997) but are also prey for blue crabs, shrimp, and fish species (Dittel *et al.,* 1996).

CHALLENGES

As one of the most important habitats for *Panopeus herbstii* is oyster reef, the declining populations of oysters, especially the Eastern oyster, *Crassostrea virginica*, could be detrimental to *P. herbstii* populations. Populations of *C. virginica* have declined along much of the mid-Atlantic Coast of the United States during the last century due to a combination of over-harvesting (Gross & Smyth, 1946), habitat degradation (Rothschild *et al.,* 1994), reduced water quality (Seliger *et al.,* 1985), disease (Ford & Tripp, 1996; Lenihan *et al.,* 1999), the interactions among these factors (Lenihan & Peterson, 1998), and ecosystem shifts (see Rothschild *et al.,* 1994; Luckenbach *et al.,* 1999; Dame *et al.,* 2002). Wild populations of *C. virginica* are harvested both commercially and recreationally in South Carolina, and aquaculture on leased grounds (culture and mariculture permit areas) is increasing. Although *C. virginica* in South Carolina have not been as extensively exploited as the *C. virginica* populations in the mid-Atlantic states, the rapid pace of coastal development has created numerous threats to tidal creek habitats with inevitable undesirable impacts (e.g., Lerberg *et al.* 2000, Van Dolah *et al*., 2004, Holland *et al.,* 2004). Threats involve increased runoff from upland clearing and associated non-pervious surfaces; contaminants (particularly detrimental to larval stages) such as pesticides and

heavy metals (see Capuzzo, 1996 and Roesijadi, 1996, respectively, for reviews); water quality closures resulting in concentrated harvest pressure on open, harvestable beds; impacts from dredging and other channel manipulations; and boat-related impacts. The potential impacts on *P. herbstii* of ocean acidification also warrant consideration (Dodd et al., 2015). Furthermore, despite a relative focus on filter-feeding species when it comes to microplastic studies, P. herbstii may be particularly susceptible to this emerging threat (Waite *et al.,* 2018).

CONSERVATION ACCOMPLISHMENTS

Due to their importance as habitat for several species of conservation concern in South Carolina, including *Panopeus herbstii*, oyster reefs are also considered critical habitats of concern in both the State Conservation Plan and this State Wildlife Action Plan. As such, the South Carolina Department of Natural Resources (SCDNR) and others are actively involved in the restoration and enhancement of oyster reef habitat. Newly created oyster reefs provide the foundation for the settlement of oyster larvae that will eventually develop into natural oyster habitat. These new oyster reefs will benefit *Panopeus herbstii* and all of the associated marine species that utilize this habitat. To ensure that populations of *C. virginica* in South Carolina remain abundant, extensive efforts at the SCDNR Marine Resources Division, both by the Office of Fisheries Management and the Marine Resources Research Institute Shellfish Research Section, continue to be directed towards assessments of the distribution of *C. virginica* statewide to monitor changes in the acreage and condition of intertidal oyster reef habitat using ground-, boat-, and helicopter-based survey techniques.

CONSERVATION RECOMMENDATIONS

- Assess the impacts of oyster reef restoration projects on *Panopeus herbstii* populations in South Carolina.
- Establish estimates of population size and determine population trends for *Panopeus herbstii* in South Carolina by widespread and long-term monitoring of their abundance, both in oyster reef habitats as well as alternative habitats.
- Understand the importance of *Panopeus herbstii* in the overall marine species community structure on oyster reef habitats in South Carolina.
- Develop a state or federal management plan for *Panopeus herbstii* based on population assessments.
- Continue SCDNR and others' oyster reef restoration and enhancement projects to ensure viable habitat exists for *Panopeus herbstii* and other marine species that rely on this important ecosystem engineer.

MEASURES OF SUCCESS

If measures of abundance and population demographics of *Panopeus herbstii* are conducted as part of regular monitoring efforts that are currently established to monitor macroinvertebrates associated with oyster reefs, this could be a cost-effective way to collect data to provide baseline information. If continued over a longer period, these data would be able to follow population trends, which will allow managers to make decisions regarding possible conservation measures for this species. The overall measure of success for *Panopeus herbstii* will be stable population

trends along the entire coast, as part of the increased conservation and restoration of oyster reef habitat in South Carolina.

Atlantic sand crab
Emerita talpoida

Contributor: Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and basic description:

Also referred to as the common mole crab, *Emerita taploida* (Say, 1817) is a member of the family Hippidae (Malacostraca: Decapoda: Anomura). Mole crabs have no pincers and the shape of their body is modified for rapidly digging in wet sand. *Emerita talpoida* is an oval-shaped, beige, or purplish crab, that is subcylindrical, ridged, longer than broad, and that measures less than 2" in total length. Its pointed abdomen is fairly well developed and is usually folded beneath its ovoid body. The antennae are short and fuzzy and are used for filtering food particles out of the water of spent waves as it flows in thin sheets back to the sea (Ruppert & Fox, 1988). This specialized method of feeding is arguably unique among the arthropods (Snodgrass, 1952). A second species, *E. benedicti*, is less common and is reported from shelly bottoms in shallow water. The last segment of the first leg of *E. benedicti* is sharply pointed while that of *E. talpoida* is bluntly pointed. A detailed description of the anatomy of *E. talpoida* and some of its relatives can found in Snodgrass (1952).

Status

The status of this species in South Carolina is known as it is not the target of any standardized surveys, does not support a directed fishery, and is not listed on any recognized Federal or state conservation list. That being said, published data on this species, particularly from North Carolina, indicate that its numbers are subject to both natural and anthropogenically-driven fluctuations that warrant an improved understanding in coastal South Carolina habitats.

POPULATION DISTRIBUTION AND SIZE

Emerita talpoida occurs from Harwick, Massachusetts, USA to the Progreso, Yucatan, Mexico (Efford, 1976; Williams, 1965, 1984). The size of the population of *E. talpoida* in South Carolina is unknown because this species is data deficient. While the general habitat requirements of *E. talpoida* in the region have been explored, and it is known to be a specialist of the swash zone, details of its distribution in South Carolina are lacking.

HABITAT / NATURAL COMMUNITY REQUIREMENTS

Emerita talpoida is a successful, specialized colonizer of the intertidal zone of sandy beaches to depths of 11 ft (3½ m, (Diaz, 1980). These crabs are renowned for their ability to move rapidly in order to maintain their position with the changing tide. While several other uncrablike burrowing crustacean are collectively referred to as mole crabs, *Emerita* is by far the most familiar and is a characteristic inhabitant of the swash zone of ocean beaches, burrowing backwards into the sand facing the sea (Ruppert & Fox, 1988).

The distribution of *E. talpoida* on the foreshore is strongly influenced by inshore processes and the grain size and morphology of the beach deposit, with a preference shown for finer grain sizes into which they can more easily burrow (Bowman & Dolan, 1985). It can occur in large aggregations (*e.g.,* Diaz, 1980) that move up the beach on the rising tide and down the beach on the falling tide, with smaller crabs generally distributed higher intertidally than larger crabs (White, 1976). Tidal rhythms of activity (*e.g.,* Enright, 1963, 1972) that underly such movements up and down the beach can be entrained by tidal cycles in temperature, salinity, hydrostatic pressure, inundation, and mechanical agitation (Palmer, 1995). Such tidal rhythms of behavior of different life stages of *E. talpoida* were investigated by Forward *et al.* (2005) and all stages were found to have a circatidal rhythm in vertical swimming and activity peaks shortly after the time of high tide. Increased activity during ebb tide implies that animals are moving with the waves and feeding at this time (Forward *et al.,* 2005).

Emerita talpoida is an important component of the diet of the SWAP-listed ghost crab, *Ocypode quadrata*, which despite previous reports that it primarily scavenges (*e.g.,* Philips, 1940; Crane, 1941) has been shown to spend little time in areas where drifted material accumulates, and have a diet comprised almost entirely (90%) of live prey, namely *E. talpoida* and *Donax variabilis* (Wolcott, 1978). Predators such as wading birds, ghost crabs (*Ocypode quadrata*) and planktivorous fishes, have also been suggested to prey heavily on *E. talpoida* such that their populations may be regulated by predation (Nelson, 2012). Long-term population stability of ghost crabs, *O. quadrata*, therefore, may also be a function of the production of *E. talpoida* and *D. variabilis*, whereas populations of these prey items are unlikely to be controlled by predation by *O. quadrata*, but rather by aspects of their K-selected life history characteristics of rapid growth and reproduction, pelagic larvae, and short life cycles (Wolcott, 1978).

In North Carolina, there are two breeding pulses for *E. talpoida*, the first of which begins in the spring and ends in June, and the second of which begins after June and ends in September when most recruitment has been observed (Diaz, 1980). Larvae are released near sunset (T. Ziegler, unpubl.) and undergo a series of zoeal stages (Rees, 1959; Diaz & Costlow, 1983) in coastal areas before returning to sandy beaches as megalopae where they metamorphose and settle out as juveniles. Bowman & Dolan (1985) observed a temporal pattern in the abundance of *E. talpoida* in North Carolina, with numbers increasing through the spring and summer to a seasonal maximum in late summer and early fall. Superimposed on these seasonal patterns can be large and rapid fluctuations in numbers related to variations in wave energy and tide level, reflecting onshore and offshore migration in response to energy conditions and feeding requirements (Bowman & Dolan, 1985). Populations of *E. talpoida* are believed to overwinter offshore along the

mid-Atlantic coast, with onshore migration beginning in the early spring (Diaz, 1980; Bowman & Dolan, 1985). Females have been observed to be more abundant in summer and to produce several clutches (Diaz, 1980). A greater proportion of females has been observed in the spring as a result of the death of larger males, and another peak in the abundance of females observed in the fall due to a large recruitment of females (63%, Diaz, 1980). A higher mortality rate for males than females results in a shorter life expectancy for the former.

CHALLENGES

The spatial distribution of *E. talpoida* is strongly affected by inshore processes and the grain size and morphology of sandy beaches such that it is perhaps not surprising that the distribution of this species has been shown to be altered by the installation of a research pier in North Carolina (Bowman & Dolan, 1982) and to be affected by beach nourishment activities (Hayden & Dolan, 1974), in both cases resulting more in the redistribution of this species than in an increase in mortality. More specifically in the case of renourishment, reductions in population densities at and immediately adjacent to the downcurrent side of the point of discharge have been observed (Hayden & Dolan, 1974). Population numbers further away from the point of renourishment down the beach in the direction of the longshore current increased, indicating a migration of mole crabs in response to nourishment (Hayden & Dolan, 1974). Tidal, wave, and current motions were found to play an essential role in reducing the mortality of the mole crabs and permitting migrations associated with beach nourishment. Population numbers at the discharge site recovered within a few tidal cycles (Hayden & Dolan, 1974). Anecdotally, in South Carolina, however, there have been reports that beach renourishment activities lead to reductions in observations of *E. talpoida*. It seems plausible therefore that *E. talpoida* is a viable indicator species for assessing the environmental impacts of large-scale coastal engineering projects and renourishment events (Hayden & Dolan, 1974).

Freshwater discharge has also been shown to influence the distribution, abundance, and life history traits (*i.e.,* size, sex, maturity, fecundity) of another closely related species within the genus *Emerita* (*E. brasiliensis*) in Uruguay (Lercari & Defeo, 1999), raising the possibility that freshwater discharges from “swashes” in South Carolina could be a potential cause of disturbance to *E. talpoida*. This species also appears to be negatively affected by hurricanes, as evidenced by their recovery from such an event in North Carolina in the fall of 1971 as documented by Diaz (1980).

CONSERVATION ACCOMPLISHMENTS

Emerita talpoida has received little or no attention in terms of past conservation efforts, likely due to the data deficient nature of this species to indicate that its number have been in decline, either as a result of natural or anthropogenic factors.

CONSERVATION RECOMMENDATIONS

A first step in the conservation of this species would be to gain a better understanding of the spatial distribution of this species in coastal South Carolina and to define essential habitat characteristics for this species. In addition, gathering baseline data on temporal variation in life history and demographic parameters (*i.e.,* size, sex, abundance, recruitment patterns) would help to inform the impacts of future disturbances (*e.g.,* hurricanes, coastal engineering projects, freshwater inputs). Additional research is also needed to understand the importance of *E. talpoida* as a prey item for wading birds, ghost crabs, and planktivorous fishes in sandy beaches habitats for which they are specialized.

MEASUREMENT OF SUCCESS

A better understanding of the spatial distribution and baseline life history of *E. talpoida* would be first order measures of conservation success. Such an understanding would enable the impacts of disturbances to be conceptualized but also provide protection to critical habitats, including at key points in their life history. Healthy populations of *E. talpoida* have important implications for the species that rely upon them as prey items, during both their larval and post-settlement life stages.

Cannonball Jellyfish

Stomolophus meleagris

Contributors (2005): DuBose B. Griffin, Thomas M. Murphy, and Peter Kingsley-Smith [SCDNR]; Reviewed and Edited (2013): DuBose B. Griffin, Pearse Webster, and Peter Kingsley-Smith [SCDNR]; Edited (2024) Lauren Faulk [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

Cannonball jellyfish (*Stomolophus meleagris*) (L. Agassiz 1860), also known as jellyballs, belong to the class Scyphozoa and order Rhizostomeae. Agassiz (1860) described and illustrated the medusa of cannonballs using specimens collected from Wassaw Island, Georgia and Charleston, South Carolina. The hemisperical bell reaches 20 to 25 cm in size and is bordered with brown pigment. It has short, protruding oral arms with secondary mouth folds (scapulets) at the base of the bell covered with mucus for trapping small prey. *Stomolophus meleagris* means "many mouthed hunter." The mucus is also thought to be a response to disturbance rather than for feeding (Phillips *et al*., 1969; Larson, 1976).

Status

The cannonball jellyfish is not a state or federally listed species; however, cannonballs are ecologically-important because they are the major prey base for Atlantic spadefish (*Chaetodipterus faber*), butterfish (*Peprilus triacanthus*) and the endangered leatherback sea turtle (*Dermochelys coriacea*) and therefore warrant conservation (Phillips *et al.,* 1969; Hayse, 1990; Page, 2015). In addition to its ecological importance, the cannonball jellyfish is economically important as an estimated 3000 tonnes of cannonball jellyfish are harvested in the southeastern United States annually (Atlantic Coastal Cooperative Statistics Program [ACCSP] 2022) to contribute to the commercial fishery for the species.

POPULATION SIZE AND DISTRIBUTION

Cannonball jellyfish have been reported in the western Atlantic from New England to Brazil (Kramp, 1961; Larson, 1976), in the eastern Pacific from southern California to Ecuador, and in the western Pacific from the Sea of Japan to the South China Sea (Kramp, 1961; Omori, 1978). They are one of the most abundant scyphomedusae along the southeastern and Gulf coasts of the United States (Mayer, 1910; Kraeuter & Setzler, 1975; Burke, 1976; Calder & Hester, 1978). Their success is based in part on their ability to grow rapidly and take advantage of ephemeral secondary production (Larson, 1986).

Current distributions of most populations are undocumented; however, numerous reports of their occurrence in the southeastern U.S exist. Mayer (1910) reported them as abundant during the winter and spring off the coast of Florida north to South Carolina. Brooks (1882) and Gutsell

(1928) reported them in North Carolina as very abundant in June and July and common throughout the summer in the sounds and ocean. In South Carolina and Georgia, they are reported as the most common scyphomedusae, occurring sporadically year-round (Kraeuter & Setzler, 1975; Calder & Hester, 1978).

The seasonal cycle of cannonball jellyfish is described by Rountree (1983) as the following:

> *"Small populations of large adults appear offshore in the spring and move inshore by early summer. The origin of these populations of adults has not been determined, but it seems likely that they are survivors from the previous season (Kraeuter & Setzler 1975). It is also possible that they are early spawned medusae from more southern waters which are carried north by prevailing spring ocean currents…Kraeuter & Setzler (1975) found the young medusae move out from estuarine waters into more saline waters as they grow. Two concurrent events are therefore hypothesized: 1) first generation populations move from offshore in the spring to inshore waters in the summer and finally into brackish waters in the fall; 2) second generation populations move out from estuarine waters beginning in the mid-summer and continuing through the fall."*

The South Carolina Department of Natural Resources (SCDNR) has been conducting surveys in the South Atlantic Bight since 1986 through a program called the Southeast Area Monitoring and Assessment Program – South Atlantic Shallow Water Trawl Survey (SEAMAP-SA). Tows were conducted each year in spring (April to May), summer (July to August), and fall (October to November) in shallow coastal waters from Cape Hatteras, North Carolina to Cape Canaveral, Florida. From 1989 to 2000, only the presence or absence of cannonball jellyfish was recorded on each individual tow. During this time, cannonballs were present in 43% of the tows during all three survey seasons.

Beginning in 2001, total numbers of cannonballs per hectare were counted for each year (102 tows per season; J. Boylan and P. Webster, SCDNR, pers. Comm.). From 2001 to 2019, cannonball jellyfish were present in 39% of the tows. These data are presented in the following graph (Figure 1 below; Zimney & Gut, 2020). Since 2001, there has been an apparent steady decline in the relative abundance of cannonballs with very low catch rates observed in 2004 and 2009. The reasons for this decline are unknown; however, anomalously low summer water temperatures in the coastal waters in summer 2003 may be related to the low numbers in 2004. In recent years, the relative abundance has increased and was 1.5 times greater than the mean of the time series (Zimney & Gut, 2020). The highest biomass (kg per tow) of cannonball jellyfish was observed in the portion of the sampling region that includes the coastal waters of Georgia and the southern portion of South Carolina (south of Charleston) with the largest jellyfish occurring in the spring sampling season (Faulk *et al.,* 2023). The lowest biomass (kg per tow) was observed in the summer sampling months, which could be a result of decreased biomass or inshore transport into estuaries and inlets outside of the SEAMAP sampling region (Faulk *et al.,* 2023). This supports the seasonal movement observed by Kraeuter & Setzler (1975) and Rountree (1983) described above. The spatial and temporal variability observed does not appear to be linearly related to salinity or temperature (Faulk *et al.,* 2023).

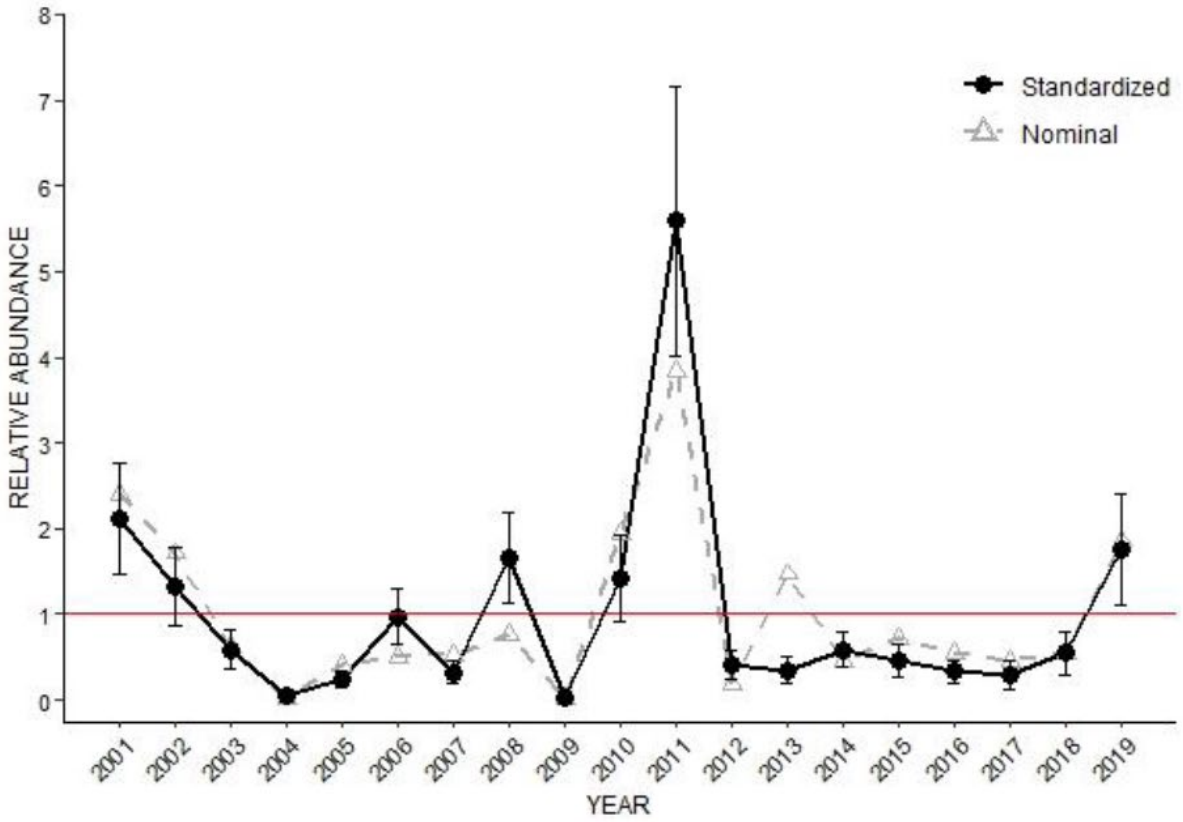

Figure 1: Nominal (grey dashed line) and delta-GLM standardized (black solid line) catch per unit effort (number of cannonball jellyfish per hectare) each year from 2001-2019. Errors bars represent the corresponding standard error.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Cannonball jellyfish are found in estuarine and saline waters. Temperature and salinity measured during the SCDNR SEAMAP-SA tows (unpub. data) indicate they are found in waters with an average temperature of 23.1°C (74°F) and in salinities from 17.7 to 36.5 parts per thousand (ppt) with an average of 33.8 ppt. Cannonballs feed on zooplankton, primarily bivalve veligers (Larson, 1991), have also been shown to prey on all stages of red drum larvae (Duffy *et al.,* 1997) but do not sting humans (Calder & Pridgen, 1977). Cannonballs are strong horizontal and directional swimmers (Shanks & Graham, 1987). They are known for their symbiotic relationships with other marine species, specifically 10 species of fishes as well as juvenile longnosed spider crabs (*Libinia dubia*). These symbionts feed on both the zooplankton taken in by the jellyfish and on the host's medusae. Symbionts may also use the bell for protection (Corrington, 1927; Gutsell, 1928; Phillips *et al.,* 1969; Rountree, 1983).

CHALLENGES

Since cannonball jellyfish are dependent on the abundance of zooplankton in nearshore waters, any activity, marine or terrestrial, that could affect water quality, should be considered a

detriment to this species. Such problems include harmful algal blooms, oil spills, and nonpoint source pollution. Also, the level of dependence of cannonball jellyfish on bivalve veligers suggests a relationship with the health of bivalves.

The potential exists for cannonball jellyfish to be adversely affected by commercial fishing. Currently, South Carolina does not regulate a commercial cannonball jellyfish fishery; however, this fishery does exist in other portions of the cannonball's range. Japan imports 5,400 to 10,000 tons of jellyfish products valued at $25.5 million annually (Omori & Nakano, 2001). Currently, Asian countries are developing fisheries management plans to conserve jellyfish because populations are unstable or declining due to pollution, overfishing, or climate change. Consequently, dealers are looking for new sources of jellyfish (Hsieh *et al.,* 2001). Interest in cannonball jellyfish from the United States increased recently because of high consumer demand in Asia (Hsieh *et al.,* 2001). A fishery in Florida has processed cannonball jellyfish since 1992 (Rudloe, 1992), and a commercial trawl fishery for cannonball jellyfish in Georgia exists (M. Dodd, GADNR pers. comm.). Rising demand in Japan and southeast Asia may create an international market for cannonball jellyfish from South Carolina coastal waters. Any development of commercial fisheries for cannonballs must consider its affect on this species' role in the food web of coastal ecosystems, as well as the effects on endangered leatherback sea turtles through incidental mortality in trawls and reduction of their food resources. Life cycles of cannonball jellyfish involve federal and state waters; therefore, cannonballs should be managed on a regional scale (Murphy *et al.,* 2006).

CONSERVATION ACCOMPLISHMENTS

In 1989, SCDNR began surveying cannonball jellyfish during SEAMAP-SA tows. These surveys have provided an index of relative abundance of cannonball jellyfish in coastal waters along the southeastern United States, which has led to a better understanding of this species. In addition, current regulations requiring the use of turtle excluder devices (TEDs) in shrimp trawling nets have also provided protection to cannonball jellyfish. Although required to reduce incidental catch of turtles, TEDs also exclude cannonballs > 10 cm, thus increasing survival. TEDs have been required for shrimp trawls since 1990.

CONSERVATION RECOMMENDATIONS

- Determine the distribution of cannonball jellyfish in state waters and how this species affects the distribution of leatherback sea turtles.
- Examine the basic life history and determine the source of the spring recruitment of cannonball jellyfish.
- Determine the effect of temperature, salinity, and rainfall on spring reproduction.
- Determine the effect of distance from estuarine habitat and wind direction on the spatial and temporal variability of cannonballs.
- Determine the southeastern U.S. population genetic structure through genetic analysis of cannonballs.
- Continue to monitor population trends through SCDNR SEAMAP-SA sampling of cannonballs.
- Determine the maximum sustainable yield for a harvest fishery.

- More fully examine the species' role in predator-prey dynamics.
- Encourage municipalities to adopt Best Management Practices (BMPs) that protect water quality and bivalve health by reducing nonpoint source runoff from highways, agricultural fields, and housing developments.
- Monitor the effectiveness of existing BMPs such as setbacks, retention ponds, and vegetated buffers for preventing nutrient and contaminant runoff into coastal waters.
- Examine the relationship between bivalve populations and cannonball reproduction.
- If a fishery develops in South Carolina for cannonball jellyfish, it should be monitored and regulated to avoid overexploitation, and appropriate harvest techniques should be identified that are protective of other marine species.
- Facilitate the development of a regional management plan for cannonballs.
- Develop an education program that stresses the importance of cannonball jellyfish to coastal ecosystems and that they are harmless to humans.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and southeastern U.S. population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect cannonball jellyfish and associated predator/prey relationships. In the event that more protective BMPs are implemented, SEAMAP data can be used to indicate whether these measures have affected cannonball jellyfish populations. Producing a regional management plan for this species would greatly benefit the cannonball jellyfish throughout the southeastern U.S. coastal area.

Colorful Sea Whip

Leptogorgia virgulata

Contributors (2005): Stacie Crowe (SCDNR), Anne Blair (NOAA), Pam Jutte (SCDNR)
Reviewed and Edited (2013, 2023): Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The colorful sea whip was first described by Lamarck (1815) and named *Leptogorgia virgulata*. Gorgonians, or soft corals, such as the sea whip, belong to the suborder Holaxonia. These colonial cnidarians are so named because they lack the permanent, rigid skeleton of scleractinian hard corals. As octocorallians, they possess 8 tentacles. Branches in gorgonians are arranged around a central axis. *Leptogorgia virgulata* colonies are moderately branching into whip-like stalks. Polyps alternate in rows along two sides of each branch; rows are separated by distinct grooves on older main branches. The color of the colony is variable and may range from shades of purple, red, orange, yellow or white. Sea whip polyps are translucent to white. The typical adult size of the colorful sea whip is 15 to 60 cm (Ruppert & Fox, 1988).

Status

Gorgonians are important benthic suspension feeders in sublittoral benthic communities and are present in tropical, subtropical, temperate and polar regions (*e.g.,* Weinberg, 1976; White, 1984; Dahlgren, 1989; Linares *et al*., 2008). The colorful sea whip is one of many coral species that commonly colonizes hard bottom substratum in high salinity areas of South Carolina estuaries and coastal shelf habitats. It serves as an indicator species that is representative of the sessile epifauna that form essential reef habitats utilized by many economically valuable or ecologically important species. These include snappers (*Lutjanus* spp.), groupers (*Epinephelus* spp.) and the black sea bass (*Centropristis striata*) (Van Dolah *et al.,* 1987). The colorful sea whip was selected over other fauna as a SWAP indicator species because it is one of the most pervasive and abundant species inhabiting hard bottom substratum. The colorful sea whip also serves as the home or prey for several specialized associates including the Atlantic wing oyster (*Pteria colymbus*), brown barnacles (*Conopea galeata*), a tissue-feeding nudibranch (*Tritonia wellsi*), and the shrimp, *Neopontonides beaufortensis* (Patton, 1972; Ruppert & Fox, 1988). No long-term studies have been completed, however, to assess the population status of the colorful sea whip.

POPULATION SIZE AND DISTRIBUTION

The colorful sea whip is a common shallow water gorgonian species that occurs over a latitudinal range that extends from Brazil to the Chesapeake Bay and perhaps as far north as the “Bay of New York” (Bayer, 1961). This species inhabits estuaries and coastal sites up to 20 m (66 ft) or more in depth (Van Dolah *et al.,* 1987; Blair, 2003).

Research indicates that the colorful sea whip is a dominant octocoral in the coastal shelf areas off the southeastern United States (Van Dolah *et al*., 1987). It is commonly found in high salinity estuarine habitats where tidal scour has exposed hard substrata (Van Dolah, unpubl. data).

The colorful whip coral is relatively common in estuarine, coastal, and offshore habitats in South Carolina. There are, however, no known estimates of population size or population trends. Additionally, factors that may limit the population are unknown.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Gorgonians are important for structuring benthic communities and driving diversity (Gili & Coma, 1998), and yet data on their trophic ecology in nature are relatively limited. This is due to the difficulties of studying feeding in organisms with such a wide spectrum of prey types. Gorgonians are capable of consuming prey and food particles ranging in size from nanometres to millimetres (Ribes *et al*., 1998, 2003). Furthermore, temporal shifts have been documented for L. virgulate in terms of diet composition, suggesting that this species may be an opportunistic feeder utilizing seasonal shifts in food availability (Leal *et al*., 2014).

Sea whips grow abundantly on shell live bottoms in sounds and tidal creeks but can also be found on floating docks, rock jetties, and oyster reefs (Ruppert & Fox, 1988) as well as on artificial reefs (Schweitzer & Stevens, 2019). They are also familiar constituents of hard-bottom reefs, which are a common topographic feature of the continental shelf off the southeastern United States. Sea whips are also found on artificial reefs constructed in this region. Furthermore, the presence of *L. virgulata* has been shown to influence mesocosm habitat selection by fish species encountering intercoastal jetties during migration, in particular the fish commonly called the ‘sergeant major’, *Abudefduf saxatilis* (Squiers & Strychar, 2021).

Unlike many gorgonian species, the colorful sea whip does not reproduce asexually through cloning or fragmentation. Fertilization is external and larvae spend 3 to 20 days in the plankton before settlement and metamorphosis. All recruits are derived from the successful settlement and survival of planktonic larvae, which require adequate substrata such as low-relief rocky outcrops or extensive hard bottom (Gottelli, 1991).

CHALLENGES

Occasionally, the colorful sea whip is damaged by shrimp trawl nets; studies have found that the overall effects were a loss of 3.9% to 38% during respective census periods (Van Dolah *et al*., 1987; Tilmant, 1979).

Another potential threat to sea whip populations is offshore disposal of dredged material. A study investigating changes in sponge and coral communities at select hard bottom reef sites adjacent to the Charleston Ocean Dredged Material Disposal Site (ODMDS) found that sessile invertebrates, including the colorful sea whip, experienced natural fluctuations in community structure and suffered limited, if any, impacts from the large-scale disposal operations occurring at the ODMDS (SCDNR, unpubl. data). Coral populations that are located closer to disposal

activities in other areas, however, could be negatively impacted by burial or decreases in the aerial extent or damage to the coral beds.

A study of the physiological effects of dredged material disposal on the oxygen metabolism of a related gorgonian octocoral, *Leptogorgia hebes*, was completed in 1992 by the EPA in conjunction with the University of Georgia's Department of Ecology. The results of that study suggested that while coral recovery from single episodes of low-level sediment exposure is likely, recovery is more difficult following repeated low-level exposures or single episodes of high-level exposure. Both long-term responsiveness and immediate short-term productivity rates were inhibited by exposure to sediment concentrations above 100 mg L-*1* [15 NTU (nephelometric turbidity units)] (Porter, 1993). Since dredging occurs frequently in the Charleston area, the potential exists for this activity to adversely affect the population size or reproductive ability of whip corals.

Populations of the colorful sea whip that inhabit sounds and tidal creeks may be subjected to increased sedimentation rates, nutrient levels (eutrophication), or contaminants due to terrestrial runoff from suburban, urban, industrial, and agricultural areas. The physiological impacts from exposure to elevated sediment concentrations in nearshore populations are described in the previous section. The possible effects of exposure to eutrophication could include impacted growth rates, reproductive ability, or mortality (Jones & Endean, 1976). Other threats to gorgonian corals include those from oil spills (*e.g.,* Frometa & Etnoyer, 2023) and potential negative impacts associated with climate change-driven increases in water temperatures.

CONSERVATION ACCOMPLISHMENTS

Inshore state waters that were historically open, including the sounds and Bulls Bay, were closed to shrimp trawling in 1986. Sea whips are common in these high salinity estuaries. Since 1978, SCDNR has monitored offshore dredge material disposal in Charleston in an effort to minimize the effects of dumping on hard bottom reef communities. Likewise, the South Carolina Estuarine and Coastal Assessment Program (SCECAP) monitors habitat quality of estuarine waters statewide and identifies specific sites with degraded water or sediment quality conditions as well as provides estimates of the overall condition of State waters (*e.g.,* Sanger *et al.,* 2022).

CONSERVATION RECOMMENDATIONS

- Conduct mapping studies of bottom habitats to better define the location of hard bottom reef areas that include sea whips.
- Examine the long-term population trends of sea whips.
- Further investigate the relationships between sea whips and commensal or cryptic species that live in association with sea whips.
- Establish detailed baseline monitoring data to allow for a better understanding of the impacts of offshore dumping on hard bottom reef habitats.
- Conduct studies on the impacts of increased sedimentation rates, nutrient levels, and contaminant levels on estuarine populations.

- Educate commercial trawl fishermen on the damage trawling causes to hard bottom reef species and collaborate with the shrimp industry to avoid trawling near sea whip communities.
- Cooperate with the United State Army Corps of Engineers to reduce sedimentation and burial of coral assemblages near disposal sites.
- Work with communities and municipalities to reduce runoff by improving and implementing Best Management Practices (BMPs).
- Work with partners to develop ways to reduce nutrient runoff that exacerbates the effects of eutrophication.
- Develop and enforce a management plan for protecting live bottom communities in South Carolina State waters.

MEASURES OF SUCCESS

Once the information regarding population distribution and trends in State waters has been documented, development of both population models for live bottom communities and a conservation plan for sea whip in South Carolina would benefit this species. Documenting stable population trends for sea whips and other members of live bottom communities within South Carolina waters would be the ultimate measure of success for this community.

Common mantis shrimp

Squilla empusa

Contributor: Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and basic description:

Squilla empusa Say, 1818 (Subphylum Crustacea; Class Malacostraca; Order Stomatopoda; Family Squillidae) belongs to a group of predatory benthic crustaceans known collectively as the mantis shrimps due to their resemblance in appearance to praying mantises. Details of the stomatopod crustaceans found in the Carolinas and Georgia, including a key to their identification, and geographic records of their collection, can be found in Manning & Heard (1997).

Stomatopods are visually active animal with large, mobile compound eyes of unique design (Trevino & Larimer, 1969; Cronin *et al.,* 2010; Feller *et al.,* 2015). Stomatopods are very common in marine waters around the world with around 500 species described (Muller, 1994) and are both ecologically and economically important. These crustaceans are dorso-ventrally flattened and have a pair of large powerful claws (second maxillipeds) which they hold beneath their body as if they were praying. The motions of these claws when they strike is one of the fastest recorded animal movements, taking 4 to 8 milliseconds to complete and traveling at a velocity of 1,000 cm per second (Burrows, 1969). As such, a wide diversity of prey may fall victim to the strikes of this species, including fish, penaeid shrimp, crabs, annelids, clams, mussels, snails, squids, and echinoderms (Piccinetti & Manfrin, 1970; Camp, 1973; Caldwell & Dingle, 1976). As a group the stomatopods are divided into 'smashers' and 'spearers' (Caldwell & Dingle, 1976), for which *S. empusa* falls into the category of a spearer mantis shrimp.

Squilla empusa is a robust, prickly animal that reaches 15-20 cm in length and inhabits an irregular, branched U-shaped burrow 2 to 4 cm in diameter (Frey & Howard, 1969; Hertweck, 1972) which in the southeastern United States reaches a depth of approximately 51cm (Ruppert & Fox, 1988), compared to up to 4m in more northern parts of its range (Myers, 1979). Other species are known to occupy these burrows, e.g., the small snail, *Cyclostremiscus pentagonus* (family Tornidae) and the copepod *Goodingius* (formerly *Hemicyclops*) *adhaerens* (Ruppert & Fox, 1988).

This species has also been documented to have nocturnal patterns of activity, such that numbers caught in trawls are typically higher during nighttime hours (McCluskey, 1977; Rockett *et al.,* 1984). Furthermore, the burrowing activities of stomatopods oxygenate and release nutrients to the benthic habitat, such that they could be considered to be ecosystem engineers.

Status

The mantis shrimp, *Squilla empusa* is not presently included in federal lists of threatened or endangered species, and there is no present-day direct human exploitation of this species in South Carolina; however, its population is likely impacted by the commercial penaeid shrimp fishery (details provided in *Challenges* below). No targeted population assessments are conducted on this species, despite its ecological significance. Understanding of the life history on this species for the South Carolina coastal region is lacking compared to that available for the northern Gulf of Mexico (as presented below).

POPULATION DISTRIBUTION AND SIZE

Squilla empusa is found in the western Atlantic Ocean and ranges from Massachusetts, USA to northern South America, including Trinidad, Venezuela, Surinam, and French Guiana (Manning, 1969). The animals burrow in sandy and muddy substrates overlain by high salinity waters (Gunter, 1950; Manning, 1969; Franks *et al.,* 1972). The species is abundant throughout its range but is especially prevalent in commercial shrimp beds and is believed to be a significant predator of penaeid shrimp. For example, Hildebrand (1954) observed *S. empusa* to be the most abundant crustacean in the offshore trawl fishery of the Gulf of Mexico, except for *Penaeus* spp. and *Callinectes* spp. Similarly, Wenner & Wenner (1989) reported that *S. empusa* ranked second to *Achelous* (formerly *Portunus) gibbesii* in total catch and that it occurred in 78% of trawls conducted between Cape Fear, NC and Cape Canaveral, FL in depths between 4m and 20m. In biomass, *S. empusa* constituted 11% of the total catch and was outranked only by the blue crab, *Callinectes sapidus*.

For *S. empusa* in the northern Gulf of Mexico, individuals are larger in body length and wet weight in the winter, but abundances are higher in the summer, with the sex ratio of males and females nearly equal regardless of season (Wortham, 2009). No difference has been found in the carapace lengths of male and female *S. empusa* (Rockett *et al*., 1984;Wortham, 2009). Females may be less likely to be captured during the summer spawning season as they are more inclined to remain in their burrows to care for egg masses, while males are more actively searching for new burrows (Wortham, 2009). The distribution of male and female *S. empusa* in the Gulf of Mexico also do not appear to differ in relation to depth, temperature, and salinity (Wortham, 2009).

HABITAT / NATURAL COMMUNITY REQUIREMENTS

Stomatopod larvae can occur in swarms, particularly within tropical regions of their range, and can constitute a considerable portion of the diet of reef fishes and

commercially-important pelagic fishes such as the tunas, skipjack tuna, mackerel, herring, and snapper (Sunier, 1917; Fish, 1925, Reintjes & King, 1953; Randall, 1967; Dragovich, 1970). Conversely, similar to the adults, the larvae of *S. empusa* are voracious predators, able to capture zooplankton of a similar size to themselves. In addition, Dahlberg & Heard (1969) reported that *S. empusa* was found in the stomach contents of a southern stingray, *Hypanus* (formerly *Dasyatis) americanus* collected in Wassaw Sound, GA. That being said, little information has been published on their larval ecology and development, and among the stomatopods, species are difficult to differentiate at the larval stage and present challenges with rearing from hatching to metamorphosis (although see Morgan & Provenzano, 1977).

While *S. empusa* has been extensively studied, including larval descriptions (Morgan & Provanzano, ,1979), preliminary growth and distributional data (Chace 1954; Manning, 1969; Rockett *et al.*, 1984), burrow and habitat preference, reproductive morphology and grooming behavior (Wortham 2001; Wortham-Neal 2002a,b), as well as abundance, distribution, sizes, sex ratios and habitat (Wortham, 2009), the majority of studies on this species have been conducted in the Gulf of Mexico.

By comparison, equivalent information on *S. empusa* from the South Atlantic Bight, and South Carolina, more specifically, is lacking. Within the southeastern United States, Howard & Frey (1975) reported that the stomatopods *S. empusa* and *Gibbesia neglecta* were collected together at a station in Sapelo Sound, Georgia, but that more than 100 other specimens of *S. empusa* were collected by them at nine other stations in Georgia at salinities ranging from 11.7-34.1%, suggesting that *S. empusa* was the more widespread species within this region. These authors also indicated that while *S. empusa* was locally common in Georgia estuaries, it was less common in deeper estuarine channels. Fox & Ruppert (1985) considered *S. empusa* to be common all year along the South Carolina coast; however, this has not been re-evaluated more recently to determine whether this remains the case.

CHALLENGES

Stomatopods are fished for human consumption in most Mediterranean countries, Japan, and the tropical Pacific (Kaestner, 1970), and constitute a significant component of the bycatch of commercial shrimp fisheries (*e.g.,* Wenner & Wenner, 1989; Hendrickx & Sanchez-Vargas, 2005). Stomatopods are also exploited by humans for use in animal feed and pet food, and as biomonitors for heavy metal toxicity following environmental disasters and from industrial pollution (Blasco *et al*., 2002; Storelli & Marcotrigiano 2002). Indeed, the abundance, recruitment, and diversity of stomatopods have been shown to be negatively correlated with contaminated waters (Risk & Erdmann, 2000).

Although eminently edible, the fishery for this species in the U.S. is currently very small indeed. In the Adriatic, there is a substantial fishery for the abdominal meat of the closely related species, *Squilla mantis* (Manfrin & Piccinetti, 1970). Given the abundance of stomatopods as bycatch of commercial trawls, however, the possibility has been raised of these species supporting a commercial fishery in their own right (Rudloe, 1971).

CONSERVATION ACCOMPLISHMENTS

The mantis shrimp *S. empusa* has received little or no attention in terms of past conservation efforts, likely due to the lack of trends data for demographic information on this species, either from fisheries-independent or fisheries-dependent sources. The species is currently not listed as either threatened or endangered at either the state or Federal level, which also explains the lack of targeted conservation efforts.

CONSERVATION RECOMMENDATIONS

Understanding the life history of *S. empusa* in the South Atlantic Bight at a level equivalent to that available from research conducted in the Gulf of Mexico is an overarching conservation priority for this species to ensure its populations remain sustainable and healthy. Its important ecological role within coastal food webs, at multiple life stages, further support the need to conduct research to better understand these linkages for *S. empusa* in South Carolina.

While there is no current fishery or management in the United States for stomatopods, based on fisheries in other parts of the world the potential for one could exist, particularly as a bycatch fishery associated with commercial penaeid shrimp trawl fisheries. Given the common nature of their co-occurrence in trawl catches, harvesting both penaeid shrimp and mantis shrimp at the same time might yield optimal economic and ecological efficiency (Wortham, 2009). This suggests the need for baseline data on the abundance, distribution, and life history of this species in South Carolina waters.

There is also the potential to use *S. empusa* as an environmental indicator of coastal habitat health, with a precedent for its use as a bioindicator of heavy metal pollution and contamination from human sewage. Research to compare *S. empusa* abundances across a range of habitats ranging in environmental quality and contamination could shed light on the future potential to use *S. empusa* in South Carolina as an environmental indicator.

MEASUREMENT OF SUCCESS

A better understanding of the ecology and life history parameters for *S. empusa* would be one measure of success to enable researchers to determine whether or not declines in abundance were occurring and whether certain life stages of the species are susceptible to negative impacts from anthropogenic and environmental disturbances.

Coquina clam

Donax variabilis

Contributor (2005): Larry DeLancey (SCDNR)
Reviewed and Edited (2013, 2023): Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

This small species of clam, described by Say in 1822 (Adamkewicz & Harasewych, 1996), is well known to visitors to sandy beaches where its shells are found in abundance. Live coquinas are often exposed by retreating waves on sandy oceanic beaches and seem to be more active in the warmer months. Coquina clams possess wedge-shaped shells, generally less than 2.5cm in length, and are characterized by variously colored bands radiating along the shells (Miner, 1950). This species is a member of the bivalve family Donacidae, with *D. variabilis* being larger and more abundant than *D. fossor* along sandy beaches in the southeastern U.S. [Note: The coquina is also discussed in the Intertidal Marine Invertebrates Guild.]

STATUS

The seemingly abundant coquina clam is considered an indicator species for the sandy beach-ocean front habitat. This filter feeder is an important link in food webs, feeding on small particles such as microalgae and detritus and, in turn, being consumed by fish such as Pompano, *Trachinotus carolinus* and "whiting", *Menticirrhus* spp. (Finucane, 1969), as well as shorebirds (Nelson, 1986; DeLancey, 1989; Wilson, 1999), including ruddy turnstones, *Arenaria interpres* (Schneider, 1982) and the Federally-threatened rufa red knot, *Calidris canutus rufa* (Cohen *et al*., 2010; Karpanty *et al.,* 2010; Heller *et al.,* 2022), as well as ghost crabs, *Ocypode quadrata* (*e.g.,* Wolcott, 1978; Lucrezi, & Schlacher, 2014). Coquina clams are also consumed by humans (Miner, 1950).

POPULATION SIZE AND DISTRIBUTION

The coquina clam ranges from Virginia south through the Gulf of Mexico to Texas (Ruppert & Fox, 1988) and is common on most ocean front beach types that occur in South Carolina. The prevalence of coquina clams in this habitat makes it an excellent indicator of the health of this ecosystem.

Although current population status for these species is unknown, it appears to be common or abundant on the beaches in South Carolina. Surveys in South Carolina and the southeastern U.S. have consistently documented the occurrence of coquinas since the 1940s and have found that it is among the most abundant macroinvertebrates present in the intertidal area during spring,

where numbers have been recorded as exceeding 1000 per m^2 (Pearse *et al.,* 1942; Shealy *et al.,* 1975; Knott *et al.,* 1983).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The coquina clam is among several taxa that are uniquely adapted to live and feed in the waves as the tides ebb and flow on sandy, ocean front beaches. Coquina clams can be seen rapidly burrowing, often in groups, as waves recede down the beach (Turner & Belding, 1957). This species migrates shoreward during rising tides and seaward during falling tides, spending most of their time in the sand but emerging several times per tidal cycle to ride waves (Ellers, 1995). Like most bivalves, coquinas are filter feeders, ingesting phytoplankton, bacteria, and other small suspended particles. The sandy beach ecosystem is one of the most familiar to the public and, like other littoral habitats, is extremely dynamic, being eroded or accreted (built up) often in a period of months. Although many organisms feed in the surf zone, this clam has unique adaptations to this habitat type, making the coquina clam a key habitat indicator species.

CHALLENGES

Rising sea levels, global warming, and beach erosion are the greatest challenges to the long-term sustainability of sandy beach habitat that is required for species such as the coquina clam. The natural supply of sand borne by rivers from sources in the mountains has been curtailed by the construction of dams and reservoirs throughout the 20th century (Komar, 1998). Although beach renourishment projects restore sand to eroded beaches, these activities can significantly negatively affect populations of coquina clams and other sand dwelling invertebrates as they are buried under tons of sediment. Populations may take at least one to two years to recover following beach renourishment activities (Reilly & Bellis, 1983; VanDolah *et al.,* 1994).

Rapid coastal development also poses a problem for coquinas and other beachfront dwelling species through its associated human activities in sensitive dune areas, potential increased erosion from groins and temporary seawalls, and the disruption of sand flow. Renourishment activities could also affect the availability of prey such as *D. variabilis* to shorebirds, ghost crabs, and surf fish. As mentioned earlier, harvest by humans could also negatively impact coquina clam populations (Velez *et al.,* 1985).

CONSERVATION ACCOMPLISHMENTS

Under South Carolina's Beach Front Management Act of 1990, activities such as groin and seawall construction that may accelerate erosion have been greatly curtailed. This Act and the current administrative policy have attempted to discourage beachfront development by denying building permits and reducing funds for renourishment. In addition, intertidal beach habitats are currently protected from most construction by municipal or state setback laws such as amendments under the South Carolina Beachfront Management Act first established in 1988 (http://www.scdhec.gov/environment/ocrm/beachfront_management.htm). There have been significant strides made in the education of the public concerning the need for the protection of dunes and stabilizing vegetation. In addition, many beaches in South Carolina do not permit

motor vehicles access because of the damage these vehicles can cause to the beaches and the dunes.

Most monitoring efforts for beach invertebrates have been conducted as part of environmental impact studies required by the US Army Corps of Engineers and SC Ocean and Coastal Resource Management (OCRM) for beach renourishment projects. Future research and monitoring activities will hopefully continue to provide at least short-term estimates of the abundances for coquinas and other oceanic sandy beach organisms that can be compared to previous studies.

CONSERVATION RECOMMENDATIONS

- Periodically conduct assessments of beach invertebrates and their communities to determine their condition.
- Prepare impact models of Coastal Zone dynamics on build-up and erosion of beaches.
- Work with coastal municipalities and communities to reduce future impacts of development on beach environments.
- Work with appropriate state, local, and non-governmental agencies to discourage development on beachfront properties.
- Educate the public as to the importance of beach and dune habitat and initiate participative projects such as dune vegetation plantings.
- Encourage planned development projects in coastal zones, particularly on barrier islands, to reduce associated impacts of development on the long-term health of sandy beach habitats in South Carolina.
- Continue to investigate and document the effects of rising sea levels and global warming on beach habitats.
- Discourage the building or repair of seas walls and groins on South Carolina's beaches to allow more natural movement of sand and, ultimately, more natural beach renourishment.
- When feasible, remove dams and reservoirs that block the flow of sand and sediment from upland areas to allow for more natural beach renourishment.

MEASURES OF SUCCESS

Normal surf zone dynamics will cause beaches to accrete, erode, and move up and down the coast over decadal timeframes. The most obvious sign of success for species such as the coquina clam is the continued presence of healthy beaches with adequate, natural supplies of sand.

Crested Oyster

Ostrea stentina (= *O. equestris*)

Contributor: Nancy Hadley (SCDNR); reviewed by Peter Kingsley-Smith (2023).

DESCRIPTION

Taxonomy and Basic Description

First described by Say in 1834 as *Ostrea equestris*, the crested oyster is now considered to be *Ostrea stentina*, as described by Payraudeau in 1826 (Shilts, 2007; ITIS, 2013*)*. The new classification combines oysters previously known as *O. equestris* (Caribbean and North Atlantic), *O. spreta* (South America), and *O. auporia* (New Zealand) with the type species *Ostrea stentina* (Mediterranean). Thus, this species has a worldwide distribution in middle latitudes. In the Mediterranean ,this oyster is known as the dwarf oyster or Provence oyster.

Members of the genus *Ostrea* are brooding oysters and are usually confined to subtidal regions to avoid dessication during the brooding period. This species is small, rarely observed larger than 5 cm, and has no commercial value. Abbott (1974) described this oyster as "usually oval; lower valve has a high, vertical crenulated margin; muscle scar almost central; interior pearly-green to gray; edge of upper valve has a row of denticles." Although oysters fitting this description, with a ruffled edge due to the folds or crenulations on the lower valve, have been observed in South Carolina, crested oysters from oyster reefs in this state are often flat, with no obvious ruffles or folds (as in the picture above). The exterior of the shell may have light purple markings on the outer edges. The crested oyster is distinguished from juvenile Eastern oysters (*Crassostrea virginica*) by the presence of small denticles (teeth) on the interior of the upper valve (Abbott, 1974). These are indicated with arrows on the picture above and are the primary characteristic that SCDNR biologists use to distinguish this oyster from juvenile *C. virginica*.

Status

The crested oyster is not a listed species but has received attention as a potential host for *Bonamia* spp. which are microcell haplosporidian parasites that infect oyster hemocytes. *Bonamia* spp. are serious pathogens of oysters, causing high mortality in susceptible species, but represent no human health threat. Until recently, *Bonamia* spp. were not known to infect *Crassostrea spp.* The only harvestable oyster in South Carolina is *C. virginica*. In susceptible species, mortality from *Bonamia* infections can exceed 90%. The European oyster industry (*Ostrea edulis*) was devastated by *Bonamia* infections beginning in the late 1970s (Balouet *et al.,* 1983; Elston *et al.,* 1986), and the New Zealand oyster (*Ostrea chilensis*) suffered massive losses in the late 1980s (Hine, 1991; Hine *et al*., 2001). *Bonamia* spp. infections were reported in the non-native oyster *C. ariakensis* during experimental introductions in North Carolina in 2003 (Burreson *et al.,* 2004; Carnegie *et al.,* 2008). In 2005, *Bonamia* spp. were observed in native *O. stentina* in North Carolina (Carnegie *et al.,* 2005, 2006), leading to concern that *O. stentina* might be serving as a reservoir and vector for the parasite (Bishop *et al.,* 2006). In 2012 and 2013, *Bonamia* infections were reported for the first time in *C. virginica* from North Carolina

and Massachusetts (Carnegie & Bushek, 2013). The parasites were identified as *Bonamia exitiosa* (Carnegie & Bushek, 2013), the species responsible for mortalities of *O. chilensis* in New Zealand (Hine *et al.,* 2001). *Bonamia exitiosa* is included on the World Organization for Animal Health list of notifiable pathogens. Ballast water is thought to be the source of *Bonamia* spp. introductions (Bishop *et al*., 2006) but its proliferation and range expansion could be facilitated by *O. stentina* (Schott *et al.,* 2008; Bishop *et al.,* 2006). Thus, greater knowledge of the distribution of *O. stentina* and its infection with *Bonamia* spp. is needed in order to fully understand the implications for the oyster industry in the southeastern United States. The extensive geographic distribution of *B. exitiosa* parasites belonging to the cosmopolitan and Atlantic Coast groups described by Hill-Spanik *et al.* (2015) may relate to both natural and anthropogenic dispersal of a single host*, O. stentina*, which is distributed from the eastern Americas to the Mediterranean and African coast to New Zealand—that is, in most regions where *B. exitiosa* has been found to occur.

POPULATION SIZE AND DISTRIBUTION

Ostrea stentina is found in high salinity waters (> 20 ppt) from North Carolina to the West Indies and in the Gulf of Mexico (Wells, 1961; Galtsoff & Merrill, 1962), along the Mediterranean coastlines, and in New Zealand. Although earlier literature indicates that this species is confined to subtidal regions (Galtsoff & Merrill, 1962), a survey in North Carolina (Markwith, 2010) found this species in a wide range of habitats from the mid-intertidal down into the subtidal. It was most abundant on floating docks, low intertidal oyster reefs, and low intertidal shell hash with a patchy distribution, with patch densities ranging from 5 to 125 oysters/0.25m^2. On North Carolina oyster reefs, *O. stentina* was found to represent up to 10% of the population in sampled areas. It is thought to prefer higher salinity regimes than *C. virginica* and population shifts have been reported in relation to drought (Hoese, 1960; Galtsoff & Merrill, 1962), with *C. virginica* dominating in wet periods and *O. stentina* dominating in dry periods. In conjunction with oyster reef studies in South Carolina, crested oysters were observed on shells of *C. virginica* at 24 sites in 2006 (SCDNR unpublished data). Abundance was quantified on restored oyster reefs at one site near Charleston, SC. Distribution was patchy, with localized abundances as high as 400 m^{-2}, although overall abundances were much lower, ranging from 46 m^{-2} in the mid-intertidal to 134 m^{-2} in the low intertidal. *Ostrea stentina* represented 68% of the live oysters found in the lowest intertidal region but only 1% in the mid-intertidal region of the restored reefs. The largest crested oyster observed in that study was 36 mm in shell height. Due to the challenges of distinguishing *O. stentina* from *C. virginica* (described above), it may be easily overlooked and therefore more abundant than previously thought.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The crested oyster has been observed on low intertidal oyster reefs in NC, SC, and GA as well as on manmade structures (*e.g.*, pilings, floating docks, buoys) and subtidal hard bottom (*e.g.,* shell hash). It appears to be limited to higher salinities (Menzel, 1955; Markwith, 2010) and the lower intertidal or subtidal regions (Markwith, 2010; SCDNR unpublished data). In natural habitats, it attaches primarily to other shell material and appears to favor degraded oyster shells, although it will also settle on scallop shells and pen shells. This species does not form reefs.

CHALLENGES

Little is known about the distribution and abundance of *O. stentina* in South Carolina. The potential of this species to harbor *Bonamia* spp. parasites and the first ever report of *Bonamia exitiosa* in *C. virginica* are cause for concern and warrant further study of South Carolina populations of *O. stentina*, especially given that *Bonamia* spp. infections have decimated oyster populations in Europe and New Zealand. The recent revelation that these parasites can infect *C. virginica* makes vigilance in controlling importations from other geographic areas paramount. The SCDNR bans the introduction of non-native species (*e.g., C. ariakensis*) and requires importation permits for native species. These importation permits are contingent on negative results from disease diagnostic testing but it is important to update testing requirements frequently as new parasites such as *Bonamia exitiosa* are identified.

CONSERVATION ACCOMPLISHMENTS

The SCDNR has an indigenous species importation policy requiring negative disease tests for all importations. The SCDNR does not allow importation of non-indigenous species. Some preliminary data on the distribution and density of *O. stentina* has been gathered incidental to other studies on oyster reefs.

CONSERVATION RECOMMENDATIONS

- Cooperate with investigators from other institutions who are evaluating the presence of disease organisms in crested oysters and related issues.
- Continue to require disease testing for indigenous shellfish importations.
- Update disease diagnostic requirements for indigenous shellfish importations at least annually and whenever alerts are received.
- Collect information on the distribution and abundance of crested oysters in SC.

MEASURES OF SUCCESS

South Carolina's oyster populations have been largely unaffected by disease issues which have been problematic in other Atlantic states. A continuing absence of disease epizootics (which might in some cases be facilitated by *O. stentina*) would be considered a measure of success.

Eastern Oyster

Crassostrea virginica (Gmelin, 1791)

Contributor: Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Eastern oyster, *Crassostrea virginica*, was first identified by Gmelin (1791) and over time has been shown to be synonymous with a number of other species. Harry (1985) recognized only 4 species in the genus *Crassostrea*, namely *C. angulata, C. virginica, C. columbiensis, and C. gigas*. Menzel (1987), observing ease of hybridization and chromosomal patterns in hybrids, suggested that *C. virginica, C. columbiensis* and *C. gigas* should be considered the same species with *C. columbiensis* and *C. rhizophorae* being subspecies of *C. virginica*. *Crassostrea v. guyensis* and *C. v. lacerate*—reported from Venezuela—are subspecies of *C. virginica* (Ahmed, 1975), and *C. crassa, C. brasiliana*, and *C. floridensis* are synonyms of *C. virginica* (Abbott, 1974; Quayle, 1980; Castillo-Rodriguez & García-Cubas, 1986). Ahmed (1971, 1975) believed *C. madrasensis* in India and Pakistan to be *C. virginica* based on their very close morphological similarities, while Lamy (1929-1930) reported many other synonyms of *C. virginica* (see also papers by Reece *et al.*, 2008, Cordes *et al.* 2008 and references therein).

The Eastern oyster, *Crassostrea virginica* (Phylum Mollusca; Class Pelecypoda or Bivalvia; Order Lamellibranchia; Family Ostreidae) is a monomyarian (anterior adductor muscle has been lost) lamellibranch with a pronounced bilateral asymmetry and restricted coelom typical of the class (Seed, 1983). The shell of *C. virginica* consists of two calcareous valves, joined by a resilient hinge ligament, and serves as an exoskeleton to support the soft internal organs and prevent the collapse of the mantle cavity. The left valve is almost always thicker and heavier than the right valve and more deeply cupped (Yonge, 1960; Galtsoff, 1964), while the post-settlement form is cemented to the substrate on the left valve. Shell hinge teeth are absent in *C. virginica*, although a buttress on the right valve fits into a depression on the left valve (Stanley & Sellers, 1986). The interior of the shell of *C. virginica* has a purple pigmented adductor muscle scar located slightly posteriorly and ventrally. This feature can be used to distinguish *C. virginica* from other similar species of *Crassostrea* (*e.g.*, lightly pigmented in *C. rhizophorae* and *C. gigas*; unpigmented in *C. rivularis*). A second muscle scar—of the Quenstedt's muscle—is situated ventral to and a short distance from the hinge (Stanley & Sellers, 1986). Species of *Crassostrea* are distinguishable from species of *Ostrea* by the promyal chamber which is well-developed in *Crassostrea* but not in *Ostrea*. The growth form of *C. virginica* is highly variable (McLean, 1941) and is strongly affected by environmental conditions.

The internal organs of bivalves are covered by a fleshy fold of tissue called the mantle that deposits the shell. The gills of *C. virginica* consist of four folds of tissue that are suspended from the visceral mass and occupy much of the mantle cavity. Together with the mantle, the gills are the main organs of respiration and create water currents that enable food particles to be captured

and sorted by the labial palps prior to ingestion at the mouth and digestion. Extensive communities of filter-feeding bivalves are capable of improving water clarity and quality through high filtration rates associated with feeding and the transfer of nutrients from the water column to the benthos (Ulanowicz & Tuttle, 1992; Dame, 1999; Dame *et al.*, 2001; Newell, 2004; Porter *et al.*, 2004). The most comprehensive work describing the anatomy and histology of *C. virginica* is that by Galtsoff (1964), with a thorough review of many aspects of the biology and ecology of this species having recently been compiled by Kennedy *et al.* (1996).

Crassostrea virginica is a protandric, gonochoristic or dioecious alternate hermaphrodite (Coe, 1943; Mackie, 1984) with an annual reproductive cycle that culminates in spawning and external fertilization in the water column. Reproduction is typically triggered by periods of higher water temperatures (*e.g.*, Loosanoff & Davis, 1963) that support abundant phytoplankton that enable larvae to grow rapidly. Adult oysters are responsive to macroscale environmental changes that stimulate gametogenesis and spawning when conditions are suitable for larval survival and gametogenesis. These processes are synchronized between the sexes such that eggs and sperm are released concurrently, maximizing the number of eggs that are successfully fertilized. Following fertilization, blastula and gastrula stages occur, and the first larval form (trochophore) hatches from the egg and begins to swim (Galtsoff, 1964). The trochophore persists for 24 to 48 hours, depending on water temperatures, before developing into the veliger (or D-shape) stage which is protected by the larval shell. The planktotrophic veliger stage, which typically lasts 2 to 3 weeks, takes its name from the 'velum'—a structure that enables the veliger to swim and feed and which is resorbed after settlement (Baker & Mann, 1994). Temperature and food supply affect the length of the larval period, with increases in time undoubtedly leading to decreased survival due to extended exposure to predators and disease (Underwood & Fairweather, 1989). Larvae that survive in the plankton to reach the "eyed" stage explore the substrate as pediveligers, searching for suitable locations to adopt the permanently benthic form whereupon cementation occurs. Early post-settlement and post-metamorphic stages in bivalves are referred to as "spat" which feed, grow, and mature into the adult form.

Status

Crassostrea virginica is not State or Federally listed, although this species plays a pivotal ecological role in the health of marine and estuarine ecosystems as an individual species and collectively as a priority habitat (reef). Populations of *C. virginica*, have declined along much of the mid-Atlantic coast of the United States during the last century due to a combination of over-harvesting (Gross & Smyth, 1946), habitat degradation (Rothschild *et al.*, 1994), reduced water quality (Seliger *et al.*, 1985), disease (Ford & Tripp, 1996; Lenihan *et al.*, 1999), the interactions among these factors (Lenihan & Peterson, 1998), and ecosystem shifts (see Rothschild *et al.*, 1994; Luckenbach *et al.*, 1999; Dame *et al.*, 2002). Newell (1988) estimated that the extant population of *C. virginica* in Chesapeake Bay was approximately 1% of the biomass present a century earlier. Furthermore, Beck *et al.* (2009) recently highlighted the imperiled status of shellfish habitats, with an estimated 85% loss of habitat on a global scale, placing them as the most threatened of marine habitats. Wild populations of *C. virginica* are harvested both commercially and recreationally in South Carolina, and aquaculture on leased grounds (culture and mariculture permit areas) is increasing. To ensure that populations of *C. virginica* in South Carolina remain abundant, extensive efforts at the SCDNR Marine Resources Division—both by

the Office of Fisheries Management and the Marine Resources Research Institute Shellfish Research Section—continue to be directed towards assessments of the distribution of *C. virginica* statewide to monitor changes in the acreage and condition of intertidal oyster reef habitat using ground-, boat-, and remote sensing survey techniques.

POPULATION SIZE AND DISTRIBUTION

The Eastern oyster, *Crassostrea virginica* is distributed in the Western Atlantic along the coasts of Brazil and Argentina northwards through the Caribbean and Gulf of Mexico to the St. Lawrence River estuary in eastern Canada, representing a range of some 8,000 km (4,971 mi.) (Buroker, 1983; Newball & Carriker, 1983; García-Cubas *et al.*, 1987; Andrews, 1991). *Crassostrea virginica* has also been introduced to a wide geographic range of localities, including the west coast of North America, Hawaii, Australia, England, Japan, and possibly other areas, but in general has not become established there (Quayle, 1988; Arakawa, 1990). A review of non-native oyster introductions and the ecological consequences and restoration implications of these actions was provided by Ruesink *et al.* (2005).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Crassostrea virginica is critically dependent on a mixture of saltwater with freshwater from land drainage (Butler, 1954) and therefore occurs commonly in estuaries and coastal areas of reduced salinity as extensive reefs on hard to firm bottoms, both intertidally and subtidally (Meyer & Townsend, 2000; Wilson *et al.*, 2005). *Crassostrea virginica* forms extensive, 3-dimensional reef habitat through the settlement of competent larvae on the shells of previous generations. The natural environmental factors governing the distribution of *Crassostrea virginica* were reviewed by Shumway (1996). Adult *C. virginica* are highly tolerant of broad ranges in salinity and temperature, making them well-suited to life in the estuary and, in South Carolina, to a predominantly intertidal distribution. Adult oysters are found in waters where the annual temperature range is from -2°C to 36°C (Butler, 1954; Gunter, 1954; Galtsoff, 1964). Galtsoff (1964) reported that oysters can survive intertidal temperatures of 46°C to 49°C when exposed at low tide. In terms of salinity, across its geographic range, *C. virginica* occurs from ~ 5 ppt to ~40 ppt (Galtsoff, 1964; Wallace, 1966). If left undisturbed in an optimal environment, oysters will continue to grow for many years. Galtsoff (1964), for example, reported a maximal shell height of *Crassostrea virginica* of 36 cm (14 in.), although the majority of oysters experience mortality prior to reaching this size.

More than 95% of the South Carolina oyster populations are intertidal (Bahr & Lanier 1981; Burrell 1986), consisting of 3-dimensional, multi-generational, vertical clusters of oysters. The vertical height of oyster reefs in an otherwise 2-dimensional sedimentary landscape and the interstitial space generated by these clusters are central to the ecosystem services that they support. Historically, both intertidal and subtidal populations of *C. virginica* were distributed widely throughout coastal South Carolina; however, reported landings of subtidal populations of *C. virginica* have seen a steep decline since the mid-1900s. Anecdotal information from SCDNR shellfish managers and commercial growers indicates that certain estuaries still support limited subtidal populations of *C. virginica*. A targeted habitat survey of subtidal oysters in South Carolina, however, has not been undertaken in more than 50 years (Keith and Cochran 1968).

Intertidal *C. virginica* populations (both natural and restored), unlike subtidal populations, form natural breakwaters that protect fringing salt marshes from erosion (*e.g.,* Meyer *et al.,* 1997; Coen & Luckenbach, 2000; Piazza *et al.,* 2005), and support the proliferation of new cordgrass (Spartina alterniflora) habitat (*e.g.,* Kingsley-Smith *et al.,* 2023). South Carolina has more acreage of salt marsh than any other Atlantic Coast state (Newell & Pearson, 2009), and much of it is protected by adjacent intertidal oyster reefs. Many of the species utilizing these habitats take advantage of their close proximity to one another as both nursery and foraging grounds.

CHALLENGES

Salinity affects the distribution of oysters directly through its physiological consequences on the oysters themselves and indirectly through its role in determining the relative incidence of predators (*e.g.,* fish, gastropods, crabs, and polyclad flatworms), pests (*e.g.,* boring sponges, mud worms, pea crabs), competitors (*e.g.,* barnacles, sponges, bryozoans, and other molluscs), and disease-causing protistan parasites, in particular those responsible for the endemic diseases MSX (*Haplosporidium nelsoni*) and Dermo (*Perkinsus marinus*). These challenges to oyster populations generally increase at higher salinities.

Crassostrea virginica has been heavily exploited and widely cultivated throughout much of its geographic range (Galtsoff, 1964; García-Cubas *et al.,* 1987; Quayle & Newkirk, 1989; Andrews, 1991; Menzel, 1991; Nascimento, 1991). Sustainable management of state and public shellfish grounds and Best Management Practice (BMP) approaches to aquaculture, are therefore important for the long-term viability of *C. virginica* populations in South Carolina. Although *C. virginica* in South Carolina has not been as extensively exploited as the *C. virginica* populations in the mid-Atlantic States, the rapid pace of coastal development has created numerous threats to tidal creek habitats with inevitable undesirable impacts (*e.g.,* Lerberg *et al.,* 2000; Holland *et al.,* 2004; Van Dolah *et al.,* 2004). Particularly, these involve increased runoff from upland clearing and associated non-pervious surfaces, contaminants (which are particularly detrimental to larval stages), such as pesticides and heavy metals, (see Capuzzo, 1996 and Roesijadi, 1996, respectively, for reviews), water quality closures resulting in concentrated harvest pressure on open, harvestable beds, impacts from dredging and other channel manipulations, and boat-related impacts. Boat wakes and intense harvesting can both easily damage intertidal reefs, and the vegetated marsh habitats protected by these reefs can rapidly erode when the reefs are compromised (*e.g.,* Kennish, 2002). Furthermore, several South Carolina estuaries including Charleston Harbor, Winyah Bay, and Port Royal Sound have been heavily impacted by industrial activities, shipping, chronic pollution, and habitat destruction related to urbanization. These threats to oyster reefs have prompted extensive efforts to protect, restore, and enhance these critical coastal habitats.

CONSERVATION ACCOMPLISHMENTS

Oyster reefs are now broadly recognized as “ecosystem engineers” (see Luckenbach *et al.,* 1999; Gutiérrez *et al.,* 2003; ASMFC, 2007) that form complex habitats utilized by numerous finfish, invertebrates, wading birds, and mammals (Coen *et al.,* 1999; Lehnert & Allen, 2002; ASMFC, 2007; Peterson *et al.,* 2003; Shervette & Gelwick, 2007, 2008). Within the Southeast Region, the South Atlantic Fishery Management Council (SAFMC) has designated estuarine marshes, oyster

reefs, associated estuarine water columns, intertidal flats, and areas of submerged aquatic vegetation (SAV) as essential fish habitat (EFH). In South Carolina, oyster reefs are also considered critical habitats of concern in both the State Conservation Plan and the State Wildlife Action Plan (formerly the CWCP), primarily due to their provision of habitat for a number of species of concern (*e.g.,* Atlantic blue crab, *Callinectes sapidus*; stone crab, *Menippe mercenaria*; southern flounder, *Paralichthys lethostigma*; and the American oystercatcher, *Haematopus palliatus*). Both the ACE Basin National Estuarine Research Reserve (NERR) and the North Inlet-Winyah Bay NERR list oyster reefs as important habitat, and The Nature Conservancy recently completed a biological assessment of the Carolinian Ecoregion that specifically identified oyster reefs as a priority conservation target (DeBlieu *et al.,* 2005).

Oyster reefs provide essential habitat for federally-managed (ASMFC) species such as red drum (*Sciaenops ocellatus*), southern flounder (*Paralichthys lethostigma*), Atlantic croaker (*Micropogonias undulatus*), spot (*Leiostomus xanthurus*), black sea bass (*Centropristis striata*), spotted sea trout (*Cynoscion nebulosus*), Atlantic menhaden (*Brevoortia tyrannus*), members of the snapper-grouper complex (managed by SAFMC), Atlantic blue crab (*Callinectes sapidus*), and penaeid shrimp species (Shervette & Gelwick, 2007, 2008). A number of prey species of the southern founder, *P. lethostigma*, a South Carolina priority species in the SWAP, for example, have been shown to be associated with edge habitats, including oyster reefs (Reagan, 1985). Many of these species depend on the inter-relationships of oyster reefs and adjacent marsh habitats for their survival during various life stages. In turn, these species provide prey for SAFMC-managed species such as Spanish mackerel (*Scomberomorus maculatus*), King mackerel (*Scomberomorus cavalla*), and cobia (*Rachycentron canadum*), as well as NOAA Fisheries-managed highly migratory species (HMS), such as sharks and billfishes.

Numerous species prey directly on oysters, including xanthid crabs, such as the stone crab, *M. mercenaria* and the Atlantic mud crab, *Panopeus herbstii* (Tolley & Volety, 2005), both species of concern in SC. In turn, several finfish species, including the naked goby (*Gobiosoma bosc*) and the striped blenny (*Chasmodes bosquianus*), are known to feed on these xanthid crabs, generating trophic complexity and the potential for the formation of trophic cascades (Grabowski, 2004). Mann & Harding (1998) investigated the trophic interactions among oysters, fishes, and benthic predators on restored oyster reefs and showed that small and intermediate sized fishes such as gobies (*e.g.,* seaboard goby, *Gobiosoma ginsburgi* and *G. bosc*) and blennies (*e.g.,* feather blenny *Hypsoblennius hentz* and *C. bosquianus*), were abundant in Chesapeake Bay oyster reef-dominated ecosystems. The presence of these species on reef structures is thought to attract larger pelagic predatory species such as southern flounder (*P. lethostigma*), striped bass (*Morone saxatilis*), bluefish (*Pomatomus saltatrix*), weakfish (*Cynoscion regalis*), sheepshead (*Archosargus probatocephalus*), and spotted seatrout (*C. nebulosus*). Other benthic predators, such as the Atlantic blue crab (*C. sapidus*)—another South Carolina priority species for conservation—have also been shown to be strongly associated with *C. virginica* reefs (Mann & Harding, 1998).

Several studies have shown that the 3-dimensional structure of oyster reefs attracts greater numbers of resident and transient nektonic species than sand- or mud-bottom habitats (Posey *et al.,* 1999; Harding & Mann, 2001; Lenihan *et al*., 2001; Plunket & Peyre, 2005; Coen *et al*., 2007; Kingsley-Smith *et al*., 2013). Breitburg (1999) defined 3 groups of nekton associated with

subtidal *C. virginica* reefs in the Chesapeake Bay: (1) reef residents whose primary habitat is the reef; (2) facultative residents generally associated with structured habitats; and (3) transient species which forage on or near the reef but are wide-ranging. Furthermore, a number of oyster reef resident fishes—including *G. bosc*, *C. bosquianus, H. hentz,* the freckled blenny (*Hypsoblennius ionthas*), skilletfish (*Gobiesox strumosus*), oyster toadfish *Opsanus tau,* and Gulf toadfish (*O. beta*) have been shown to be dependent on oysters for reproduction, depositing their eggs on or inside oyster shells (Breitburg, 1999; Coen *et al.,* 1999). In summary, it appears that the diverse range of organisms associated with oyster reefs creates complex food webs that sustain higher trophic levels than surrounding sediment or marsh habitats (Wrast, 2008; Quan *et al*., 2012). Additionally, oyster reefs serve as critical foraging habitat for the American oystercatcher, *Haematopus palliatus* (a Species of Concern of Highest Priority) and other shorebirds such as egrets, herons, sandpipers, plovers, and godwits, all of which are listed in the South Carolina SWAP as species of highest priority. The largest concentration of overwintering *H. palliatus* occurs in South Carolina, utilizing oyster reefs as foraging grounds (Tomkins, 1947; Sprunt & Chamberlain, 1949; Nol *et al.,* 2000). A recent study by Sanders *et al.* (2004) also highlighted the importance of washed shell rakes as roosting sites for *H. palliatus*.

In recognition of the value of oyster reefs as critical habitats, considerable efforts have been made to successfully secure Federal funding in support of research and community-based restoration and enhancement projects utilizing a variety of traditional (bagged and loose oyster shell) and alternative materials (*e.g.,* revitalized abandoned and unwanted crab traps, manufactured wire reefs) to increase the availability of oyster reefs as habitat for a diverse array of associated fauna, including a number of high priority conservation species. Furthermore, as protection for existing *C. virginica* populations, the South Carolina Department of Natural Resources regulates the importation of oysters for placements in its State waters, primarily for mariculture, requiring inspections for the presence of "hitch-hiker species" upon arrival in the State and restricting importation from areas of known diseases (such as Dermo and MSX). Disease testing is required prior to importation, with zero tolerance for the presence of known diseases. Hatchery certification is also available to permit the importation of oyster seed from other states, provided a number of criteria, protocols, and procedures related to water quality and disease are satisfied.

CONSERVATION RECOMMENDATIONS

- Apply both traditional and alternative approaches to oyster reef habitat restoration and enhancement activities, and engage the community in conservation and stewardship through volunteer opportunities.
- Conduct scientifically rigorous monitoring to evaluate the habitat value of oyster reefs to conservation priority species as well as commercially, recreationally, and ecologically-important species of finfish, invertebrates, and birds.
- Regularly update importation policies for cultured oysters to reflect changes in threats to native oysters and to make the best use of all available information and technology.
- Regulate recreational and commercial harvesting of wild oyster populations and mariculture activities in collaboration with SCDHEC in order to ensure sustainable harvesting and to protect human health.

- Monitor the population status of oysters statewide using on-the-ground efforts, aerial surveys and remote sensing techniques, and GIS applications.
- Collaborate with the appropriate agencies and municipalities to improve and implement Best Management Practices in terms of responsible urban planning to minimize and mitigate the effects of terrestrial freshwater inputs on oyster populations.

MEASURES OF SUCCESS

Determining that populations of *C. virginica* in South Carolina are remaining stable through the collection of annual fishery statistics and population monitoring would constitute a measure of success. An absence of human health problems would also be a measure of success in demonstrating the effectiveness of the collaborative resource management implemented by the SCDNR and SCDHEC. Continued monitoring of the fauna associated with natural, restored, and enhanced reef habitats—and in particular demonstrating their value to priority conservation species—would also be a measure of success.

DESCRIPTION

The members of the Estuarine Sensitive Taxa Guild are benthic macrofauna commonly found in South Carolina estuaries that have been identified as pollution sensitive by a benthic index of biological integrity for assessing habitat quality in estuaries of the southeastern USA (Van Dolah *et al.,* 1999). Benthic macrofauna serve as ecologically important components of the food web by consuming detritus, plankton, and smaller organisms living in the sediments and in turn serve as prey for finfish, shrimp, and crabs. Benthic macrofauna are also relatively sedentary, and many species are sensitive to changes in environmental conditions. As a result, these organisms are important biological indicators of water and sediment quality and are valuable to monitoring programs that assess overall coastal and estuarine health (Hyland *et al.,* 1999; Van Dolah *et al.,* 1999).

Taxonomy and Basic Description

Amphipods are in the taxonomic order Amphipoda of malacostracan crustaceans which have no carapace and generally laterally compressed bodies. Amphipods in the family Ampeliscidae are distributed worldwide. Ampeliscid amphipods are often the dominant amphipod group in fine sediment areas where they live in infaunal tubes that they construct from 'amphipod silk' and sediment (Barnard, 1960, 1969). *Ampelisca* species have four eyes, each with a thickened lens (Ruppert & Fox, 1988). Members of the Ampeliscidae can be difficult to distinguish from one another. The common species in South Carolina estuaries, *Ampelisca abdita*, is characterized by subtle differences from other species in its epimeral plates and uropods.

Neohaustorius schmitzi, Parahaustorius longimerus and *Protohaustorius wigleyi* are burrowing amphipods of the family Haustoriidae. Haustorids are characterized by their white, barrel-shaped body, and the lack of a true rostrum and dactyls on pereopods 3-7.

The amphipod family Phoxocephalidae is a strictly marine group of abundant, free-living benthic amphipods that primarily inhabit soft substrates as burrowers. *Rhepoxinius hudsoni* is a common phoxocephalid amphipod in southeastern U.S. estuaries, differentiated from a similar species, *R. epistomus*, by a spine and the setal patterns of the uropods and epimera (Barnard & Barnard, 1982).

Cyathura spp. are members of the crustacean order Isopoda that are small (1") and often confused with amphipods. Unlike amphipods, isopods are dorsoventrally flattened (depressed) and have no carapace. *Cyathura* species commonly found in South Carolina, namely *C. polita* and *C. burbancki*, are distinguished by whether or not the sixth pleonal segment is fused to the telson.

Species of the genus *Tellina* are members of the bivalve family Tellinidae. Tellin clams are small (usually < 1"), laterally compressed, and usually have a slight twist at the posterior end (Abbott, 1974). Color can vary from iridescent white to pale pastels.

Aphelochaeta, *Caulleriella, Monticellina* and *Tharyx* are all genera belonging to the polychaete family Cirratulidae. Members of this family are cylindrical, elongate (up to 1"), and characterized by cone or wedge-shaped heads that have no antennae. Cirratulid bodies are generally cylindrical, tapering at both ends, and are characterized by a large number of long, simple, thread-like hairs along the body. Some of the "hairs" occur as clusters of tentacles on the head and are grooved to facilitate deposit-feeding. Species in the genus *Mediomastus* are members of the polychaete family Capitellidae. Capitellid worms are red or purple in color with thread-like, flexible bodies that grow up to 4" in length. They are characterized by their conical shaped head and reduced appendages.

The polychaete worm, *Streblospio benedicti*. Photo courtesy of Southeastern Regional Taxonomic Center (SERTC).

Streblospio benedicti is a member of the tube-dwelling polychaete family Spionidae. Spionids, or palp worms, are characterized by their small heads and two long grooved palps used for deposit or suspension feeding. Spionids are mostly small (<6"), but large species do exist.

Tubficoides wasselli and other *Tubificoides* species are worms in the class Oligochaeta. Oligochaete worms are distinguished from polychaete worms by their lack of parapodia and a reduced prostomium (head) which lacks appendages. Marine oligochaetes resemble earthworms in appearance although they are much smaller (~1", Ruppert & Fox, 1988).

Status

None of the species in this guild are officially recognized as threatened or endangered, but all are part of the benthic macrofaunal community in southeastern U.S. estuarine habitats. The benthic macrofaunal community serves as an important source of food for juvenile finfish such as spot (*Leiostomus xanthurus*) and weakfish (*Cynosion regalis*) and is also used as an early indicator of degraded habitats.

POPULATION SIZE AND DISTRIBUTION

The ampeliscid amphipod, *A. abdita*, is found in fine or silty sand in the protected waters of estuaries and bays from central Maine to the Indian River Lagoon system in Florida (Bousfield, 1973; LeCroy, 2000). Population size estimates are difficult to establish due to spatial and seasonal variation; however, the South Carolina Estuarine and Coastal Assessment Program (SCECAP) has recorded abundances as high as 25,000 individuals per m^2 in estuarine areas (Bergquist *et al.,* 2009, 2011; Van Dolah *et al.,* 2002a, 2004, 2006, 2013).

Haustorid amphipods are very abundant along the intertidal gradient of the US East Coast (Bliss *et al.,* 1983). The haustorid amphipods in this guild range from Saco Bay, ME through Cape Canaveral, FL (Bousfield, 1973; Grant & Lazo-Wasem, 1982). Although the distribution of this group is well documented, population size can vary considerably by location and season and would be difficult to quantify.

The phoxocephalid amphipod, *R. hudsoni*, is found burrowed in sandy areas from Maine to South Carolina at depths from 4 to 161 m. Abundances recorded from the SCECAP program range from 22-9,150 individuals per m^2 (Bergquist *et al.,* 2009, 2011; Van Dolah *et al.,* 2002a, 2004, 2006, 2013).

Isopods in the genus *Cyathura* range from Maine to Florida in the Eastern US. Abundances recorded from the SCECAP program range from 22-1,089 individuals per m^2 (Bergquist *et al.,* 2009, 2011; Van Dolah *et al.,* 2002a, 2004, 2006, 2013).

Members of the family Tellinidae, especially the genus *Tellina*, are very common on the South Carolina coast (Ruppert & Fox, 1988). Due to the numerous species within this genus, population size is difficult to estimate. Most of the species commonly found in the southeastern U.S. range from the Mid-Atlantic (Virginia/North Carolina) to Florida (Abbott, 1974).

Cirratulids in the genera *Aphelochaeta*, *Caulleriella, Monticellina* and *Tharyx* are found worldwide, and most species range from the Gulf of Maine through Florida on the East Coast of the US. Little information has been reported on population estimates of cirratulids; however, a benthic invertebrate survey in New York reported *T. acutus* abundances of 80 individuals m^{-2} (USACE, 2004).

Mediomastus sp. are very abundant on the East Coast of the US. Identifications to species level in the genus *Mediomastus* are often difficult due to the collection of incomplete worms, but there are several species that occur in high abundances on the U.S. Atlantic Coast.

The spionid polychaete, *Streblospio benedicti* occurs along the Atlantic US coast from Maine south to Florida. Studies on *S. benedicti* abundance on the East Coast have reported the species to be among the most abundant and characteristic taxa occurring in Gulf of Maine mud flats (Larsen & Dogget, 1991) and among four taxa dominating North Carolina saltmarsh macrofauna (Cammen, 1979). In South Carolina, *S. benedicti* is one of the most abundant invertebrates found in estuarine samples with abundances ranging from 25 to ~14,000 individuals per m^2 (Bergquist *et al.,* 2009, 2011; Van Dolah *et al.,* 2002a, 2004, 2006, 2013).

Members of the family Tubificidae (*T. wasselli*, *Tubificoides* sp.) found in the southeastern U.S. appear to be specific to the zoogeographic region from Cape Hatteras to Florida (Baker, 1984). SCECAP abundances from 1999-2010 range from 22 to 14,589 individuals per m^2 (Bergquist *et al.,* 2009, 2011; Van Dolah *et al.,* 2002a, 2004, 2006, 2013).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Members of the estuarine sensitive taxa guild are benthic macrofauna that live in estuarine habitats in South Carolina's Coastal Zone. The sheltered waters of estuaries provide habitat for many organisms that are specially adapted for life in a range of salinities. The macrofauna in this guild are found in the many types of habitats in and around estuaries, including shallow open waters, salt marshes, swamps, sandy beaches, mud and sand flats, rocky shores, and oyster reefs.

Ampeliscid amphipods are infaunal organisms that live in protected sand flats. They prefer muddy or sandy bottoms where they build lined tubes embedded with sediment grains. The tubes protrude above the surface of the sediment where the amphipods use water currents or their appendages for filter feeding.

Haustorid amphipods are free-swimming amphipods which are adapted for burrowing in sandy or silty substrate. They prefer a variety of intertidal areas including exposed and protected beaches, inlet entrances, and estuaries with fine sand or mud. They can be found from mean low water to a depth of 50 m, in salinities from 6 ppt to fully marine, depending on the species (Bousfield, 1973).

Phoxocephalids, such as *R. hudsoni*, are free-living benthic amphipods that primarily inhabit soft substrates as burrowers. They are omnivorous, detritivores, and opportunistic predators found in all oceans and at all depths.

Cyathura species of isopods burrow in mud and muddy sand and have a high tolerance for changes in physical factors such as salinity that occur commonly in shallow water estuarine habitats (Schultz, 1969).

Tellinid clams are mud or sand dwellers with a worldwide distribution. The tellinids are active infaunal burrowers in soft sediments, usually in the silty sand of protected beaches (Ruppert & Fox, 1988). Unlike other bivalves, tellinids are deposit feeders who burrow horizontally through the sediment to seek fresh deposits of particulate organic material.

Capitellid worms, such as *Mediomastus* sp., are sedentary deposit feeders that often occur in mud or muddy sand on the lower shore to sublittoral zone. They may be found under pebbles or small stones, with the burrows at or near the surface of the sediment where they feed on deposited organic material (Ruppert & Fox, 1988).

Members of the polychaete family Cirratulidae (*Aphelochaeta* sp., *Caulleriella* sp., *Monticellina* sp., *Tharyx acutus*) are sluggish-type worms that inhabit medium to fine sand or muddy sediments. Cirratulids mostly burrow in soft sediments, but some live in rock crevices. They can be found buried just below the surface of the sediment with only their feeding appendages exposed.

Streblospio benedicti prefers soft sediments in which it can form a mucoid tube just below the sediment-water interface that allows it to deposit feed. *Streblospio benedicti* is relatively tolerant of elevated levels of sediment organics (Reish, 1979), a trait that contributes to its success as an opportunistic species.

Tubificoides wasselli and other *Tubificoides* species are common in estuarine habitats in South Carolina, especially those habitats with a high organic content (Ruppert & Fox, 1988).

CHALLENGES

South Carolina's Coastal Zone includes a variety of sensitive habitats that serve as critical nursery grounds for most of the State's commercial and recreational fisheries resources. Rapid population growth and development along South Carolina's coastline threaten the vitality of our state's natural marine resources. In addition to their natural beauty and ecosystem functions, these resources support recreational and commercial fishing industries worth hundreds of millions of dollars and tourism that brings billions of dollars to the State annually. As with most coastal states, population growth in the coastal counties has been rapidly increasing in recent years, a trend that is expected to continue. The ongoing urbanization of our coast, combined with increased recreational utilization of our coastal waters, will result in an escalating potential for serious impacts on South Carolina's estuarine and coastal habitats.

CONSERVATION ACCOMPLISHMENTS

In South Carolina, the SCECAP program was established in 1999 to begin evaluating the overall health of the State's estuarine habitats. SCECAP represents an expansion of ongoing monitoring programs being conducted by both state and federal agencies and ranks among the first in the country to apply a comprehensive, ecosystem-based assessment approach for evaluating coastal habitat condition.

CONSERVATION RECOMMENDATIONS

Effective habitat management requires monitoring on a periodic basis to evaluate coastal habitat condition. SCECAP's goal is to monitor the conditions of the State's estuarine habitats and provide periodic reports to both coastal managers and the general public. The program monitors a suite of water quality, sediment quality, and biological condition parameters at a large number

of sites throughout the State's Coastal Zone each year and integrates these measurements into an overall assessment of estuarine habitat condition at individual sites and statewide. The program also expands historical monitoring activities that have primarily focused on open water habitats (*e.g.,* bays, sounds, tidal rivers) to include an assessment of environmental conditions in tidal creeks, which serve as important nursery habitats for most of the State's economically valuable species. Many of these tidal creeks are also the first point of entry for upland runoff and therefore provide an early indication of stress related to coastal development, agriculture, and industrial activities (Holland *et al.,* 1997; Sanger *et al.,* 1999a,b; Lerberg *et al.,* 2000; Van Dolah *et al.,* 2000b).

MEASURES OF SUCCESS

The members of this guild inhabit the estuarine areas of South Carolina's extensive Coastal Zone and are thereby directly affected by increased utilization of that area. Measures of success for this guild will directly correlate with continued efforts to protect our coastal habitats from degradation.

DESCRIPTION

Taxonomy and Basic Description

Fiddler crabs are true crabs in the infraorder Brachyura. The Brachyura are the most advanced of the decapods. The crab body is generally short, wide, and flat, and is characterized by a reduced abdomen that lacks a tail fan and is flexed under the body. In all but a few small groups, all 5 pairs of walking legs are large and the first pair is always claws. The majority of brachyuran species pass through a number of planktonic larval stages, with the megalopal stage being the last larval stage before settlement to the crab form. The megalopa stage resembles the adult; however, the abdomen has yet to fold under the body. Fiddler crabs are in the family Ocypodidae that is characterized by eyes that are set close together at the end of long eye stalks.

Fiddler crabs are easily recognized by their square body and a marked difference in size between the right and left claws of males. As the male grows to maturity, the relative weight of its cheliped, or large claw, changes from approximately 2% to 65% of its total body weight. In most fiddler crab species, males can have either an enlarged left or right, with a typical handedness ratio of close to 50:50 in the population. In all fiddler crab species, fights between males of the same handedness are very different to those between opposite handed males. When facing each other, males with different handedness have their claws lined up on the same side, while males with the same handedness have their claws lined up on the opposite side. It may be easier for males of different handedness to judge each other's size, but it may be easier to interlock claws when their claws line up on the same side.

Mud fiddler crabs, *Minuca pugnax,* have an H-shaped depression in the middle of the carapace and their eyestalks are long and thin. They are brown in color, with the front of the shell and eyestalks ranging from blue to turquoise. The large claw of the male is usually yellowish-orange to yellowish-white, and its walking legs are dark and banded. The propodus of the large claw in males has an oblique ridge of small granules on the inner surface that extends from the lower margin to the junction with the dactyl (Williams, 1984; Crane, 1975).

The carapace of the sand fiddler crab, *Leptuca pugilator,* is typically a pinkish-purple color, with a bright patch of purple in the center of the carapace. The legs range in color from orange to brown. The inner surface of the large claw in males lacks the row of tubercles which can be used to distinguish sand fiddler crabs from other *Uca* species.

Sand Fiddler Crab

Red-jointed fiddler crabs (*Minuca minax)* are larger than the other two species. The joints of the large claws in males are red and possess a row of tubercles. The merus (fourth segment) of the second walking leg lacks dense pubescence (soft down or short hairs) on the ventral margin.

Red-jointed Fiddler

http://animaldiversity.ummz.umich.edu/site/accounts/information/Uca_minax.htm

Status

Although fiddler crabs have no directly quantifiable commercial value, they do occupy an important role in the ecology of salt marshes and are a good environmental indicator as they are sensitive to environmental contaminates, especially insecticides. Their population densities are an example of the high productivity of coastal marshes. Their burrowing activity can erode or undermine marsh banks and can affect the aeration of sediments, which increases the growth of marsh grasses. These activities stimulate the turnover and mineralization of important nutrients. Fiddler crabs are also important regulators of cordgrass-derived production and decomposition. Fiddler crabs are often used as fishing bait, especially for sheepshead (*Archosargus probatocephalus*) and black drum (*Pogonias cromis*) and are an important food source for many other estuarine species, such as blue crabs, clapper rails and other marsh birds (Grimes *et al*., 1989).

POPULATION SIZE AND DISTRIBUTION

Mud fiddler crabs range from Massachusetts to Florida and are common in marshes along the Southeastern coast. The sand fiddler crab occurs along the Atlantic and Gulf Coasts from Massachusetts to western Florida. Red-jointed fiddler crabs are found along the East and Gulf Coasts of the United States from Cape Cod to Texas. South Carolina is well within the natural range of all 3 species, and they can be found throughout the State's Coastal Zone (Ruppert & Fox, 1988).

Fiddler crabs are extremely abundant in South Carolina; however, assessments of fiddler crab populations are scarce. It would be extremely challenging to count these small creatures directly, in part due to their high mobility, and therefore surrogate measures of fiddler crab density can be made from counting burrows. Fiddler crab burrow density was measured along a transect from

the forest to the creek bank in North Inlet, SC. Burrow density ranged between 40 and 300 burrows m^{-2} with highest densities at the creek bank (McCraith *et al.,* 2003). Standing stock of the mud fiddler crab at North Inlet, SC was estimated at 29 g m^{-2} dry weight (Krebs *et al.,* 1974). In Georgia, the density of fiddler crab populations was reported as 27 crabs per m^2 (Teal, 1958).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Fiddler crabs are one of the most conspicuous inhabitants of the marsh surface and intertidal zone. They can often be seen foraging in large groups along creek banks at low tide.

Mud Fiddler Crab

The mud fiddler crab prefers a muddy marsh environment where the substrate is relatively free of heavy plant roots, yet stable enough to allow for the construction of its burrows, which can be up to 60 cm deep.

Male fiddler crabs wave their oversized claw up and down to attract the attention of females for mating and to intimidate potential male competitors. They also stomp their walking legs and make noises with them in an effort to attract mates. Such displays reach a peak during spring tides, and mating occurs thereafter inside the males' burrows. The females remain inside their burrows during the two-week incubation period and come out to release their eggs, which are swept out to sea by neap tides (*i.e.,* especially weak tides that occur during quarter moons).

After hatching, larvae go through several developmental stages (5 zoeae and a megalopal or first post-larval stage) over the two-week period that they are adrift in the ocean. Larvae are then transported back inside estuaries on the subsequent spring tide. Larvae are predatory and feed on zooplankton in the water column. They remain pelagic for some time after reaching the megalopal stage, gradually adopting a benthic existence.

Adult fiddler crabs feed on organic material extracted from mud, which is rolled into small balls after the food is removed and deposited back onto the substrate. They appear different from pellets formed during burrow excavation; excavated pellets are much larger than feeding pellets. Mud fiddlers are adept at regulating their metabolism over a wide range of temperatures, which may explain their widespread abundance.

Sand Fiddler Crab

The sand fiddler is an abundant species on sandy and muddy intertidal areas near salt marshes and banks of tidal creeks. Burrows are constructed along the edges of marshes; however, the sand fiddler crab may occur on the marsh surface when the substrate contains more sand than mud. Sand and mud fiddler crab populations may intermingle, and large populations can be seen feeding in the intertidal areas bordering marshes along tidal creeks in the southeastern United States. The sand fiddler crab burrow is unbranched and dug at an angle to the surface. The biology of the sand fiddler crab is similar to that already described for the mud fiddler crab above. Sand fiddler crabs have specialized spoon-shaped bristles on their maxillipeds (appendages used in feeding) that enable the crab to remove algae and other organic matter from

sandy sediments. Once the sediment has been “cleaned” by the fiddler crab, the mouthparts shape the inorganic matter into balls that are deposited around the openings of burrows (Williams, 1984; Heard, 1982).

Red-jointed Fiddler Crab

The red-jointed fiddler crab occurs in low salinity and freshwater tidal marshes. It is generally found on mud and sandy substrates with high organic content. This species can withstand low oxygen conditions. Red-jointed fiddler crabs may move near terrestrial areas away from the intertidal zone of marshes. Feeding habits and biology are similar to other fiddler crabs occurring in the Southeastern United States.

CHALLENGES

Contaminants, such as polychlorinated biphenyls (PCBs) and insecticide/fertilizer mixtures, will adversely affect the health of fiddler crab populations (Krebs *et al.*, 1974). Fiddler crabs apparently concentrate these toxins from seawater or food. Fiddler crabs accumulate PCBs from contaminated sediments and detritus and can transfer them to aquatic, avian, and terrestrial food webs when preyed upon by fishes, birds, and small mammals. When the insecticide, Dieldrin, is concentrated in crab tissues, it impairs locomotion, eventually killing crabs at higher concentrations (Krebs *et al*., 1974). Chemical contaminants can drastically reduce populations of fiddler crabs in the marsh (Krebs *et al*., 1974). Fiddler crabs have also been found to be sensitive to mercury (DeCoursey & Vernberg, 1972) and cadmium (O'Hara, 1973). Heavy metals such as mercury, copper, and zinc are toxic to fiddler-crab larvae, causing a significant delay in larval development as well as deformities.

Spraying marsh habitats with pesticides for mosquito control can also cause a significant decrease in the natural fiddler crab populations downwind of the pesticide application area (Rookery Bay NERR, 1996). Studies in Florida have shown that the mortality of fiddler crabs can be markedly reduced when high-pressure nozzles are used in combination with the mosquito adulticide, Dibrom. Methods that reduce the size of the pesticide droplets not only improve the effectiveness of a pesticide to kill mosquitoes but also significantly reduce the amount of pesticide needed (Rookery Bay NERR, 1996).

Nonpoint source runoff from residential areas, roads, and golf courses can have negative impacts on marsh creek ecosystems by impacting water quality. Any one discharge may involve only small amounts of chemicals that are diluted by the receiving streams, but when combined with other chemicals from multiple other discharges, significant concentrations of pollutants may result. Pollution may disrupt the food web in the salt marsh by killing off certain species and prompting others to greatly increase in abundance.

CONSERVATION ACCOMPLISHMENTS

Non-point source pollution is difficult to control. A remedy to the problem that has been adopted in many communities in South Carolina is the maintenance of buffer zones and retention ponds

(George *et al*., 2001). Studies have shown that fiddler crab populations respond in a positive way when wetlands are restored and good water quality is maintained (Knott et al. 1997).

CONSERVATION RECOMMENDATIONS

- Assess burrow density before and after impacts to marsh habitat to evaluate its recovery.
- Evaluate the effects of mosquito control on fiddler crab populations in South Carolina.
- Conduct studies to investigate the use of high-pressure nozzles in combination with the mosquito adulticide, Dibrom, to determine the effectiveness of this method in reducing the mortality of fiddler crabs.
- Encourage the continued use of Best Management Practices (BMPs) to reduce nonpoint source pollution runoff.

MEASURES OF SUCCESS

By evaluating the effect of mosquito adulticides and application technology on fiddler crab populations, South Carolina Department of Natural Resources (SCDNR) would be able to recommend changes in application techniques to the South Carolina Department of Health and Environmental Control (SCDHEC), resulting in more stable fiddler crab populations. In addition, by monitoring population trends in fiddler crabs, SCDNR will be better able to assess the health of and protect marsh habitat for all fish and wildlife species.

DESCRIPTION

Taxonomy and Basic Description

There are two species of stone crab in the southeastern United States, namely the Florida stone crab, *Mercenaria mercenaria* and the Gulf stone crab, *M. adina*. While an active hybridization zone was long thought to occur in the eastern Gulf of Mexico and into parts of the South Carolina coast (*e.g.,* Bert & Harrison, 1988), recent genetic evidence suggests that hybridization of the two species has not occurred for thousands of years (Seyoum et al., 2021). This work also suggests that a strong barrier to gene flow between the two species occurs in Apalachicola Bay, Florida and thus that all the stone crabs found on the Atlantic Coast of the U.S. are of one species, *M. mercenaria* (Seyoum et al. 2021).

The Florida stone crab, *M. mercenaria* Say, 1818 is a true crab in the family Xanthidae. The xanthid family of crabs is commonly called the mud crabs. This is a highly diverse family whose members are characterized by having a body that is transversely oval or hexagonal, with a broad front, without a rostrum, and notched centrally. The last pair of legs is unmodified (Williams, 1984). The carapace of the stone crab is nearly smooth to the unaided eye.

The lateral margins of the carapace are divided into 4 lobes. The pincers are large and heavy, unequal in size and nearly smooth. The inside of the palm has a patch of fine, oblique and parallel striations. The walking legs are stout and hairy towards the ends (Williams, 1984). The claws of the stone crab are asymmetrical; there is a major or crusher claw and a minor or pincer claw. Only the claws of stone crab are harvested and a legal-size claw has a propodus base measurement of > 70 mm. In South Carolina, only the larger of the two claws may be taken.

The color of juveniles is generally dark purplish-blue, often with a white spot occurring on the inner carpus. Juveniles also exhibit three prominent white spots in the form of an inverted triangle on the carapace. Older individuals vary in color from brown to green on the anterior half of the carapace, with tan to cream coloration on the posterior half. The carapace is mottled with darker blotches. The fingers are dark and the walking legs are either entirely purple or brown, or with partial dark and light coloration (Caldwell, 1986).

Status

The stone crab is not a state or federally listed species; however, they are dependent upon coastal nursery grounds and thus may be a potential indicator species of the health of estuarine habitat. In addition, stone crab claws are harvested in South Carolina; it is not clear what impacts that activity may be having on the population.

POPULATION SIZE AND DISTRIBUTION

Stone crabs are found from North Carolina south, around peninsular Florida, to the Yucatan Peninsula and Belize, and throughout the Bahamas and Greater Antilles (FL FWC, 2003). In South Carolina, the stone crab is a conspicuous inhabitant of estuaries and inlets. They occur along the coast in high salinity areas, bays, sounds and along jetties (Wenner & Stokes, 1984). No long-term surveys exist to determine the population size of the stone crab in South Carolina or trends in its abundance. Adequate information to determine population abundance and health is not available.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Across its geographic range, stone crabs inhabit jetties, dead shell, mud and grass flats, and oyster reefs (Williams, 1984). Stone crabs occur in areas characterized by high salinities and live oyster beds. Although stone crabs may dwell on a variety of bottom types throughout their geographic range, the shell substrate of oyster reefs provides reinforcement for the creation of stable burrows, as well as protection from predators. Adult stone crabs live in burrows below the low tide mark around oyster bars and mud flats. The burrows provide protection for molting crabs and those females incubating eggs (Williams, 1984).

In South Carolina, the Eastern oyster, *Crassostrea virginica* is the principle food of the stone crab, which uses its major cheliped to crush the shell. Thus, stone crabs in South Carolina are generally found in proximity to intertidal oyster beds. Stone crabs may also eat other bivalves and crustaceans such as blue crab. Wenner & Stokes (1984) found that stone crabs were most abundant in areas immediately adjacent to the ocean and inlet areas with steep banks; fast current speeds yielded more stone crabs than did creek sites that had a gradual slope and slower current.

Few studies on the life history of the stone crab have been conducted in South Carolina. Egg bearing females occur from May to October with a peak from May to August. Females with mature ovaries occur during spring and summer. Juvenile stone crabs occurred throughout the year (Caldwell, 1986). Mating is similar to that of other crabs in that the male protects the female while copulation occurs. Individual females have been reported to spawn several times during a year (Porter, 1960). Once the eggs are extruded, larvae hatch as a larval form called zoea and develop through 5 zoeal stages, followed by a single more advanced larval stage called a megalopa before metamorphosis into the first crab stage. Juvenile crabs occur on shell bottom and consume a variety of foods including polychaete worms, small bivalves, oyster drills and occasionally other stone crabs (Bender, 1971). Crabs mature at around 2 years of age.

CHALLENGES

Stone crabs can be affected by water pollution. Urban contaminants such as heavy metals, polychlorinated biphenyls (PCBs), hydrocarbons, pesticides, and herbicides entering coastal waters via runoff from farmlands and suburban yards could negatively affect stone crab populations. Stone crab productivity is considered to be dependent on the maintenance of coastal nursery grounds, especially oyster reefs. Disease and pollution that affect oyster reefs could indirectly have a negative impact on stone crab populations. C. M. Bearden observed thousands

of dead stone crabs washing ashore on beaches just north of Charleston Harbor in the late 1960s, presumably because of a mass die off caused by disease (D. Whitaker, SCDNR, pers. comm., 2005).

Stone crab claws are harvested in South Carolina; however, there is no directed fishery for stone crabs (the major fishery for the stone crab is located in Florida). Stone crab claws are generally taken incidentally to the blue crab fishery in South Carolina, although there may be some individuals who directly target stone crab. Approximately 18,000 lbs of stone crab claws are landed annually in South Carolina. The stone crab fishery depends on the ability of crabs to regenerate a lost limb. This unique fishery lands only the large, meaty claw of these crabs. One claw is removed from each trapped crab and the animal is released alive. If carefully treated, adult stone crabs can regenerate their claws several times. Most of the stone crabs sampled in South Carolina had at least one legally harvestable claw. Of those captured with both claws, most possessed unregenerated claws (Wenner & Stokes, 1984). Estimates of the proportion of the harvest composed of claws regenerated after natural claw loss is around 10% for South Carolina. Survival depends partly upon the skill of the fisherman, who must separate the claw from the crab's body at the proper joint. If the joint is pierced or snapped quickly enough, the crabs own defense reflex contracts its muscles and sheds the claw cleanly. If a crab is de-clawed incorrectly (if, for example, part of the body is taken with the claw), the crab may bleed excessively or may be unable to regenerate a new claw, which significantly increases the likelihood that the crab will die (Wenner & Stokes, 1984, Duermit *et al.,* 2015); however, claw removal has been found to impact the ability of stone crabs to forage in that stone crabs with one claw removed ate fewer bivalves than stone crabs with both claws intact and stone crabs with both claws removed switched to a primarily fish based diet (Duermit *et al.,* 2015). Declawed stone crabs also exhibit reduced movement and likely higher rates of mortality than crabs without removed claws (Duermit *et al.,* 2017). Since molting and thus claw regeneration is a slow process in larger stone crabs, claw removal likely has long term consequences (Duermit *et al.,* 2015).

Landings of stone crab claws in South Carolina may increase because of added interest and awareness of the potential for a fishery. It is unlikely, however, that South Carolina stone crab populations could withstand the level of fishing effort found in the Florida fishery. Until data are available on effort and yield of claws from crabbing operations in South Carolina, it will not be possible to properly assess the impact of fishing on existing stocks of stone crab. In other parts of its range, scientists and fishers believe that the population is heavily fished, although landings have remained stable (FL FWC, 2003).

CONSERVATION ACCOMPLISHMENTS

At present, the minimum legal size of a harvestable claw is 70 mm, which allows most females to mature and reproduce in at least one season prior to attaining legal size. Although a declawed female can bear eggs and contribute to the spawning stock, mortality can result from incorrect claw removal or because the female is unable to adequately feed or protect herself. Although not yet studied in stone crabs, claw regeneration has been shown to impact female fecundity in other crabs (*e.g.,* Norman & Jones 1993). Protection of egg bearing females is a conservative measure that may be beneficial to the resource. Stone crabs have relatively high fecundity. A single

female may produce 4 to 6 egg masses or "sponges" during a single mating season with an average of 4.5 spawning events per molt (USFWS, 1984). Each egg sponge may contain between 160,000 and 1,000,000 eggs.

Declawing crabs immediately upon their capture is also a legal stipulation that represents a good conservation measure. If crabs are held for long periods before declawing, they are subjected to air exposure and desiccation.

The South Carolina Department of Natural Resources' Marine Resources Division, through both its research and fisheries management sections, is actively involved in the restoration of oyster habitat by planting shell and/or deploying suitable reef-building substrate in coastal waters, which provides a foundation for settlement of oyster larvae. Over time, these new reefs will collect oysters through natural larval settlement. Eventually, these areas should develop into natural oyster habitat. Maintenance, enhancement, and restoration of oyster reefs secondarily provide excellent habitat that benefits the stone crab and other marine species that use such habitat.

CONSERVATION RECOMMENDATIONS

- Determine the impact of stone crab bycatch in the blue crab fishery on reproductivity and survivorship of stone crab.
- Monitor stone crab populations in order to determine population status.
- Explore the impacts of declawing on reproductive output of female stone crabs.
- Educate fishers about the proper method to remove a stone crab claw to achieve higher survivorship following claw harvest.
- Continue SCDNR oyster habitat restoration and enhancement projects to ensure that essential habitat for stone crab populations is maintained in South Carolina waters.
- Work with municipalities to include Best Management Practices (BMPs) in development plans throughout the Coastal Zone. Such plans should include installation of retention ponds, modified septic systems, and stream bank protection measures.

MEASURES OF SUCCESS

In the event that municipalities implement BMPs along coastal waterways, improved water quality in marine ecosystems should result. In turn, the improved water quality will benefit many sensitive marine species, including the stone crab. Continuation of the oyster bed restoration project will provide habitat for the stone crab, which will result in stable to increasing population trends.

Four-Handed Box Jellyfish

Chiropsalmus quadrumanus F. Muller, 1859

Contributor: Daniel Sasson (SCDNR, 2024)

DESCRIPTION

Taxonomy and basic description:

Chiropsalmus quadrumanus F. Muller, 1859 (Phylum: Cnidaria, Class: Cubozoa, Order: Chirodropida, Family: Chiropsalmidae) is a box jellyfish named for its four appendages hanging below the four corners of its gelatinous bell. From these appendages hang bundles of tentacles which *C. quadrumanus* uses to capture its prey. Their tentacles can be up to four meters in length and have a powerful sting, which, in rare cases or young children, can result in death (Bengston *et al.,* 1991).

Reproduction is believed to occur externally and histological evidence suggests that *C. quadrumanu*s is iteroparous (García-Rodríguez *et al.,* 2023). Sexual maturity likely occurs quickly as oocytes have been found in medusae of all sizes (Garcia-Rodriguez *et al.,* 2023).

In Brazil, the diet of *C. quadrumanus* consists primarily of crustaceans, although other prey items such as fish eggs were occasionally consumed (Nogueira Júnior & Haddad, 2008). To date, no such similar studiees of prey items of *C. quadrumanus* have been conducted in the Northern Hemisphere.

While *C. quadrumanus* is currently considered one species across its entire range, phenotypic comparisons of specimens from the Atlantic Coast of the United States and specimens from Brazil have led some researchers to suggest these may be multiple species (Gershwin, 2006).

Status

Chiropsalmus quadrumanus is not currently included in federal lists of threatened or endangered species and there is no present-day direct human exploitation of this species in South Carolina. No targeted population assessments are conducted on this species, despite its potential ecological significance as a predator. Relatively little is known about the presence or ecological impacts of *C. quadrumanus* in South Carolina.

POPULATION DISTRIBUTION AND SIZE

Chiropsalmus quadrumanus is distributed throughout the Eastern Atlantic Coast, ranging from Brazil to the Carolinas, in the Gulf of Mexico, and in the Caribbean. It has occasionally been observed in the Pacific Ocean as well, with reports from Hawaii and Australia; however, there is some question whether there is only one species across its range (see ‘Description’ section

above). It can be found both offshore in open waters and inshore, with occasional reports of large numbers washing ashore.

HABITAT / NATURAL COMMUNITY REQUIREMENTS

Little is known about the environmental conditions necessary for *C. quadrumanus*. Experimental work in other box jellyfish have found that salinities above 20 ppt are required (Mooney & Kingsford, 2016), but it is unclear whether that applies to all Cubazoa. As in some other Cnidaria, it may be that Cubazoa may be especially sensitive to environmental conditions when in the polyp stage (e.*g.,* Kingsford & Mooney 2014; Goldstein *et al.,* 2017).

CHALLENGES

Chiropsalmus quadrumanus is not used for any commercial purpose.

CONSERVATION ACCOMPLISHMENTS

Cubazoa in general have received little to no attention in terms of conservation efforts, likely due to a lack of demographic information. The species is currently not listed as either threatened or endangered at either the state or Federal level, which also explains the lack of targeted conservation efforts.

CONSERVATION RECOMMENDATIONS

Little is known about the abundance and ecological impacts of *Chiropsalmus quadrumanus* in South Carolina waters. It is also unclear whether *Chiropsalmus quadrumanus* consists of one species throughout its range.

MEASUREMENT OF SUCCESS

A better understanding of the ecology, distribution, and taxonomic classification of *Chiropsalmus quadrumanus* in South Carolina would improve our ability to recognize changes in abundance patterns that might result from shifts in environmental conditions.

DESCRIPTION

Taxonomy and Basic Description

These small decapod shrimp are collectively known as ‘carideans.’ Common names include grass shrimp, jumpers, glass shrimp, popcorn shrimp, glass prawns, and hardbacks.

Grass shrimp have a well-developed 'horn' or ‘rostrum’ (hence the name of one of the species, daggerblade) with teeth along the dorsal and or ventral surfaces. The presence and position of these and other nearby teeth are used to separate out the species in the genus. Important distinguishing characteristics are a lack of claws on the third pair of walking legs and their diminutive size. They are rarely larger than 5 cm; this differentiates them from commercial shrimp. Because of their morphological similarities and the need of a dissecting scope to view key characteristics, the species are often misidentified. Grass shrimp are nearly transparent. Males can be separated from females by the presence of the ‘appendix masculina’ attached to the ‘appendix interna’ of the endopod of the second pair of pleopods. Also, the endopod of the first pleopod is larger in males versus females. A significant positive correlation between female length and egg number has been also observed as it has in many decapod crustaceans (Hines, 1982; Anger *et al*., 2002).

Spawning occurs from February through October, although this may vary with location. More than one brood may be produced during the spawning season. During mating, which occurs within 7 hours of molting, the male transfers a spermatophore to the female. The eggs are fertilized externally as they are extruded. The female attaches the eggs to her pleopods, where they remain until hatching 12 to 60 days after they are fertilized. Ovigerous females—those carrying eggs—are easy to recognize because the eggs are visible through the carapace. Egg incubation varies among species and is shorter in the southeastern United States. Females molt again after spawning, thereby producing a second brood. Grass shrimp larvae undergo a series of developmental stages: 10 zoeae and a postlarva. Juvenile grass shrimp mature when they are perhaps 1.5 to 2 months old or about 15 to 18 mm long; they live from 6 to 13 months. Older, overwintering individuals usually spawn early in the year and die by the following winter. Most young-of-the-year spawn late in the fall as adults. Post-larvae that survive fall and winter spawn the following spring. Since some grass shrimp populations reproduce two broods each year,

length-frequency distributions may be polymodal (two or more peaks), with growth rates difficult to characterize. Growth rates vary somewhat between species, sexes, habitats, and times of the year. In colder coastal waters, growth patterns are different with salinity also affecting growth (Anderson, 1985).

Grass shrimp eat a wide variety of foods but are considered by many to be primarily detritivores. Nevertheless, they can be quite carnivorous in captivity, where they are often also cannibalistic (E. Wenner, pers. obs.). Grass shrimp are also predators of meiofauna and small infaunal polychaetes, oligochaetes, and nematodes (Bell & Coull, 1978; Smith & Coull, 1987; Gregg & Fleeger, 1998).

Status

Grass shrimp are not state or federally listed; however, they are an important species from an ecological perspective because they serve as a link for energy transfer between trophic levels in the coastal food web. Their feeding on the epiphytic algae that occur on marsh grass assists with the mechanical breakdown of organic material (Orth *et al*., 1984). The fecal pellets from the unused part of their diet are rich in nutrients and, therefore, an important component of energy cycling in estuarine ecosystems. Marsh grass shrimp are hosts to several ectocommensals, including the bopyrid isopod *Probopyrus pandalicola*, as well as microsporidians, trematodes, coccidian, and leeches (Anderson, 1985). Marsh grass shrimp have been extensively documented as the prey of fishes and other carnivores. They are instrumental in transporting energy and nutrients between various estuarine trophic levels: primary producers, decomposers, carnivores, and detritivores (Haertel-Borera *et al*., 2004). Grass shrimp are consumed in large quantities by commercially important fishes and forage species, including spotted seatrout (*Cynoscion nebulosus*), red drum (*Sciaenops ocellatus*), and mummichogs (*Fundulus heteroclitus*) (Heck & Thoman, 1981; Anderson, 1985; Wenner, 1990; Posey & Hines, 1991; Wenner & Archambault, 1996).

POPULATION SIZE AND DISTRIBUTION

Grass shrimp are found in large numbers in estuarine waters along the Atlantic and Gulf Coasts, where they occur from Massachusetts to Texas. Although there are many freshwater members of the genus, the three species considered here are common in estuaries and tidal creeks in South Carolina waters.

Although there are no estimates of population sizes of grass shrimp in South Carolina, they are amongst the most widely distributed, abundant, and conspicuous of the shallow water benthic macroinvertebrates in our estuaries, often reaching hundreds to thousands per meter (Coen & Luckenbach, 2000; Leight *et al*., 2005).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Grass shrimp are very common estuarine species in southeastern U.S. marshes and tidal creeks where they are usually associated with beds of submerged or emergent vegetation, oyster reef habitats or structures such as oyster shell, fouling communities, woody debris (Ruiz *et al*., 1993),

docks, or pilings (Coen *et al*., 1981). The marsh grass shrimp (*P. vulgaris*) tolerates somewhat higher salinities than its congener, the daggerblade grass shrimp (*P. pugio*). This has led some to suggest a separation of the 2 species based on preferred habitat, although biotic interactions such as competition for food and space may be more important (Thorp, 1976; Coen *et al*., 1981). Grass shrimp are eurythermal. In estuarine waters, daggerblade grass shrimp can survive at temperatures from 5ºC to 38ºC; however, optimal temperatures range from 18 to 25ºC. Marsh grass shrimp are more tolerant of high salinity water and less tolerant of low salinity water than daggerblade grass shrimp. Although salinities as low as 3 ppt have been lethal to adult marsh grass shrimp, they have been collected in freshwater (Anderson, 1985). Although brackish grass shrimp are also considered euryhaline, they have typically been collected from waters with salinities of 5 ppt to 39 ppt.

Grass shrimp can inhabit very shallow areas near their margins but have been reported at depths as great as 15.2 m (50 ft). In winter during temperature lows, and in summer when water temperatures approach seasonal highs, daggerblade grass shrimp may move from shallow to relatively deeper water. The extent of the movement of grass shrimp among various depths often coincides with the distribution of oyster shell substrates, which, in some waters, are preferred by both daggerblade grass shrimp and marsh grass shrimp. They are abundant in these structured estuarine and marine habitats as they provide abundant food and protection from predators such as various fish species (Thorp, 1976; Coen *et al*., 1981; Heck & Thoman, 1981; Heck & Crowder, 1991).

CHALLENGES

The main challenge to conserving grass shrimp is the degradation of habitat associated with extensive anthropogenic development along the South Carolina coast. Estuaries and tidal creeks are increasingly being affected directly and indirectly through runoff and spraying, to name just a few impacts. As epibenthic predators and sediment disturbers, grass shrimp can significantly alter infaunal community structure. For example, in North Carolina, a sharp decline in the abundance of marsh grass shrimp due to predation by mummichogs *(Fundulus heteroclitus)* may have changed marsh infaunal composition (Anderson, 1985).

Since grass shrimp often rely on aquatic vegetation or other structured habitats (Boesch & Turner, 1984), activities that reduce structural complexity can negatively affect grass shrimp populations (Weaver & Holloway, 1974; Thorp, 1976; Coen *et al*., 1981; Heck & Thoman, 1981; Heck & Crowder, 1991). In West Bay, Texas, dredging, bulkheading, and filling of coastal marshes caused a permanent loss of intertidal vegetation (Trent *et al*., 1976). The reduction of detrital input into the adjoining aquatic systems caused a noticeable decrease in the abundance of grass shrimp. Coen *et al.* (1999 a,b) found that juvenile grass shrimp were collected in much higher numbers (20 to 60 times greater) over marsh than other adjacent estuarine habitats (mud or oyster reefs).

Changes to water regimes that alter salinity or dissolved oxygen through diversion or rediversion may also alter grass shrimp abundance patterns.

Grass shrimp have been used extensively by researchers in South Carolina and across the US as a bioassay organism for contaminant and toxicological research (*e.g.,* APHA, 1975Mayer, 1987); a great deal of information is available regarding mortality and sublethal effects. Researchers conducting toxicological work with the genus *Palaemon* have noted that grass shrimp adults are generally more sensitive than fish (Scott *et al*., 1994; Strozier, 1996; Van Dolah *et al*., 1997); however, this may vary greatly upon the toxicant (Scott *et al*., 1987). Grass shrimp larvae are also generally more sensitive to many organophosphates (Key & Fulton, 1993; Lund, 1997; Key et al., 1998b; Lund *et al*., 2000). Overall, grass shrimp appear to be more sensitive to organophosphate and pyrethroid insecticides and less sensitive to several organochlorine insecticides at high versus low salinities (Scott *et al*., 1989; Fulton & Scott, 1991; Key & Scott 1993). Concentrations of heavy metals (mercury, cadmium, and chromium) are acutely toxic to adult grass shrimp, usually in the order of 100 to 1,000 parts per billion. Work in Charleston by NOAA and other scientists at Fort Johnson have focused on grass shrimp as an invaluable model organism (Scott *et al*., 1992, 1994; Key & Fulton, 1993; Fulton 1993, 1997; Cochran & Burnett, 1996; Lund, 1997; Finley *et al*., 1999; Wirth *et al*., 2001; Bolton-Warberg, 2005; Leight *et al*., 2005).

CONSERVATION ACCOMPLISHMENTS

Extensive research on grass shrimp population dynamics has been conducted around sites with known pollution sources in South Carolina, including suburbanized Murrells Inlet, Charleston Harbor, North Inlet, the Broad and Okatee Rivers (Van Dolah *et al*., 1999), and the ACE Basin NERR. Thus, an extensive historical database exists for grass shrimp population dynamics within South Carolina. Egg number per female has also been compared among tidal creeks, rivers, and intertidal habitats to evaluate impacts.

CONSERVATION RECOMMENDATIONS

- Determine species' associations, critical habitats, and population abundance patterns for grass shrimp.
- Determine grass shrimp predator-prey relationships.
- Determine the effects of contaminants on the reproduction, growth, and longevity of grass shrimp.
- Protect important habitats, such as fringing marsh and oyster habitats, from the direct and indirect impacts of development, and increase our directed restoration efforts. Oyster habitats have only recently begun to be appreciated for their unique ecosystem services (see Oyster Habitat document and references therein).
- In order to conserve grass shrimp habitat, protect aquatic vegetation by directing dredge and fill operations away from intertidal marshes.
- Partner with NOAA-NOS to develop and implement ways to use grass shrimp as an indicator of ecosystem health.
- Work with municipalities to encourage the use of Best Management Practice (BMPs) that reduce non-point source runoff and reduce acute and chronic effects on grass shrimp.
- Encourage the use of conservation buffers that intercept pollutants to mitigate the movement of sediment, nutrients, and pesticides within non-point source pollution.

- Development and implementation of nutrient management plans (NMP) by farmers to help minimize nutrient loss while maintaining yield, decreasing the flow of nutrients into waterways, and reducing eutrophic effects.

MEASURES OF SUCCESS

By implementing the above recommendations, the SCDNR will be able to protect important marsh habitat and monitor water quality. The measurement of success will be to observe stable populations of grass shrimp (during annual surveys) that should result from this proactive management approach.

Hard Clams Guild

Northern Quahog, *Mercenaria mercenaria*
Southern Quahog, *M. campechiensis*

Contributors: Nancy Hadley (2005) and Loren Coen (2005). Reviewed and Edited: Nancy Hadley (2013), Peter Kingsley-Smith (2013, 2024) & Andy Hollis (2024)

DESCRIPTION

Taxonomy and Basic Description

Members of the genus *Mercenaria* are bivalve mollusks in the family Veneridae. Common names for *Mercenaria mercenaria* (Linnaeus 1758) include the hard clam, quahog, quahaug, northern quahog, littleneck clam, and cherrystone clam, although the latter two are actually referring to commercial size classes. The sister species, *M. campechiensis*, is commonly known as the southern quahog.

The hard clam has two thick, equal-sized valves that are elliptical in shape and marked with conspicuous concentric rings (Eversole, 1987). The valves are joined dorsally by a dark brown external ligament just below the anteriorly-inclined umbo. Opposite the hinge is a distinct heart-shaped lunule. The external shell is generally tan-colored or off-white and may have reddish markings (*notata* form). The internal shell is white or pale yellow with a dark purple margin. The prominent adductor muscle scar may also be purple.

The body of the hard clam is surrounded by a mantle that secretes the shell. The clam filters through a pair of siphons fused at the bases. The incurrent siphon has sensory tentacles that are involved in food selection. The siphons are generally creamy white, but the margins may be colored in a range of yellows, browns, purples, or reds. The clam has a large hatchet-shaped foot that is used for digging.

Clams may live for up to 46 years (Peterson, 1986) and reach a size of 150 mm although the mean size is usually 60 to 70 mm (Stanley & Dewitt, 1983).

Status

Hard clams are not state or federally listed; however, clams and other filter feeders are ecologically very important in marine ecosystems. Filter feeders affect nutrient cycling in estuarine habitats and improve water quality by removing suspended particles along with phytoplankton (Officer *et al*., 1982; Dame, 1996; Dame *et al*., 2001; Newell, 2004). A large adult clam filters an average of 7 to 8 L hr^{-1}. Clams also readily ingest bacteria, viruses, and other water-borne pathogens that can cause human health problems. Although hard clam stocks

appear to be stable based on high densities observed in some locations, they are a high priority for conservation in marine ecosystems.

Hard clams are harvested both recreationally and commercially and are the most valuable commercially harvested clam species in the United States (Pritchard, 2004). In South Carolina, the hard clam fishery was at one time valued at $3 million but has decreased in recent years, both in volume and in value due to depressed market factors. Since the effort for harvesting wild clams is considerably greater than growing them in mariculture operations, a vast majority of the hard clam landings come from mariculture permits. There are approximately 20 hard clam mariculture permits currently active in South Carolina. The Southern Regional Aquaculture Center has two fact sheets on hard clam biology and aquaculture (Hadley & Whetstone, 2007; Whetstone *et al*., 2005).

POPULATION SIZE AND DISTRIBUTION

Mercenaria mercenaria is found from the Gulf of St. Lawrence to the Atlantic coast of Florida. This species has been introduced to other areas of the United States, notably Humboldt Bay, California (Murphy, 1985), Washington State, and Puerto Rico. It has also been introduced into Great Britain and Southern Brittany, where it is now well established, as well as the Mediterranean (France, Italy, Sicily, the Adriatic Sea) and China. A sister species, *M. campechiensis* (Gmelin 1791), is distributed primarily along the Atlantic Coast from North Carolina to Florida and in the Gulf of Mexico (Dillon & Manzi, 1989a). A subspecies, *M. mercenaria texana* (Dillon & Manzi, 1989b) is found primarily along the Gulf coasts of Texas and Louisiana. The two species *M. mercenaria* and *M. campechiensis* readily hybridize where their ranges overlap. Both *M. campechiensis* and hybrids have been reported in South Carolina (Dillon, 1992; Dillon & Manzi, 1992), but only represent small percentages of the overall population. Kraeuter & Castagna (2001) provide a review of the biology of the hard clam.

Hard clams are contagiously distributed (randomly clumped) in South Carolina estuarine waters at relatively low densities of 6 to 24 per m^2 (Dame, 1979; Rhodes *et al*., 1977; Anderson *et al*., 1978). A statewide survey in the 1970s (Anderson *et al*., 1978) estimated that 10% of estuarine waters in South Carolina contained hard clams, predominantly at low densities (< 4 per m^2). Most of the clams in this survey (68%) were in substrates composed of sand and shell; the fewest specimens were found in mud and sand mixtures. Small clams may be found in saltmarshes where the rhizomes provide protection from predators. Larger clams are often found in association with oyster reefs, burrowed under and adjacent to oyster clusters (Anderson *et al*., 1978). Larval clams (70 to 350 µm in length) are planktonic; they drift with the currents and may be distributed considerable distances from where they were spawned (Wood & Hargis, 1971).

HABITATS AND NATURAL COMMUNITY REQUIREMENTS

Hard clams occupy intertidal as well as subtidal habitats and burrow into the substrate to depths up to 20 cm, but more commonly to a depth of 1 to 2 cm (Roberts *et al*., 1989; Eversole, 1987). Hard clams are found in a variety of substrates including sand, mud, shell, and mixtures of these; however, studies have demonstrated a preference for coarser substrates that may relate to associated water currents (Stanley & Dewitt, 1983). They are often most abundant where there is

an overlying layer of shell or coarse sand (Anderson *et al.,* 1978) which provides predator protection. Although clams are infaunal, they can 'migrate' horizontally, as well as vertically (Toll *et al.,* 2003). Adult clams have been shown to repopulate a harvested area in a relatively short period of time (Toll *et al.,* 2003).

The hard clam is a moderately euryhaline osmoconformer. Although it has been found in salinities ranging from 4 to > 35 ppt (Eversole, 1987), growth is optimal at salinities between 24 and 28 ppt. Hard clams can tolerate long periods of reduced salinity by closing their valves (Eversole, 1987) and are tolerant of low dissolved oxygen, surviving up to 3 weeks at 1 mg L^{-1} (Stanley & Dewitt, 1983). Hard clams, especially larval and juvenile stages, are sensitive to pH outside the range of 7.0 to 8.75 (Calabrese & Davis, 1966).

Growth and reproduction in hard clams are largely controlled by temperature. Hard clams usually reach sexual maturity at a size of about 35 mm shell length. In South Carolina, hard clams usually spawn intermittently from May through October when water temperatures reach or exceed 24 °C (75 °F). The planktonic larval stage may last as long as 2 weeks during which time the larvae may be distributed widely by currents and winds. At the end of this stage, the clam metamorphoses to the adult form and rapidly burrows into the substrate (MacKenzie *et al*., 2002).

CHALLENGES

High turbidity—which can result from runoff, dredging, and boating activities, as well as natural causes, such as storm-induced flooding and winds—can negatively impact hard clams (reviewed in Ward *et al.*, 1994; Coen, 1995; Ward & Shumway, 2004). As with other filter-feeding bivalves, high turbidity may interfere with feeding by potentially clogging the gills or even limiting the time that hard clams attempt to feed (Stanley & Dewitt, 1983).

Hard clams, like other filter feeders, can be adversely affected by blooms of certain types of phytoplankton (Gainey & Shumway, 1988; Shumway & Cucci, 1987; Shumway, 1990; Bricelj & MacQuarrie, 2007). Most phytoplankton blooms result from a combination of physical, chemical, and biological mechanisms and interactions that are only partially understood. Some phytoplankton species produce toxins and, in a bloom situation, can adversely affect other organisms. Even when such blooms do not harm the filter-feeding organisms, the toxins can accumulate in the filter-feeders and reach levels that can endanger consumers, including humans. Harmful algal blooms have increased in frequency and become more widely distributed in the last few decades; this suggests that human activities may be affecting bloom occurrence or distribution (Hallegraeff, 1993; WHOI, 2004). A specific concern associated with hard clams occurs when healthy bivalves from 'open' approved areas that have experienced harmful algal blooms are transferred to other bays or creeks that have not experienced such blooms. Such transfer is of interest because many of the phytoplankton species that cause harmful algal blooms can survive digestion (Burkholder & Shumway, 2011).

Mariculture-related importations of clams or other bivalves could inadvertently introduce new predators or diseases into South Carolina waters. The SCDNR has documented 27 other species, including oyster drills and a number of crab species—at least one of which is not indigenous to

South Carolina—in hard clams transferred from Florida as part of a mariculture operation. Mariculture operations could also potentially modify local population genetic structure (Metzner-Roop, 1994; Arnold *et al*., 2003). Research has suggested that hard clam populations may differ in susceptibility to certain diseases (Ford *et al*., 2002; Ragone-Calvo & Burreson, 2002; Camara *et al*., 2004; Ragone-Calvo *et al*., 2003). Hard clams imported for mariculture in South Carolina could be of strains that are more susceptible to certain diseases. Interbreeding with local populations could then result in an increased susceptibility of native stocks to disease.

Relatively few diseases have been reported in *M. mercenaria*. The most notable is the parasite QPX (Quahog Pathogen Unknown), which was originally observed in the 1960s in New Brunswick, Canada, where it caused observable mortalities. Epizootics have since been observed in hard clam aquaculture plantings in parts of Atlantic Canada, Massachusetts, New Jersey, and Virginia (Whyte *et al*., 1994; Ragone-Calvo *et al*., 1998; Smolowitz *et al*., 1998; Ford, 2001) and in wild populations near Raritan Bay (Bobo *et al*., 2004; Lyons *et al*., 2007). Lyons *et al*. 2007 reviewed the epizootiology of QPX, which has not been reported south of Virginia. The parasite is more prevalent in intermediate size clams (25-55 mm) and in cultured populations. Research has found that southern (South Carolina and Florida) hard clam populations are more susceptible to QPX mortality than northern populations (Ford *et al*., 2002; Ragone-Calvo & Burreson, 2002; Calvo *et al*., 2007). QPX has not been reported in South Carolina, either in wild or aquacultured populations (Bobo *et al*., 2004). Importations for mariculture from areas of QPX infestation could spread this disease into local waters where it could be a threat to wild populations as well as cultured clams.

CONSERVATION ACCOMPLISHMENTS

The South Carolina Department of Health and Environmental Control (DHEC) restricts harvest of shellfish, including clams, in approximately 30% of estuarine waters in South Carolina for human health reasons. There have been no outbreaks of human disease related to hard clam consumption in South Carolina.

The South Carolina Department of Natural Resources (SCDNR) regulates importations of hard clams and other bivalves for placement in South Carolina waters, primarily for mariculture (SCDNR OFM, 2004). Importation from areas of known diseases, such as QPX, is restricted. Disease testing is required prior to importation, with zero tolerance for the presence of any known diseases. Shipments are also inspected by SCDNR staff for the presence of predators, non-native species, and other undesirable associated organisms.

The SCDNR regulates and monitors the commercial clam fishery, including annual compilation of fishery statistics. The SCDNR also makes limited assessments of oyster populations on State Shellfish Grounds on an annual basis to determine which State Grounds may need to be temporarily closed to allow populations to recover; however, a thorough fishery independent assessment of the resource status has not been conducted since 1978 and is long overdue.

CONSERVATION RECOMMENDATIONS

- Regularly update importation policies of cultured clams to reflect changes in threats to native clams.
- Continue to regulate and monitor mariculture activities given that these practices have the greatest potential for introducing diseases or non-indigenous predators and for affecting the native population genetic structure.
- Monitor for signs of the QPX disease in wild and cultured clam populations.
- Continue to monitor fishery trends.
- Conduct a thorough fishery independent assessment of the statewide hard clam population.
- Work with appropriate agencies to improve and implement Best Management Practices (BMP) in order to protect water quality and prevent turbidity caused by urban and agricultural runoff.

MEASURES OF SUCCESS

Determining that populations of hard clams are stable through annual fishery statistics and population monitoring within South Carolina would result in a measure of success. Another way to measure success is the absence of disease in native clam populations. Furthermore, the absence of human health problems associated with the consumption of hard clams would indicate successful conservation actions for this species.

- Bigclaw snapping shrimp (*Alpheus heterochaelis)* Say, 1818
- Green snapping shrimp (*Alpheus normanni*) Kingsley, 1878

Contributors: Peter Kingsley-Smith (SCDNR), Melissa Hughes (College of Charleston)

DESCRIPTION

Taxonomy and basic description:

The genus *Alpheus* is found in tropical, subtropical and temperate oceans and represents the most speciose genus of Caridea, with approximately 250 described species (Chace, 1988). These relatively large caridean shrimp are common in the intertidal regions. The *Alpheus edwardsii* group is notoriously difficult to decipher systematically as two or more very similar and highly variable species usually occur in sympatry.

The bigclaw snapping shrimp, *Alpheus heterochaelis* Say, 1818 (Crustacea: Decapoda: Alpheidae) is the largest and most colorful of four species of snapping or pistol shrimp found in the southeastern United States. It is typically dark translucent green with orange

and blue tipped uropods (Nolan & Salmon, 1970; Spence & Knowlton, 2008). Detailed descriptions of *A. heterochaelis* are provided by Brooks & Herrick (1892) and Williams (1984). Ovigerous females can measure up to 54 mm in body length, while males reach 40 mm (Willliams, 1984). In addition to size and coloration differences, *A. heterochaelis* can also be differentiated from other alpheids in South Carolina in that its larger claw has a notch in both the upper and lower margins at the base of the fingers (Ruppert & Fox, 1988). Within *A. heterochaelis*, males collected near Beaufort, NC had a greater ratio of claw length to total body length than females (Schein, 1975), although the degree of sexual dimorphism in claw size varies seasonally (Dinh & Patek, 2023). Sexual dimorphism of the minor chela can be used to determine sex in this species, with the male having a curved dactyl ("balaeniceps" claw) bearing many more setae than the female's straight dactyl (Nolan & Salmon, 1970; McClure & Wicksten, 1997; Spence & Knowlton, 2008).

The green snapping shrimp, *A. normanni* reaches a maximum body size of 10 mm carapace length (Williams, 1984), but other than its smaller size morphologically is quite similar to *A. heterochaelis*. The minor claw of the male, as in *A. heterochaelis*, is balaeniceps in shape. It is not known if the major chela is also sexually dimorphic, as in *A. heterochaelis*; the shape of the major chela differs from *A. heterochaelis* and the other species here in tapering dramatically towards the distal end (Williams, 1984) There are also other characteristics that allow these two species to be differentiated. In *A. normanni*, the orbital hoods of the carapace form an anterior toothlike projection, which is lacking in *A. heterochaelis*. Additionally, only the outer margin on the large claw of *A. normanni* is notched compared to both margins being deeply notched in *A. heterochaelis* (Nolan & Salmon, 1970). Its color likely varies among localities with Williams (1984) compiling several color descriptions of *A. normanni*: body gray or dullish green, sometimes with median lateral whitish stripe, often mottled with dark green or brown; pale spot behind each eye; major chela darker green and usually banded with yellow or yellowish brown on inner surface, occasionally with 2 pale bands and blackish fixed finger. Color variants should be treated with caution as cryptic species that can be morphologically distinguished solely by color in living specimens may be common in this genus (Knowlton & Keller, 1983). In SC, *A. normanni* typically has distinct light brown bands on the abdominal segments and chelae.

The estuarine snapping shrimp, *A. estuariensis* was distinguished morphologically from *A. heterochaelis* and *A. angulosus (*formerly *A. angulatus)* by McClure & Wicksten (1997). In contrast with *A. heterochaelis* and *A. angulosus*, this species is not sexually dimorphic in its minor chela, *i.e.,* in both sexes, the fingers are straight and distinctly longer than in the other species. It is not known if the major chela is sexually dimorphic in size. In contrast with the other species, the major chela of *A. estuariensis* has a pronounced square tip (see McClure & Wicksten, 1997 for comparison of major and minor chelae of these species). Like *A. normanni*, the abdomen is typically banded, although darker in coloration.

Alpheus angulosus was first described in 1997 (originally *Alpheus angulatus*); this species has likely been confused in older collections with *A. heterochaelis*, *A.*

estuariensis, and *A. armillatus* (a species now considered to be restricted to the tropics; McClure & Wicksten, 1997). Both the major and minor chelae differ in shape from the other species considered here; see McClure & Wicksten, 1997, Fig. 4, for comparison. The minor chela is not sexually dimorphic and is shorter and stouter than the minor chelae of *A. estuariensis* or females of *A. heterochaelis* or *A. normanni* (McClure & Wicksten, 1997). The major chela is sexually dimorphic in both size (with the size of both male and female major chelae vary seasonally, Heuring & Hughes, 2019) and – unique among these species – shape; the distal tip of the male major chelae is broader than the distal tip of female major chelae (McClure & Wicksten, 1997). Body colors in *A. angulosus* range from green to brown and can be dark or light; darker individuals tend to be females. While individual captured further south on the Atlantic coast and in the Gulf are described as having blue antennae (Spence & Knowlton, 2008), in SC, antennae are greenish brown or orange. Genetic analyses confirm these color variations are not cryptic species (Heuring *et al.,* 2017).

Status

POPULATION DISTRIBUTION AND SIZE

The bigclaw snapping shrimp, *A. heterochaelis* occurs from the lower Chesapeake Bay (Van Engel & Sandifer, 1972) to Aransas County, Texas, Cuba, Curaçao, and Surinam (Chace, 1972), with other authors listing the range as extending as far as Sao Paulo, Brazil (Whitaker, 1984). These range limits should be treated with caution, however, as they may include cryptic species and/or more recently described species (e.g., *A. angulosus*, see below; McClure, 1995).

The green snapping shrimp, *A. normanni* occurs in Bermuda, around Cape Charles, Virginia and the lower Chesapeake Bay, through the Gulf of Mexico and West Indies to Brazil (Kingsley, 1878).

The estuarine snapping shrimp, *A. estuariensis* ranges from Florida and the Gulf of Mexico southward to Brazil (Christoffersen, 1984).

Alpheus angulosus occurs in the Gulf of Mexico (Mathews, 2002) and southern Atlantic coast through South Carolina (Hughes *et al.*, 2014), with some collections occurring as far north as Beaufort, NC. The full extent of their range is not known, given their relatively recent description.

HABITAT / NATURAL COMMUNITY REQUIREMENTS

The recently described *Alpheus angulosus* is the most commonly collected alpheid species intertidally in South Carolina (*e.g.,* Song *et al.,* 2021) and as it was not described until the late 1990s (McClure, 1995), it is likely confused with other species, including *A. heterochaelis* in prior collections of alpheids (Hughes, M., pers. obs.). By comparison, *A. estuariensis* and *A. normanni* are found less often, perhaps because they have different habitat requirements (Hughes, M., pers. obs.). Within South Carolina anecdotally and

based on collection (Hughes, M. unpubl. data), *A. heterochaelis* may be more common intertidally along more northern parts of the coast, and perhaps due to limited upper temperature tolerances may be more common intertidally in the winter than the summer, moving more subtidal when temperatures rise.

Intertidal alpheids, unlike their subtidal counterparts, all build their own burrows under hard substrate or take advantage of existing cavities. Similarly, unlike subtidal species, they are generally not associated with other species (although at least in the mid-Atlantic region, *A. heterochaelis* may sometimes form commensal relationships with mud crabs; Silliman *et al*., 2003). There is little information on the impacts that their burrowing activities have on other dwellers of intertidal habitats in South Carolina.

Members of the family Alpheidae are ubiquitous producers of sound (Johnson *et al*., 1947) and members of the genera *Alpheus* and *Synalpheus* (generally a more subtidal group) are capable of producing vigorous snaps (Johnson, 1944; Everest *et al.*, 1948; Kaji *et al*., 2018; Song *et al*., 2021). These snaps have been detected across a range of habitats, including estuaries of the southeastern United States (*e.g.,* Monczak *et al*., 2019, 2020; Mueller *et al*., 2020)

The snapping sounds produced by members of the genera *Alpheus* and *Synalpheus* have been the subject of considerable literature, reviewed by Knowlton & Moulton (1963). The snaps are produced by the rapid closure of the larger of the asymmetrical claws, resulting in the production of a rapid jet of water and pressure differential (Versluis *et al*., 2000). Consequently, small bubbles of dissolved gases grow in size and form a larger cavitation bubble, which then collapses creating a short-duration acoustic pulse, which operates over short distances (~ 9mm; Herberholz & Schmitz, 1999). The most well-known function of this snapping sound is as an agonistic communication behavior during intraspecific encounters (Nolan & Salmon, 1970; Schein, 1975, 1977). Competitors can also assess body size based on the signal of an open major chela (Hughes, 2000). The snaps may also function as a physical weapon to defend territory by stunning or killing prey (Schein, 1975, 1977; Schmitz & Herberholz, 1998; Schultz, 1998). Additionally, the lower frequencies of snaps may act as acoustic cues for larvae seeking appropriate settlement habitats (Simpson *et al*., 2005; Lillis *et al*., 2013, 2015) and have been documented to occur at higher rates around physically complex habitats of gregarious reef building organisms such as corals and oyster reefs (Spence & Knowlton, 2008). As such, soundscapes may present an indirect measure of habitat quality in the context of habitat enhancement and restoration (Butler *et al*., 2017; Monczak *et al*., 2020). Additionally, *A. heterochaelis* has been shown to be more abundant around oyster reefs than adjacent non-reef study plots (*e.g.,* Tolley & Volety, 2005; Kingsley-Smith *et al.,* 2012).

While the role of snapping shrimp in coastal SC food webs is not well known, in other ecosystems they have been identified as keystone species (Wu *et al*., 2020). Snapping shrimp are common prey items for a diverse assemblage of predators, ranging from teleost fishes (Morato *et al*., 2000; Šantić *et al*., 2009; Lopez-Lopez *et al*., 2011, Šantić *et al*., 2011; Jeyabaskaran *et al*., 2020; Chen *et al*., 2023) including flatfish (Dou, 1995;

Sartor & De Ranieri, 1996; Fanelli *et al*., 2009), sharks and rays (Lowe, 2002; Šantić *et al*., 2011, 2012; Queiroz *et al*., 2023), and octopus (Quetglas *et al*., 2009, Serrano-Tadeo *et al*., 2021) to terrestrial predators such as snakes (Jayne *et al*., 2018) and presumably wading birds and shorebirds that are regularly observed in their habitat at low tide (Hughes, pers. obs.).

The diets of these Alpheus species are not known, although most probably range from scavenging to attacking small prey. Under laboratory conditions, *A. angulosus* and *A. heterochaelis* will both attempt to depredate small hermit crabs by snapping directly on their shells (Hughes, pers. obs.). In the case of *A. heterochaelis*, this species will prey upon small bivalves by similarly crushing shells with their major chela (Beal, 1983).

THREATS

From a conservation perspective, the dominant threats to intertidal alpheids that may make them vulnerable on a local and regional scale to extirpation are likely to be related to habitat loss and degradation, particularly given the rapid rate of coastal development and its associated negative impacts (e.g., losses of intertidal oyster reef habitat and/or salt marsh habitat, pollutants and contaminations.

CONSERVATION ACCOMPLISHMENTS

Species in the genus *Alpheus* have received little or no attention in terms of past conservation efforts in South Carolina, likely due to the data deficient nature of this species to indicate that its number have been in decline, either as a result of natural or anthropogenic factors.

CONSERVATION RECOMMENDATIONS

Soundscape ecology, including that focused on snapping shrimps, can provide a long-term non-invasive approach to improving our understanding of animal movement and behavior patterns, assessments of habitat quality and community structure and species interactions over temporal and spatial scales. Furthermore, the comparison and interaction of biological and anthropogenic soundscapes can be used to determine the degree of human disturbance in relation to sound in coastal landscapes (*e.g.,* Transue *et al.*, 2023). Understanding the impacts of anthropogenic sound on coastal organisms directly and through its interference with biological soundscapes will be important for the conservation of species that rely on sound for communication, defense, prey capture, and other ecological functions.

More basic information is needed on the distribution, habitat associations, and basic life history for the species in the genera *Alpheus* in coastal South Carolina. Without such baseline data, it is impossible to detect whether or not these species abundances are in decline and species in need of targeted conservation actions. Furthermore, population sizes for all of these species are largely unknown (Hughes, M. pers. comm.). Additionally, there have been misidentifications and taxonomic confusion for these

species in the recent past, such that a robust field for these species in the South Atlantic Bight would be a valuable tool to aid in the collection of field data on these species to inform our knowledge on this important guild.

The array of functions and consequences of shrimp snaps are such that characterizing the parameters of the sounds of the different alpheid species inhabiting coastal South Carolina habitats is important to better understand their functions and to discern their signals within coastal soundscapes. The impacts of these sounds on other organisms also warrant further investigation. The snaps of *A. heterochaelis* and *A. angulosus* have been described by Song *et al.* (2021), but equivalent information for other members of the guild described here is lacking.

MEASUREMENT OF SUCCESS

Success would constitute a thorough understanding of the distributions and life histories of these species and a greater confidence in differentiating among species in the field. In addition, the application of distribution and abundance information as a metric of habitat quality would be informative within the broader disciplines of habitat conservation and restoration in coastal habitats of South Carolina.

DESCRIPTION

Species in the intertidal shorebird foraging habitat guild are critical food resources for many shorebirds including species of national concern, such as the piping plover (*Charadrius melodus*) and red knot (*Calidris canutus)*. Prey availability has been shown to be a critical factor affecting the distribution of shorebirds (Fraser *et al.,* 2005; Lyons, 2005; Spruzen *et al.,* 2008a, b), and therefore represents an important measure of habitat quality. Recent studies of overwintering habitat quality in South Carolina have investigated potential prey items found in sediment cores taken from known foraging areas of piping plover and red knot (Bergquist *et al.,* 2011; Thibault & Levisen, 2013; Coastal Eco-Group, Inc., 2013). Fecal samples have also been collected from overwintering locations in South Carolina to identify invertebrate taxa consumed by piping plover and red knot (USFWS, unpublished data; Thibault & Levisen, 2013). The dominant taxa from cores and fecal samples included amphipod crustaceans, polychaete worms, bivalve mollusks, and eggs of the American horseshoe crab *Limulus polyphemus* (subphylum Chelicerata) [a separate species account is afforded to this species], all of which comprise this guild.

Shoreline modification projects and other human disturbances of coastal habitats have been shown to reduce the foraging success and fitness of migratory shorebird populations (Verhulst *et al.,* 2004; Peterson *et al.,* 2006). Physical changes resulting from beach re-nourishment may be associated with changes in infaunal macroinvertebrate distributions and subsequent reductions in shorebird utilization of the affected habitat (Peterson *et al.,* 2006).

Red Knot (*Calidris canutus*) foraging on an intertidal flat at Kiawah Island, SC. Photo by Janet Thibault, SCDNR.

The invertebrates included in this guild become species of concern because disruption of the biological characteristics of overwintering areas, including reduced abundance of these available prey items, could have substantial and long-lasting impacts on migratory shorebird populations.

Taxonomy and Basic Description

Amphipods are in the taxonomic order Amphipoda of malacostracan crustaceans which have no carapace and generally have laterally compressed bodies. These inconspicuous crustaceans are prominent members of marine communities worldwide.

Species in the family Gammaridae that are represented in marine intertidal habitats include *Gammarus palustris* and *Gammarus mucronatus* both of which are estuarine species. These gammarid amphipods range in size from 6-14 mm as adults and have compressed, anteriorly smooth bodies.

Species in the family Haustoriidae are well represented in intertidal habitats, particularly in the sandy substrate of open beaches, but some species can also be found intertidally along salt marsh creeks and bars. Haustorids are burrowing amphipods that are characterized by their white barrel-shaped body the lack of a true rostrum and no dactyls on peraeopods 3-7 as well as fossorial appendages with numerous spines that assist in digging within sandy substrates. The species that occur in South Carolina are usually small (<0.5", 13 mm) and include species in the genera *Acanthohaustorius, Haustorius, Lepidactylus, Neohaustorius, Parahaustorius, Protohaustorius* and *Pseudohaustorius.*

The coquina clam, *Donax variabilis*, is a member of the bivalve family Donacidae. Coquina clams possess wedge-shaped shells, generally less than 0.8 in. (2 cm) in length, and are characterized by pastel colored bands radiating from the umbo to the margins of the valve (Ruppert & Fox, 1988). [A separate species account is afforded to this species.]

The dwarf surf clam, *Mulinia lateralis*, in the family Mactridae, is one of the smallest clams found on southeastern U.S. beaches, with lengths of only 0.6" (1.5 cm). *Mulinia lateralis* is characterized by its moderately inflated shape, solid strong valves and triangular hinge. The shell is pale cream-white in color with a radial ridge on each side of the posterior slope.

Tellin clams include species in the family Tellinidae and are small (usually < 1"), laterally compressed, and usually have a slight twist at the posterior end (Abbot, 1974). Shel color can vary from iridescent white to pale pastels.

The false angel wing, *Petricolaria pholadiformis*, is a small (2") bivalve in the family Petricolaridae that has a thin, white elongated shell marked by strong, scaly, radial ribs. It can superficially resemble the Angel wing, *Cryptopleura cosata*, but is much smaller.

The scorched mussel, *Brachidontes exustus*, is a small (1") fan shaped intertidal bivalve in the family Mytilidae that attaches to hard surfaces using a strong byssus. It has dark brown or yellowish values crossed by radial ribs.

Polychaete worms are in the taxonomic class Polychaeta which are segmented annelid worms. They are characterized by an elongated body bearing appendages called parapodia which bear many bristles, called chaetae. *Arabella mutans* and *Drilonereis longa* are both members of the family Oenonidae. Oenonids are typically large (as long as 12-14") earthworm-like worms which burrow in sand and mud on protected beaches. Species of Oenonidae can be distinguished using such characters as the shape of the head and the presence or absence of eyespots.

The bloodworms, *Glycera americana and Glycera dibranchiata,* are both members of the family Glyceridae. Glycerid worms are bright red, segmented worms that can reach up to 9" in length. Glycerids are ferocious epi- and infaunal polychaetes that prey upon small invertebrates. They are characterized by their pointy snout used for burrowing in sediment and their eversible pharynx containing 4 poisonous fangs used for capturing prey.

Laeonereis culveri and *Nereis succinea* are both members of the polychaete family Nereididae. Adult nereid worms can range from approximately 2.5-6" and are characterized by their conspicuous heads with 2 short antennae, 4 eyes, 2 bulbous palps, and 4 pairs of long tentacular cirri (Ruppert & Fox, 1988).

Tharyx acutus is a segmented worm of the polychaete family Cirratulidae. Members of this family are cylindrical, elongated, and characterized by reduced heads that lack appendages.

Capitella capitata and *Mediomastus* sp. are members of the polychaete family Capitellidae. Capitellid worms are red or purple in color with thread-like, flexible bodies that grow up to 4" in length. They are characterized by their conical shaped head and reduced appendages.

Paraonis fulgens is a segmented worm of the family Paraonidae. Paraonids are slender-bodied worms with many segments than can grow up to 1.3" in length. *Paraonis fulgens* is characterized by its lack of a median antenna on the head and hooked neurosetae on the postbranchial region of the body.

Scolelepis sp. and *Streblospio benedicti* are members of the tube-dwelling polychaete family, Spionidae. Spionids, also called palp worms, are characterized by their small heads and two long grooved palps used for deposit or suspension feeding. Spionids are mostly small (~6"), but large species do exist.

The American horseshoe crab, *Limulus polyphemus,* is the only member of the Arthropoda subclass Xiphosura found in the Atlantic Ocean. Horseshoe crabs are not true crabs as their name suggests, but members of the subphylum Chelicerata, which are more closely related to spiders, scorpions, and ticks. *Limulus polyphemus* are characterized by their lack of antennae and jaws and have 7 pairs of legs, including a pair of chelicerae.

Ribbon worms are non-segmented worms that belong to the phylum Nemertea and include the intertidal predator *Cerebratulus lacteus* which can reach 20" or more. It is smooth, milky white to pink and lacks external appendages.

Acorn worms are large non segmented worms belonging to phylum Hemichordata, a relatively advanced invertebrate taxa that includes a primitive nerve chord called a stomochord. The two common species in our region are *Saccoglossus kowalevskii* which grows to 15-20 cm and the much larger *Balanoglossus aurantiacus* which can reach up to 1 meter.

Exosphaeroma diminutum is a small (2 mm) marine isopod in the family Sphaeromatidae. It is characterized by a series of interlocking plates that allow it to fully curl itself into a sphere for protection which is the source of the family name.

Brachyuran crabs in the family Pinnotheridae are relatively small decapods with a membranous carapace that lacks lateral spines and ranges in width from 3.5-21 mm, however most species have a carapace width of less than 10 mm (Williams, 1984).

Status

None of the species in this guild are officially recognized as threatened or endangered, but all are part of the macroinvertebrate prey community in coastal habitats of the southeastern U.S. which serve as critical habitats within the overwintering/foraging range for threatened, endangered, and conservation priority shorebirds. There have been some concerns regarding reduced numbers of adult horseshoe crabs at some locations due to loss of habitat and overharvesting, which would result in fewer eggs and larvae available as prey items.

POPULATION SIZE AND DISTRIBUTION

Gammarus palustris and *Gammarus mucronatus* are distributed in estuaries from Northern Florida through the mid-Atlantic and north to the Cape Cod region and Piscataqua estuary with the range of *G. mucronatus* extending to the Gulf of St. Lawrence (Bousfield, 1973). Population size varies by location and season and has not been previously quantified.

Haustorid amphipods are very abundant along the intertidal gradient of the US East Coast (Bliss *et al.,* 1983). The haustorid amphipods in this guild range from Saco Bay, ME through Cape Canaveral, FL (Bousfield, 1973; Grant & Lazo-Wasem, 1982). Although the distribution of this group is well documented, population size could vary considerably by location and season and would be difficult to quantify.

Donax variabilis is a familiar species on sandy intertidal beaches in the southeastern U.S., where its shells are found in abundance. In the U.S., *D. variabilis* ranges from New Jersey to Florida and the Gulf of Mexico (DeVictor *et al.,* 2010). Surveys in the southeastern U.S. have found that it is among the most abundant macroinvertebrates present in the intertidal area during spring, where numbers have been recorded in excess of 1,000 per m^2 (93 per $ft.^2$; Pearse *et al.,* 1942; Shealy *et al.,* 1975; Knott *et al.,* 1983). [A separate species account is afforded to this species.]

The dwarf surf clam, *Mulinia lateralis*, can be an abundant species in shallow water sandy areas on the Atlantic Coast of the U.S. This species ranges from Maine to North Florida and has been found in abundances as high as 21,000 individuals per m^2 (Santos & Simon, 1980).

Tellinid clams are mud or sand dwellers found worldwide. Members of the family Tellinidae are very common on the South Carolina coast (Ruppert & Fox, 1988). Because there are many species in this genus, population size is difficult to estimate. Most of the species commonly found in the Southeast range from the Mid-Atlantic (Virginia/North Carolina) to Florida (Abbott, 1974).

The false angel wing, *Petricolaria pholadiformis* can be found along the Western Atlantic coast from Canada to Uruguary (Porter & Houser, 1997). Current population estimates are not available for this species but future monitoring may be necessary as it expands beyond its native range to both the west coast of North America and the Eastern Atlantic.

Brachidontes exustus occurs in the western Atlantic from North Carolina to Venezuela. This species can form dense mats in the low intertidal zone and is often one of the dominant mollusk species in estuaries (Barber *et al.,* 2005).

The glycerid worms, *Glycera americana* and *Glycera dibranchiata*, are very common in shallow water areas of South Carolina (Ruppert & Fox, 1988). In the eastern U.S., *G. americana* ranges from Massachusetts to Florida, while *G. dibranchiata* ranges from Maine to Florida (Day, 1973). Since these species can be epifaunal as well as infaunal, population size is difficult to estimate.

Polychaetes of the family Oenonidae (*A. mutans, D. longa*) are commonly found burrowed in sand and mud on protected intertidal beaches. In the eastern U.S., *A. mutans* ranges from South Carolina to Florida and *D. longa* ranges from Massachusetts to Georgia (Day, 1973). Although members of this family are more conspicuous than other polychaetes, population size is unknown.

Alitta succinea enjoys the widest distribution of any invertebrate species in the southeastern U.S., occurring in all benthic habitats except outer beaches (Ruppert & Fox, 1988). In the North Atlantic, *N. succinea* ranges from the Gulf of St. Lawrence to Florida, while *Laeonereis culveri* ranges from Connecticut to Florida (Gardiner, 1975). Studies in the Chesapeake Bay indicated that *N. succinea* may occur in considerable abundance, with densities of 400 individuals per m^2 in disturbed, partially anaerobic sediments (Hamilton, 1972).

Tharyx acutus ranges from the Gulf of Maine through North Florida on the East Coast of the U.S. Little has been reported on population estimates of *T. acutus*; however, a benthic invertebrate survey in New York reported abundances of 80 individuals per m^2 (USACE, 2004).

Capitella capitata and *Mediomastus* sp. are both very abundant on the East Coast of the U.S. *Capitella capitata* is a cosmopolitan species (occurring worldwide) that is often found in very high densities up to several thousand per m^2 in sediments that have been enriched with organic pollutants (Ruppert & Fox, 1988). Identifications to species level in the genus *Mediomastus* are often difficult due to the collection of incomplete worms, but there are several species that occur in high abundances on the U.S. Atlantic Coast.

Paraonis fulgens ranges from Maine to Florida in the Atlantic coastal waters of North America. Little is known regarding the population size of this species.

The spionid polychaete, *Streblospio benedicti* occurs along the US Atlantic coast from Maine south to Florida. Studies on *S. benedicti* abundance on the East Coast have reported the species to be among the most abundant and characteristic taxa occurring in Gulf of Maine mud flats (Larsen & Dogget, 1991) and among 4 taxa dominating North Carolina saltmarsh macrofauna (Cammen, 1979). The other spionid in this guild, *Scolelepis* sp., ranges from New England to Florida in the North Atlantic and has been found in abundances higher than 100 individuals per m^2 on the studied beach (Degraer *et al.,* 2003).

Horseshoe crabs range from northern Maine to the Yucatan Peninsula. Adult horseshoe crabs migrate from deep bay waters and the Atlantic continental shelf to spawn on intertidal sandy beaches as well as salt marshes in South Carolina (Kendrick *et al.,* 2021).

The geographic range of *Cerebratulus lacteus* in the western Atlantic begins in Florida and extends north to Prince Edward Island. It is a common inhabitant of sand and mud flats throughout its range; however, population size estimates are not currently available.

Saccoglossus kowalevskii and *Balanoglossus aurantiacus* can be found in the western Atlantic from Florida extending north to Newfoundland and have also been reported along the Gulf Coast. A study of *Saccoglossus* in Virginia estuaries found that this species can occur at densities of up to 500 m^2 (Schrage, 2021).

Exosphaeroma diminutum occurs from North Carolina through central South America intertidally on sandy beaches. A study of benthic infauna collected from a sand bar in the Charleston Harbor estimated the density of *Exosphaeroma diminutum* to be 24 individuals m^{-2} (Tweel & Sanger, 2016).

Numerous genera of pinnotherid crabs are found in the western Atlantic with most species ranging between central South America and extending north to Newfoundland. The small size and cryptic life history of these species makes population estimates difficult.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Marine invertebrate members of the shorebird foraging habitat guild live in the intertidal zone on sandy ocean beaches. The intertidal zone lies between the high tide line and the low tide line and is alternately submerged and exposed depending on the stage of the tide. As the tide moves up and down the beach, sand formations such as bars and runnels can form which border elongated tidal pools that run parallel to the waterline. These tidal pools are excellent habitat for the invertebrates in this guild.

Gammarus palustris and *Gammarus mucronatus* are free-swimming benthic estuarine amphipods that occur intertidally on muddy, grassy and stony beaches and marsh banks from about mid tide to mean high water. These species have an optimal salinity range of 5-20 ppt but can tolerate full short periods of fresh water, in cold winter conditions, or oceanic sea water (~36 ppt) in warmer summer months (Bousfield, 1973). Both species are important contributors to the breakdown of marsh grasses and the formation of detritus in salt marshes (Heard, 1982) as well as providing a food source for fish and birds (Thomas, 1976; Heard, 1982).

Haustorid amphipods are free-swimming amphipods which are adapted for burrowing in sandy or silty substrates. They prefer a variety of intertidal areas including exposed and protected beaches, inlet entrances, and estuaries with fine sand or mud. They can be found from mean low water to 50 m in depth and in salinities from 6 ppt to fully marine, depending on the species (Bousfield, 1973).

Donax variabilis is well-adapted to live and feed in the wave-washed swash zone of sandy, intertidal beaches. Coquina clams are shallow burrowers that have the ability to alternately emerge and burrow in the sand to move up and down the beach with the tide in order to filter feed on the phytoplankton and other small suspended particles.

Mulinia lateralis live shallowly buried in sand or mud on the lower ocean beach where, like other bivalves, they filter feed on suspended materials. They are tolerant of low salinities and are also found in estuaries and lagoons.

Tellinid clams include numerous genera which inhabit muddy or sandy bottoms in a range of depths and salinities. Two common species, *Ameritella agilis and Oudardia iris,* most often live in high-salinity estuaries but can also be found offshore in depths up to 75'. Tellin clams feed primarily on detritus and are consumed by fish and wading birds.

Petricolaria pholadiformis is an intertidal bivalve that bores into dense sediments such as clay or peat associated with marsh vegetation or on hard substrates intermingled with other bivalves such as mussels (Ruppert & Fox, 1988). This species has been observed in the marsh relic habitat of barrier islands. This unique habitat is characterized by dense clay and root mats that are the remnants of old marsh habitat on the estuarine side of the island that was covered over by sand as the island migrated landward and later exposed by erosion on the ocean facing side of the island. Marsh relic habitat has been identified as potentially important foraging grounds for wading birds such as piping plover and red knot which have been observed feeding on bivalves, including *Petricolaria*, on front facing beaches where marsh relic occurs.

Brachidontes exustus can tolerate a broad temperature range and spawning periods correlate with changes in water temperature with both spring and fall spawns triggered by changes in water temperature (Barber *et al.,* 2005). Adults can tolerate a range of salinity allowing them to colonize hard surfaces throughout estuaries as well as rocks and pilings on ocean facing beaches. Dense mats of *Brachidontes* can provide habitat for other invertebrates in much the same way as reef building oysters. Like the false angel wing, these mussels have been observed in marsh relic habitat where they are likely preyed on by wading birds.

Capitellid worms, such as *Capitella capitata* and *Mediomastus* sp., are sedentary deposit feeders that often occur in mud or muddy sand on the lower shore to sub-littoral zone. They may be found under pebbles or small stones, with the burrows at or near the surface of the sediment where they feed on deposited organic material (Ruppert & Fox, 1988).

Polychaete worms of the family Nereididae (formerly Nereidae) are commonly found in all water depths, hiding under rocks or burrowing in sand or mud. *Laeonereis culveri* constructs tubes in shoals of sand mixed with mud and shell fragments (Gardiner, 1975). *Nereis succinea* is

often found on pilings, oyster clumps, under rocks, and in shoals of sand mixed with some mud or shell fragments. They prefer estuarine and intertidal habitats to 40 m in depth (Day, 1973).

Tharyx acutus, of the polychaete family Cirratulidae, is a sluggish-type worm that inhabits medium to fine sand or muddy sediments. This species is usually found buried just below the surface of the sediment with only its feeding appendages visible.

Paraonis fulgens, like other members of the Paraonidae, are burrowers and deposit feeders that occur in the intertidal zone to depths of 10 m (Day, 1973). They prefer fine sands as the deeper portion of their burrows are spiraled to provide better anchorage in the sediment (Ruppert & Fox, 1988). *Paraonis fulgens* is often found in association with the spionid worms *Scolelepis* sp. and *Streblospio benedicti. Streblospio benedicti* prefers suitable soft sediments where they can form mucoid tubes just below the sediment-water interface that allow them to deposit feed. *Streblospio benedicti* is relatively tolerant to elevated levels of sediment organics (Reish, 1979), a trait that contributes to its success as an opportunistic species. *Scolelepis* sp., unlike other spionids, are not deposit feeders. They construct inconspicuous sandy tubes at the surface of the beach where they can catch suspended particles in the sticky mucus of their palps (Ruppert & Fox, 1988). *Scolelepis* sp. prefer a physically stressed habitat where there is rapid water movement.

Adult horseshoe crabs (*L. polyphemus*) mate in the spring and deposit up to 88,000 eggs in large bowl-like depressions in the intertidal region of quiet, sandy beaches, while also spawning in salt marshes (Kendrick *et al.,* 2021). Planktonic larvae hatch from the eggs within 2-4 weeks, although some larvae may overwinter within nests and hatch out the following spring (Botton *et al.,* 1992). Juvenile *L. polyphemus* remain in the intertidal flats, usually near breeding beaches.

Cerebratulus occurs in estuaries and on beaches where it burrows in the soft sediment of sand and mud flats preying upon bivalves and polychaetes. It swims in the water column at night and returns to the bottom during the day (Ruppert & Fox, 1988). *Cerebratulus* fragments itself voluntarily in response to predation, leaving behind a tail that moves vigorously to distract predators, allowing the head to escape and regenerate. The genetic signature of this species was identified in fecal samples collected from piping plover indicating it is a likely prey item.

Acorn worms are relatively large burrowing deposit feeders that live in the protected intertidal sand and mudflats of estuaries and beaches. Both *Saccoglossus kowalevskii* and *Balanoglossus aurantiacus* break apart easily when collected, making complete specimens rare. Large burrowing fauna such as acorn worms are potential prey items for wading birds.

Exosphaeroma diminutum is found intertidally on beaches associated with tide pools, under rocks or other debris or amongst encrusting communities that colonize pilings, rocks and other hard substrates. This species has been documented in waters ranging from 20-30°C with a salinity range of 20-36 ppt.

Pinnotherid crabs are small commensal or parasitic decapods that are most often associated with a bivalve, tunicate, polychaete or echinoderm host. Species from numerous genera are found intertidally each forming a symbiotic relationship with a specific host. *Zaops ostreum*, for

example, commonly live on the gills of oysters while *Austinixa cristata* is associated with callianassid decapod burrows. Adult pinnotherid crabs generally inhabit intertidal habitat and can tolerate a range of salinity and temperature. Spawning occurs only in the warmer months (May-September) in the northern portion of the range (New England and Canada) and becomes more protracted in the southern portion of the range with spawning of some species occurring year-round in Florida waters (McDermott, 2005).

CHALLENGES

Habitat loss and degradation from coastal development and rising sea levels are the main challenges to the beach invertebrate/shorebird feeding guild. Intertidal macroinvertebrate fauna play a key role in the sandy beach food chain, where filter feeders and deposit feeders turn over high amounts of particulate organic matter and meiofauna (McLachlan & Brown, 2006). In turn, they are an important food source for different kinds of predators such as shorebirds.

Although beach re-nourishment projects restore sand to eroded beaches, these activities can significantly negatively affect populations of sand-dwelling invertebrates as they are buried under a thick layer of sand. Re-nourishment may alter the physical environment of a beach by adding non-native sand, potentially resulting in a changed sediment composition and beach morphology. If these environmental changes are permanent, long-term changes in the macroinvertebrate community may occur.

CONSERVATION ACCOMPLISHMENTS

In South Carolina, critical habitats for the piping plover overwintering population have been designated by the U.S. Fish and Wildlife Service to help protect the species during its migratory period. Because of the official designation, standardized monitoring protocols which include assessing overwintering habitat quality (*i.e.,* identity and quantity of prey organisms included in this guild) are required in conjunction with shoreline modification projects.

CONSERVATION RECOMMENDATIONS

Effective habitat management requires a better understanding of the factors that determine habitat value to shorebirds. Piping plover conservation efforts continue to concentrate on increasing the population and on ensuring protection and maintenance of overwintering habitat for distinct populations (USFWS, 2009). The red knot is currently a candidate species for federal listing under the Endangered Species Act due to the rapid decline of this species in the last 15 years. It is theorized that population declines may be influenced by a lack of food availability, most notably horseshoe crab eggs, during migration. A fishery management plan is in place for horseshoe crabs on the East Coast through the Atlantic States Marine Fishery Commission (ASMFC) which implements regulations to limit the harvest of this species. Monitoring efforts to investigate potential impacts to the quality of overwintering piping plover and red knot habitat associated with shoreline construction projects is ongoing in South Carolina and will continue to provide estimates of the abundances of available prey items described in this guild.

MEASURES OF SUCCESS

Measures of success for this guild will directly correlate with conservation efforts to increase the populations of shorebirds such as the piping plover and red knot, as well as maintaining the quality of overwintering foraging habitats utilized for these distinct populations.

Lettered olive
Oliva sayana

Contributor: Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and basic description:

The lettered olive, *Oliva sayana* Ravenel, 1834 (Gastropoda: Neogastropoda: Olividae) as a member of the family of olive snails, is characterized by a long, narrow, streamlined shell with a very large body whorl. This last body whorl accounts for most of the of the shell and the spire is short, inconspicuous, and pointed (Ruppert & Fox, 1998). The shell length can measure up to 2½" (64 mm). The shell aperture is long and narrow, with the inner margin bearing numerous wrinkles or folds. The long axis of the shell is held parallel to the long axis of the animal as it crawls across the sand. Living in the sand, the shell is protected from abrasion by being surrounding by the large foot and mantle (Ruppert & Fox, 1988). The shell lacks an operculum, the siphonal canal is poorly developed, and the smooth, glossy shell is characterized by dark brown or purples letter-like markings (Ruppert & Fox).

Three previous subspecies of *O. sayana*, namely *O. sayana sarasotensis* Petuch & Sargent, 1986, *O. sayana texana* Petuch & Sargent, 1986, and *O. sayana sayana* Ravenel, 1834, have since all been recognized as *O. sayana* Ravenel, 1834, such that these subspecies names are no longer accepted according to the World Register of Marine Species (https://www.marinespecies.org/).

Status

This species in the South Carolina State Shell and received its common name because of the markings that look like writing. Another member of the Olividae found in South Carolina, *Olivella mutica*, is much smaller, has an operculum, and has a larger spire to shell length ratio (DeVictor *et al*., 2010). The species is currently not listed as threatened or endangered on any recognized state or Federal listing; however, this is likely in part explained by its data deficient nature.

POPULATION DISTRIBUTION AND SIZE

The geographic range of *O. sayana* extends from North Carolina to Florida, the Gulf states of North America, including Louisiana and Texas, and further south to the east

coast of Mexico, including Campeche State, Yucatan State and Quintana Roo, with the species reportedly collected live at depths of up to 27 m (Malacolog version 4.1.1).

HABITAT / NATURAL COMMUNITY REQUIREMENTS

The lettered olive is often found in the surf zone of outer beaches, on shallow sand flats near inlets, and offshore in sand (Ruppert & Fox, 1998). In the surf zone, it feeds on coquina clams (*Donax variabilis*) and Atlantic mole crab (*Emerita talpoida*), both of which are species included in the South Carolina State Wildlife Action Plan, which it asphyxiates with its foot. Details of spawning and a description of the egg capsules of O. sayana were described by Olsson & Crovo (1968) and briefly outlined later by D'Asaro (1970). The life history of this species includes the deposition of transparent, roughly spherical egg capsules of average diameter of 1.6 mm containing a large amount of albumen that forces the embryos against the inner surface of the capsule wall. Counts of embryos range from 14 to 48, with an average of 24, and the species has a long-term planktotrophic veliger (D'Asaro, 1970).

THREATS

This species is likely susceptible to disturbances to its natural habitat from the effects of coastal development and beach renourishment activities, as well as dredging and trawling activities in nearshore waters. Additionally, in a forecasting effort for how marine molluscan fauna might respond to environmental change over the remainder of the 21st Century, Saupe *et al.* (2014), *O. sayana* was among those species found to show reductions in suitable area of moth than 20% by 2080.

CONSERVATION ACCOMPLISHMENTS:

This species has not received any directed conservation actions, likely due to the lack of a fishery for this species, and the data deficient nature of this species. This species has been included in the State Wildlife Action Plan since at least 2015 in recognition of its probably importance as a predator of other SWAP-listed species and its status as the State Shell of South Carolina.

CONSERVATION RECOMMENDATIONS

Searching the literature and other information online yielded very little, both at a local and geographic range scale. While limited life history information is available from aquarium studies (see D'Asaro, 1970), studies of natural life history from South Carolina for this species are completely lacking. Baseline information on demographics, trophic interactions, and physiological tolerances would all serve to improve our understanding of the current status of this species and its future needs from a conservation perspective. Studies of the natural interactions between this and other SWAP-listed species (e.g., *Donax variabilis, Emerita talpoida*) could be conducted at a habitat level scale of study, perhaps focusing on the role of *O. sayana* within the surf zone.

MEASUREMENT OF SUCCESS

Success would constitute a better understanding of the distribution of this species in coastal habitats of South Carolina and therefore the prioritization of areas for monitoring and protection to ameliorate impacts from anthropogenic activities and the potential loss of habitat due to climate change.

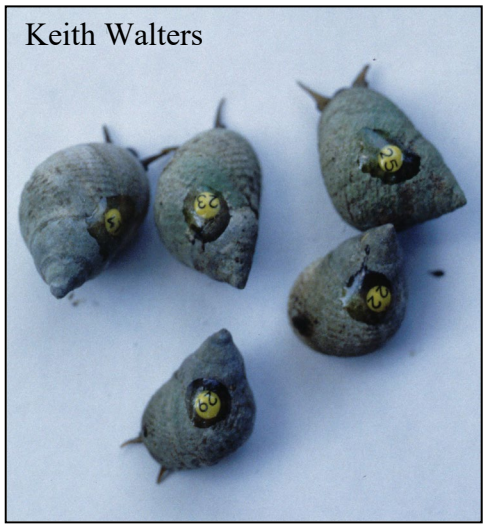
Marsh Periwinkle

Littoraria irrorata

Keith Walters

Contributors (2005): Keith Walters (Coastal Carolina University) and Loren Coen (SCDNR). Reviewed and Edited (2013, 2023): Andrew Tweel and Peter Kingsley-Smith (SCDNR)

DESCRIPTION



Taxonomy and Basic Description

The marsh periwinkle was first described in the United States by Say in 1822 from specimens collected along the Atlantic shoreline (Say 1822). This gastropod, in the order Mesogastropoda, belongs to an important genus of common marsh snails. They can reach a size of up to 30 mm in shell height. Individual snails are hermaphroditic and capable of reproduction throughout the summer. In South Carolina, maximum settlement of young typically occurs in early to late spring with shell growth to maximum length taking approximately 2 to 3 years. Adult snails can range in color from dark brown to an almost bleached white.

Status

Although the marsh periwinkle is not a threatened or endangered species, it is an important component of the intertidal salt marsh community. Periwinkles may be a major participant in the decomposition of cordgrass, *Spartina alterniflora*, leaves (Bärlocher & Newell, 1994; Silliman & Newell, 2003) through a mutualistic association with leaf fungi (Silliman & Newell, 2003). Marsh periwinkles can serve as an indicator species of the health of saltmarsh habitat, a type that is critical for many species of marine invertebrates and migratory birds.

POPULATION SIZE AND DISTRIBUTION

Keith Walters

The marsh periwinkle is distributed from New England to the Gulf Coast of Texas. In South Carolina, it can be found within vegetated landscapes, from the low water line up to the terrestrial scrub community in most estuarine saltmarshes, including those that contain *Spartina cynosuroides* as well as black needlerush, *Juncus roemerianus* (Failon *et al.,* 2020, Anderson *et al.,* 2022). Although it is an abundant and common species, little is known in South Carolina regarding long-term population trends and related information. Seasonal densities in the mid-marsh can range from 50 to 300 individuals per m^2 with greater densities observed during winter months.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The marsh periwinkle is an obligate saltmarsh resident in which cordgrass may be considered a critical habitat. Individuals can be found inhabiting high-marsh areas around freshwater seeps and low-marsh stems submerged in full strength seawater (> 25 ppt). Short-term studies (less than 2 years) indicate densities within the low marsh zone tend to be lower (less than 100 per m^2) compared to mid-marsh elevations (over 300 per m^2). In some cases, densities in excess of 1,000 per m^2 have been reported (Silliman & Bertness, 2002). Snails are also commonly found above the high water line on the stems of marsh plants; evidence suggests this climbing behavior is in response to blue crab predators (Hamilton, 1976; Vaughn & Fisher, 1992). Marsh periwinkles feed on microalgae and detritus; they may also garden and consume fungal decomposers found on the surface of marsh plants (Silliman & Newell, 2003).

Photo: Periwinkles occurring in very high densities as part of a “snail front” in a salt marsh near Charleston, SC.

CHALLENGES

Major challenges to the conservation of saltmarsh periwinkle populations include the loss of habitat and dramatic alterations to predator populations. The marsh periwinkle has been implicated as a critical consumer of cordgrass and increased snail densities may be responsible for observed declines in intertidal cordgrass, (*Spartina alterniflora*) coverage (Silliman & Bertness, 2002). marsh periwinkle densities have been attributed to reductions in predator pressure (Silliman & Bertness, 2002). Later research has demonstrated that these relationships are more complicated, with potential feedbacks and interactions between both top-down and bottom-up controls (*e.g.,* drought stress; Silliman *et al.,* 2005). Reductions in marsh acreage or quality will also affect snail foraging and survival. Periwinkles appear to have an obligatory relationship with *S. alterniflora*, and the loss of *S. alterniflora* habitat would suggest a negative

effect on snail populations. Periwinkles, however, also appear to have a reciprocal negative effect on *S. alterniflora* in the absence of "natural densities" of predators. The cause of what appears to be an out-of-balance predator-prey dynamic between blue crabs and the marsh periwinkle needs to be determined.

CONSERVATION ACCOMPLISHMENTS

The marsh periwinkle has received little or no attention in terms of past conservation efforts, likely in part because of the ubiquitous distribution of this species within coastal saltmarshes.

CONSERVATION RECOMMENDATIONS

- Further investigate the theory of top-down regulation of *Spartina alterniflora* biomass by the marsh periwinkle.
- Determine whether blue crab predation, in particular, is capable of regulating the distribution and abundance of periwinkles.
- Determine the preferred food(s) of marsh periwinkles.
- Determine whether recruitment is responsible for the initial distribution and abundance of marsh periwinkles.
- Determine the dispersal capabilities of the marsh periwinkle.
- Determine whether *Spartina alterniflora* characteristics and/or environmental conditions determine diet preferences of the marsh periwinkle.
- Determine the fraction of the overall productivity of a marsh that is processed by marsh periwinkles.
- Determine the role of the marsh periwinkle in observed declines of *Spartina alterniflora*, including interactions between drought, wrack depositional events, and periwinkle abundances.
- Determine factors other than predation and *Spartina alterniflora* quality that may account for the naturally patchy distribution of the marsh periwinkle, such as drought or wrack depositional events.

MEASURES OF SUCCESS

A better understanding of cordgrass-marsh periwinkle-predator dynamics is one measure of success. Conservation of predator populations, including blue crabs, may restore balance to the salt marsh systems which would be another measure of success.

Penaeid Shrimp Guild

Contributors: Larry DeLancey (2015, retired), Michael Kendrick, Graham Wagner, and Greg Rothman (2024, SCDNR)

- **White Shrimp** *Penaeus setiferus* (Linnaeus 1767) (top)
- **Brown Shrimp**, *Penaeus aztecus* (Ives, 1891) (middle)
- **Pink Shrimp**, *Penaeus duorarum* (Burkenroad 1939) (bottom)

DESCRIPTION

Taxonomy and Basic Description

These penaeid shrimp species are among the most well-known shrimp due of their importance in fisheries along the southeastern US coast, including the Gulf of Mexico. They are members of the family Penaeidae, a large group that also contains smaller species common in this geographic area. White shrimp are most abundant in SC, and therefore make up more of the commercial catch, than brown shrimp, and finally pink shrimp. The giant tiger prawn, *Penaeus monodon* is also known from SC waters but is not native to the region.

Penaeid shrimp possess a prominent rostrum with small teeth on both upper and lower margins, and lack postorbital spines. The first three pairs of walking legs are chelate (pincer like). White shrimp can be distinguished from brown and pink shrimp by their lack of a groove along the dorsal midline of the carapace (shell) and last section of the tail (telson). The groove on brown shrimp is wider than on pink shrimp (it is difficult to insert a fingernail in the pink shrimp telson groove). Despite the common names, color is often not a distinguishing characteristic for these shrimp. Pink shrimp usually possess a dark spot on their abdomen, hence the alternative common name “spotted shrimp”. These species can grow to relatively large size, up to 19 cm (8 in.) total length or greater, and are generally harvested starting at about 10 cm total length.

Female penaeid shrimp possess a specialized structure composed of plates on the ventral surface near the last pair of walking legs (thelycum) that receives the spermatophore from male shrimp during mating, prior to releasing fertilized eggs. The male uses specialized appendages located on the first pair of swimming legs (petasma) to place spermatophores on the female (Williams, 1984) using direct fertilization, which differs from broadcast spawning used in some other shrimp.

The spawning season varies by species, but occurs from spring through fall in oceanic waters. White shrimp and pink shrimp have a protracted spawning season from late March to early September, whereas brown shrimp spawning peaks in spring and fall (Williams, 1955; Lindner & Anderson, 1956; Joyce, 1965). Fertilized eggs fall to the bottom where they hatch into a swimming nauplius stage in about 24 hours, which is different than the caridean shrimp that brood their eggs. The nauplius than passes through several protozoea and mysis stages before molting

into the postlarval stage (Pearson, 1939). This process takes several weeks, depending on water temperature and time of year (Lindner & Cook, 1970). Postlarvae move into estuarine areas through inlets, utilizing coastal winds and tidal currents (Bearden, 1961; Wenner *et al*., 2005). Pink shrimp postlarvae are the most abundant penaeid postlarvaal species despite being least abundant subadult and adult stages in SC waters (Wenner & Beatty, 1993).

Penaeid shrimp grow rapidly in shallow estuarine nursery areas in the warm months of the year, predominately in tidal creeks adjacent to salt and brackish water marshes (Williams, 1955; Zein-Elden & Renaud, 1986), then eventually move downstream to areas close to and into the ocean, where they are harvested by both recreational and commercial fishermen. They continue growing and developing as they make their way seaward, and eventually move out of estuarine waters to spawn (Figure 1 below). Commercial fishing involves trawling, which is generally not allowed within estuarine waters.

Penaeid shrimp are omnivorous, feeding on living and dead animal and plant material, including small benthic invertebrates (Hunter & Feller, 1987; McTigue & Zimmerman, 1991). They in turn, are consumed by numerous species, especially finfish, providing an important link between primary and secondary producers and larger predators (Minello & Zimmerman, 1983).

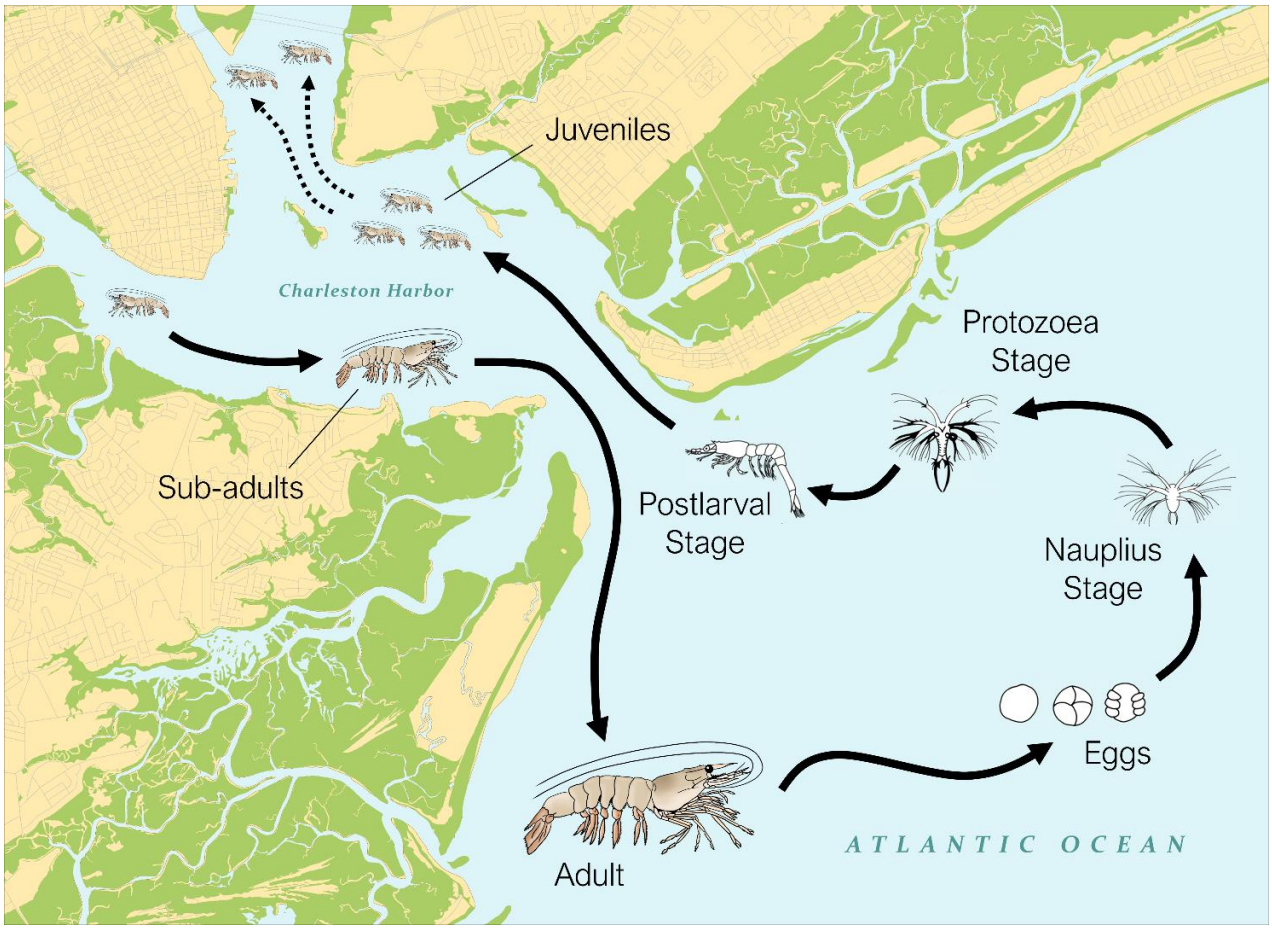

Figure 1: Penaeid shrimp stages of development.

Culturally, Penaeid shrimp are important in South Carolina, with a large emphasis on “boils”, where large amounts of shrimp are consumed at a gathering or event. Many local seafood restaurants also promote serving locally-sourced shrimp. In recent years, however, there has been an increase in Penaeid shrimp imports from overseas, which has negatively impacted the fishery, and caused the declarations of economic disasters in some localities.

Status

Penaeid shrimp have been intensively fished since the early part of the 20th Century leading to management and regulation of commercial and recreational harvests of penaeid shrimp at the state and Federal level in the US. In South Carolina, the Department of Natural Resources (SCDNR) sets openings for the shrimp seasons, and the closing of the commercial trawl season in state waters. In the Exclusive Economic Zone (EEZ), NOAA and the South Atlantic Fisheries Management Council (SAFMC) promulgate regulations through a management plan (http://safmc.net/resource-library/shrimp). The stocks of penaeid shrimp represent some of the most abundant nekton along the coast. Declines in landings in recent years may be driven by multiple factors, including reduced effort driven by high fuel prices and imported shrimp, and/or changes to shrimp population dynamics.

POPULATION SIZE AND DISTRIBUTION

Penaeid shrimp range from at least the mid-Atlantic coast down along the Atlantic and through the Gulf of Mexico (Williams, 1984). Although no population estimates of overall numbers exist off the Atlantic Coast, numbers of all three species are thought to exist in the billions in the Gulf of Mexico, where commercial landings exceed Atlantic landings by an order of magnitude (http://www.st.nmfs.noaa.gov/commercial-fisheries/index; Hart 2011a, b, c). In South Carolina, the commercial trawl fishery averaged over 500 licensees in the most recent decade and is the most valuable commercial fishery in the state in most years. Recreationally, penaeid shrimp are caught in the thousands by fishermen in South Carolina for consumption and bait for fishing by baiting for shrimp or using modified cast net for ‘deep holing’, the latter of which has become increasingly popular in recent years.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

White shrimp occur primarily in shallow waters less than 30 m in depth (Williams, 1984). This reflects some of the adaptations that differ from those of brown and pink shrimp (McMillen-Jackson & Burt, 2003). As year-round residents of shallow water, white shrimp are prone to periodic cold kills from winter cold fronts that generally do not severely impact brown shrimp, which reside in deeper waters in the winter (Williams, 1984), or pink shrimp which burrow into the sediment (Williams, 1955). Larval stages of the penaeids are planktonic in oceanic waters and are therefore influenced by factors such as currents, planktonic food supply, and abundance of various predators such as medusae and fish (Temple & Fisher, 1967; Wong *et al*., 1989; Mills, 1995; Lindquist & Hay, 1996). When penaeid shrimp enter estuaries as postlarvae, they are carried by tidal currents into suitable nursery habitats using cues such as optimal salinity regimes to settle out onto preferred bottom types (Zein-Elden & Renaud, 1986; Wenner & Beatty, 1993). All three species are found over soft bottoms (mud, sand, and clay) with varying levels of detritus, but

juvenile pink shrimp are most abundant in seagrass beds that exist in North Carolina and the Florida Keys (Williams, 1955; Murphey & Fonseca, 1995).

All three species can tolerate a wide range of physical factors, but generally water temperature that falls below 8°C is lethal for white shrimp, which are more tolerant of very low salinity waters (Zein-Eldin & Renaud, 1986; Lam *et al*., 1989).

CHALLENGES

The factors that drive trends in penaeid shrimp wild populations are primarily climatic in nature, whereas the shrimp fisheries have been strongly influenced by both climatic and economic factors. In the second decade of the 21st Century, the stocks and the fishery are in decline in South Carolina and in the neighboring states. Prolonged drought conditions can negatively impact white shrimp stocks and may approximate effects of future freshwater usage demands by a growing coastal human population (DeLancey *et al.,* 2008). Rising sea level, establishment of exotic species such as the tiger shrimp, *Penaeus monodon*, and the black gill are all factors that could be detrimental to penaeid shrimp stocks. Outbreaks of black gill are correlated with large-scale climate indices (Kendrick *et al.,* 2021), can lead to shifts in shrimp susceptibility to predation (Gooding *et al.,* 2019), and are related to infections by multiple parasites (Zuidema *et al.,* 2022). Viruses are another challenge to the penaeid shrimp, especially in South Carolina, particularly via the importation of infected commodity seafood as well as through non-native species. Some recent examples of viruses known to impact penaeid shrimp that have been reported from South Carolina include white spot syndrome virus (Sasson *et al.,* 2024) and infectious hypodermal and hematopoietic necrosis virus (Krol *et al.,* 2024).

A general trend observed over the last four decades of an apparent increase in the frequency of warmer-than-normal winters appears to be resulting in increased survival of white shrimp spawners. Mild winters may be interfering with brown shrimp recruitment mechanisms, however, potentially affecting populations of that species. Also, reduced annual rainfall and increasing salinities in the estuaries appear to be having negative impacts on both white and brown shrimp populations. [Whitaker 2012, SCDNR Climate Change Workshop presentation.]

Climate may be altering migratory and/or reproduction cues, leading to shifts in the timing of spawning. Since the white shrimp fishery is managed, in part, based on ovarian development, the timing of opening of the commercial white shrimp season may shift accordingly. This could have implications for management strategies related to female spawning status for white shrimp, and altered migration patterns could in turn shift estuarine community structure.

CONSERVATION ACCOMPLISHMENTS

Coastal Zone protection laws and regulations have been the most important factors in ensuring adequate and productive estuarine habitats for penaeid shrimp, with destructive activities such as dredging and filling marshland a thing of the past for the most part in South Carolina. More subtle impacts of increased human population growth in the Coastal Plain include increased freshwater usage and non-point source runoff that can degrade water quality. These factors can impact the

ability of the estuaries to produce sustainable shrimp crops (Holland *et al.*, 1996). Efforts to educate the public about resource protection and less impactful development practices have been fruitful and will hopefully continue to inform planning and management decisions affecting shrimp and all coastal resources in the years to come.

CONSERVATION RECOMMENDATIONS

- Continue support for long-term monitoring programs for penaeid shrimp stocks
- Continue research on environmental impacts on species life history and production, especially as it relates to management of the commercial fishery (*i.e.*, spawning)
- Develop population models and innovative disease diagnostic tools
- Improve our understanding of parasite and pathogen communities associated with shrimp, particularly regarding black gill
- Ensure that coastal habitat protection efforts continue
- Collectively pursue alternative energy strategies to lessen dependence on fossil fuels
- Continue to support conservation easements for land in estuarine watersheds

Additional information on penaeid shrimp can be found on the SCDNR website: http://www.dnr.sc.gov/marine/pub/seascience/shrimp.html.

Plumed worm

Diopatra cuprea

Contributor: Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and basic description:

Commonly referred to as the plumed worm, and also the decorator worm, or sometimes ornate worm, *Diopatra cuprea* (Bosc, 1802) is a species of polychaete worm in the family Onuphidae.

Onuphid polychaetes have captured the imagination of scientists for more than a century, with some of the earliest reports remarking on the size, beauty, and charismatic behavior of incorporating debris into an elaborate tube (Verrill & Smith, 1874; Saint-Joseph, 1898; Linville, 1903). The skin of *D. cuprea* is brilliantly iridescent and there are five long antennae protruding from the head beneath which are impressive, spiraled gills.

As its common name of the decorator worm suggests, *D. cuprea* builds conspicuous tubes that project a few inches above the sediment surface that are typically composed of plant fibers, shell fragments, seaweeds, sticks, and other debris bound together by a mucous polysaccharide material secreted from glands beginning at the sixth segment (Linville, 1903). The worm captures material for its tube by extending several centimeters from its tube, capturing material with its palps and its jaws, maneuvering materials into position, and integrating them into the tube wall using the mucous secretions. Myers (1972) reported that *D. cuprea* prefers 'tabular' materials and appears to use progressively smaller items along the axis from the tube opening towards the sediment surface.

The part of the tube beneath the sediment surface is comprised of a parchment material entirely secreted by the worm itself. It has the appearance off a smooth, collapsible, straight, grey tube, the upper end of which is turned downwards facing the substrate surface to prevent sediment from entering the tube (Ruppert & Fox, 1988). The tube of *D. cuprea* can reach deep (> 1 m) into the sediment (Berke, 2022), emerging above the surface in a decorated 'tube cap' (Hartman, 1959; Day, 1967).

Diopatra cuprea is an active omnivorous predator that feeds on its own gardens as well as those of other conspecifics. Algae and invertebrates found in the stomachs of *D. cuprea* suggest that 'gardening' plays a major role in explaining why this species decorates its tube (reviewed by Berke *et al*., 2006; Berke, 2012). In North Inlet, SC, *D. cuprea* has also been documented to scavenge on dead fish (Berke, 2022).

Status

The status of *D. cuprea* in South Carolina is currently known as it is not the target of any standardized surveys, does not support a directed fishery, and is not listed on any recognized Federal or state conservation list. That being said, its ecological importance is in little doubt, given its role as an ecosystem engineer and its facilitation of trophic connections to other species and increases in biodiversity of mudflat habitats, described in more detail in this account. It also faces a number of threats that support the need for its conservation status to be further explored.

POPULATION DISTRIBUTION AND SIZE

The plumed worm, *Diopatra cuprea* occurs from Massachusetts to Brazil on muddy tidal flats (Fauchald, 1977), with its northern limit set by cold temperature (Mangum, 1969; Mangum & Cox, 1971; Myers, 1972).

HABITAT / NATURAL COMMUNITY REQUIREMENTS

At cold temperatures, *D. cuprea* stops feeding between 5°C and 8°C (Mangum, 1969; Mangum & Cox, 1971) and stops maintaining its tube below 1.8°C (Myers, 1972). As is the case for most estuarine organisms, *Diopatra* spp. exhibit a wide salinity tolerance, from 15 to 40 ppt (Berke, 2022). Typical habitats of *D. cuprea* include protected intertidal and shallow subtidal flats of muddy sand or sandy mud, while generally avoiding areas of pure sand, pluff mud, or clay (Verrill & Smith, 1874; Mangum *et al*., 1968; Peckol & Baxter, 1986; Berke, 2012).

The ecosystem engineering effect of the tube-building behavior of *Diopatra* is one of the earliest examples of facilitation (Woodin, 1978; Wright & Jones, 2006; Cuddington *et al*., 2007; Berke, 2010), with biogeographic variation in this ecosystem engineering role described in Berke (2012). The tubes of *D. cuprea* stabilize the sediments and provide refuge for infauna (Woodin 1978, 1981) by physically excluding predators, such as epibenthic fish, skates, rays, crabs, shorebirds, and horseshoe crabs; these effects are summarized in Berke (2022). The tubes can also serve to increase recruitment by the entrainment of passively dispersed larvae (Eckman, 1983), although this effect varies with tube density (Woodin 1978, 1981). In the northwest Atlantic, juvenile fish have been shown to have a diel pattern of habitat use for *D. cuprea* tubes, spending daylight hours sheltering in beds of tubeworms but venturing out into open habitats to forage at night (Diaz *et al*., 2003). A summary of the ecological interactions involving *D. cuprea* was recently written and presented illustratively by Berke (2022), summarizing that *D. cuprea* increases the diversity and abundance of other organisms.

By actively attaching algae to its tube, *D. cuprea* can also create an algal canopy on intertidal flats that would otherwise lack stable, attached algal populations, thereby acting as a foundational species in a facilitation cascade (Thomsen & McGlathery, 2005; Thomsen *et al*., 2010; Gribben *et al*., 2019). The single tube of a *D. cuprea* worm can support > 300 mg of algal biomass representing multiple species (Berke, 2012), although

the degree of interaction with algae can vary spatially, particularly in relation to current velocity (Berke, 2022). The facilitation of algal communities by *D. cuprea* extends beyond that of native algal species; indeed, *D. cuprea* has been implicated in the facilitation of the non-native algal species, *Agarophyton vermiculophyllum* (formerly *Gracilaria vermiculophylla*) (Keller *et al*., 2019; Thomsen *et al*., 2005; Wright *et al*., 2014). While invasive, however, *A. vermiculophyllum* provides habitat to native species, including epibenthic invertebrates (Wright *et al*., 2014) and juvenile blue crabs (Johnston & Lipcius, 2012; Gribben et al., 2019), thereby potentially increasing secondary production in some habitats (Thomsen *et al*., 2018).

THREATS

Species of *Diopatra* are impacted by anthropogenic activities on multiple fronts, including climate change, harvesting for the bait trade, human-assisted transport, and interactions with invasive species. At least in terms of *D. cuprea*, as of 2022 (Berke, 2022), in relation to climate change-driven changes in geographic extent, its northern range limit appears to be stable. The extent to which *D. cuprea* will be impacted by higher temperatures in subtropical habitats, such as the coast of South Carolina, however, remains largely unexplored, according to Berke (2022). This includes an assessment of how intertidal vs subtidal populations may be differently affected by temperatures over the course of daily, seasonal, and annual timeframes in terms of the effects of both increased air and water temperatures.

Intertidal *Diopatra* are dug for use as fishing bait throughout western Europe, however the extent to which South Carolina populations of *D. cuprea* are affected by this human disturbance is currently unknown.

Superblooms of *A. vermiculophyllum* can lead to sediment anoxia and *D. cuprea* death such that under certain circumstances this invasive alga can present a threat to this important ecosystem engineer (Keller *et al*., 2019), potentially leading to long-term population declines. The conditions that lead to *A. vermiculophyllum* blooms, their frequency and effects on invertebrates, including D. cuprea, warrant investigation.

CONSERVATION ACCOMPLISHMENTS

The plumed worm, *Diopatra cuprea* has not been the subject of targeted conservation efforts likely due to the data deficient nature of this species to indicate that its number have been in decline, either as a result of natural or anthropogenic factors. The species is currently not listed as either threatened or endangered at either the state or Federal level, which also explains the lack of targeted conservation efforts.

CONSERVATION RECOMMENDATIONS

In general, there appears to be more information available on the effects of *D. cuprea* on other organisms than there is on the worm itself. More information is needed on the environmental tolerances of *D. cuprea*, as well as more research on its feeding biology,

reproductive cycles, and population dynamics, especially for populations subject to harvesting or close to geographic range limits. The potential impacts of climate change on *D. cuprea* populations in South Carolina are poorly understood, which is concerning given the important nature of the ecological interactions between this species and other native fauna on intertidal mudflats.

A better understanding of the spatial distribution and baseline life history of *D. cuprea* would be first order measures of conservation success. Such an understanding would enable the impacts of disturbances to be conceptualized but also provide protection to critical habitats for this species. The conservation of healthy populations of *D. cuprea* has important implications for the species that utilize it as prey directly, or that feed on fauna that comprise components of its 'gardens'.

Furthermore, there is a research need to compare the functionality of *D. cuprea* + *A. vermiculophyllum* and *D. cuprea* + native algae in terms of ecosystem services provided by these different facilitations.

Berke (2022) also commented that the taxonomy of the genus *Diopatra* is in a period of rapid revision and urges those working on this genus to stay apprised of taxonomic developments in their geographic region and recommends that retention of voucher specimens and tissue samples for genetic analyses whenever possible.

MEASUREMENT OF SUCCESS

More information is needed regarding population distribution and trends in State waters for *D. cuprea*, as well as a better understanding of the life history of the worm itself (as compared to studies on its provision of services to other species which by comparison has received more attention). A better understanding of the threats to this species, particularly in terms of pressures from climate change, could form part of a conservation plan for *D. cuprea* in South Carolina. Documenting stable population trends for *D. cuprea* within South Carolina waters would be the ultimate measure of success for this species and its associated communities.

DESCRIPTION

Taxonomy and Basic Description

The family Portunidae comprises the swimming crabs, whose final segment (dactyl) of the fifth walking leg is flattened to a paddle-like appearance to enhance swimming ability. This modified swimming appendage has allowed members of this family to be effective and aggressive predators. Additionally, portunid crabs are a food source for a number of commercially- and recreationally important finfish species. As such, it is thought that members of this family play an important role as a link in the food web between benthic primary consumers, and higher-order benthic and pelagic consumers. Two portunid crabs are non-native in SC, including the Indo-Pacific swimming crab *Charybdis hellerii* (A. Milne-Edwards, 1867) and Bocourt's swimming crab *Callinectes bocourti* A. Milne-Edwards, 1879, and present potential threats to native portunids. Many portunid crabs will also eat carrion and detritus, strengthening their position as links in marine and estuarine food webs.

The family Portunidae is of global economic importance, supporting large fisheries in the Americas and Asia. In South Carolina, there is representation from several genera within the family Portunidae; however, the Atlantic blue crab, *Callinectes sapidus*, being of commercial, recreational, ecological and cultural importance, has resulted in a greater focus to study its life history and biology when compared to the other species in this family. Therefore, our understanding of the ecological role of this family within marine and estuarine environments is often inferred from that of *C. sapidus*.

The genus *Callinectes* Stimpson 1860, is one of the more predominant genera of portunid crabs in South Carolina. This genus can be distinguished from other genera within the family by the absence of a mesiodistal spine along the carpus of the cheliped, as well as the abdomen of males being T-shaped. The Atlantic blue crab, *Callinectes sapidus*, can be distinguished from the closely related lesser blue crab, *C. similis*, by its larger adult size (> 13 cm carapace width), red coloration on the chelipeds (claws), and the presence of two interorbital teeth of the frontal margin of the carapace compared to the four interorbital teeth present in *C. similis*, *C. bocourti*, *C. ornatus*, and *C. exasperatus. Callinectes sapidus* also displays a more bluish-green color on the carapace, whereas *C. similis* is characterized by a more violet hue on the carapace and legs (Williams, 1984). *Callinectes bocourti* is olive green in color with prominent red markings, and red to brown chelipeds. These crabs are native to the Caribbean and South America but have been reported from commercial crab pots in South Carolina. *Callinectes ornatus* is olive to dark brown with a large roundish spot of orange on each side posteriorly. The chelipeds are spotted with blue or soft purple, and the walking legs are blue with a band of scarlet at each joint. *Callinectes exasperatus* has a purplish-red carapace, and the dorsal surface of all legs are purplish-red with intense orange-red on articulations.

Arenaeus cribrarius can be distinguished from other portunid crabs by a carapace that is more than twice as wide as it is long, light brown or gray in color, with many small rounded white or yellow spots.

Charybdis hellerii is native to the Indo-Pacific Ocean, but has been documented in the south Atlantic (Lemaitre, 1995), specifically in South Carolina. It has a more rounded carapace that is dark olive or brown, and dark purple tips of chelipeds. There are six prominent teeth on the front margin of the carapace. It is unknown how this non-native portunid affects the native portunids and the greater marine and estuarine systems in South Carolina.

Achelous spinimanus and *A. gibbesii* can be differentiated from other portunid crabs by their relatively long chelipeds, a spine on the upper propodus, and purple and/or red markings on the carapace. *Achelous spinimanus* has a carapace that is considerably less than twice as wide as it is long, and yellowish or reddish brown in color, as well as white blotches on the chelipeds. *Achelous gibbesii* has a carapace that is approximately twice as wide as it is long, brownish-red in color, purple walking and swimming legs, and considerable iridescence.

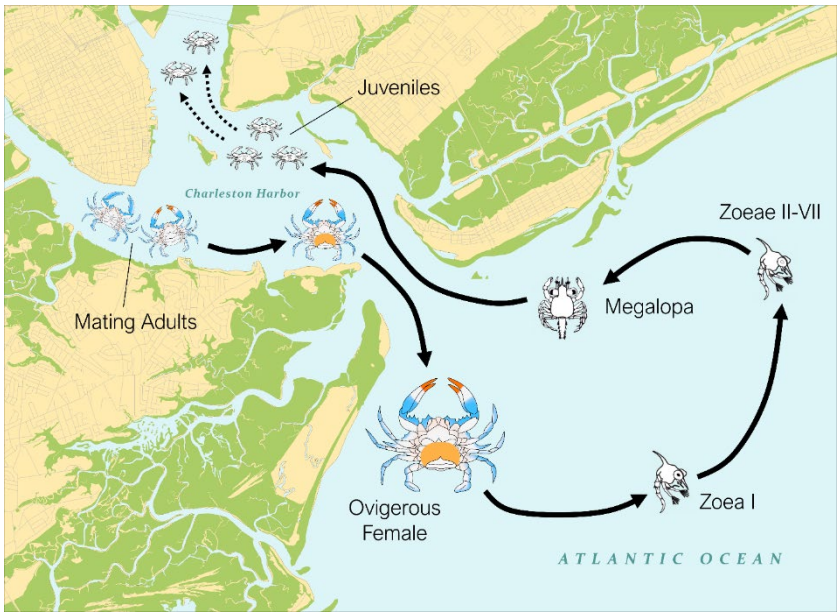

Figure 1: Atlantic blue crab *C. sapidus* development cycle.

Much of the life history information for portunid crabs as a family is inferred from that of the Atlantic blue crab, as its commercial and cultural importance have resulted in a greater research focus. Generally, spawning in *C. sapidus* occurs after the female undergoes a terminal molt and is impregnated by the male crab while she is in a "soft" state, prior to the exoskeleton hardening (Van Engel, 1958). Females will carry sperm internally until they deposit eggs that attach to setae on specialized pleopods, forming an egg mass (sponge). Several sponges can be produced from a single mating event (Hines *et al.*, 2003); however, there is evidence that the quality of the sperm, and therefore the resulting brood of eggs, degrades over time (Hines *et al* 2003). Figure 1 above represents the general life cycle of portunid crabs. Mature females migrate close to or into the ocean prior to eggs hatching; in South Carolina, this occurs from March through early fall for *C. sapidus* (Eldridge & Waltz, 1977). In the case of *C. similis,* summarized data on spawning of *C. similis* in areas including South Carolina, suggesting a spring and fall spawning season (Williams, 1984). Among the other genera, less is known about these periods of spawning, particularly in South Carolina; however, it is noted that ovigerous females of both *A. spinimanus* and *A. gibbesii* are known to occur in North Carolina from May – October and May – August, respectively (Williams, 1984). Much of the research related to the reproduction of *Arenaeus cribrarius* has taken place in Brazil, where mating occurs in the fall, and ovigerous females can be found year-round, with peaks in abundance occurring in spring and summer (Pinheiro & Fransozo, 2002).

Eggs hatch into a zoea stage and are carried offshore where they undergo development through several zoeal stages (Costlow & Bookhout, 1959; Epifanio, 1995). After a period of several weeks, the last zoea stage molts into the megalopa stage and returns to coastal waters from offshore, utilizing tidal and wind driven currents, and eventually entering the estuaries (Boylan & Wenner, 1993; Epifanio, 1995). Megalopae transform into juvenile crabs which gradually move upstream into nursery areas, such as tidal creeks in South Carolina, or seagrass beds in North Carolina and the Chesapeake Bay, as they pass through a series of molts (Orth & van Montfrans, 1987; Mense & Wenner, 1989; Whitaker *et al*., 1998; Etherington & Eggleston, 2000). Atlantic blue crabs mature in 6 months to two years, depending on geographic location, with crabs maturing faster in warmer climes (Tagatz, 1968).

Status

Since the late 1970s, SCDNR crustacean biologists have monitored the health of the *C. sapidus* population in South Carolina to manage the species for future generations. The team currently operates multiple surveys to study the status of *C. sapidus* status across the state. Data from these multiple surveys show that, beginning with a severe drought around 2000, *C. sapidus* has experienced two decades of decline.

The status of the other members of the family Portunidae in South Carolina is not known, but threats from climate change and non-native species, including congeners and confamilials, may threaten native portunid crabs.

POPULATION SIZE AND DISTRIBUTION

Callinectes sapidus ranges from Massachusetts, down the Atlantic Coast, through the Gulf of Mexico, and into South America (Williams, 1984). Recent stock assessments for the Chesapeake Bay estimate the number of blue crab to be approximately 500 million individuals in that area (http://dnr.maryland.gov/fisheries/crab/dredge.asp), with annual landings averaging approximately 50 million lbs (http://www.st.nmfs.noaa.gov/commercial-fisheries/index).

Most of South Carolina's *C. sapidus* harvest is commercial. Recreational crabbers are believed to represent a relatively small fraction of harvest pressure in South Carolina. Economic and environmental pressures elsewhere along the east coast of the United States strongly impact South Carolina's commercial blue crab fishery. Shortages of crabs in the mid-Atlantic United States, for example, have driven prices high coast-wide, subsequently increasing harvest pressure in South Carolina. Landings have declined in recent years, reaching a 50-year low in 2021. At the same time, because of soaring prices nationally, the total value of landings is near record levels. In recent years (2015-2022) the number of commercial crab licenses sold has ranged from 358-389 per fiscal year. In 2021 (fiscal year) there were 389 licensed crab harvesters with a total number of 36,242 licensed pots/traps. The number of pots per license holder ranged from 50 (the minimum) to 800, although most commercial harvesters (93%) fished 200 pots or fewer. Additionally, there were 35 licensed peeler (soft-shell) dealers and a single crab trawl permit issued in 2021 (SCDNR, 2023).

Callinectes similis ranges from Delaware Bay, down the Atlantic Coast, and through the Gulf of Mexico. *Callinectes exasperatus* ranges from the mid-Atlantic through the Gulf of Mexico and Central America and into Brazil. *Callinectes ornatus* ranges through the western Atlantic, from North Carolina down into the Gulf of Mexico and through the Caribbean. *Arenaeus cribrarius* ranges from Massachusetts, down the Atlantic coast of the US, through the Gulf of Mexico, and down into Brazil and Argentina in South America. Despite having a wide latitudinal distribution, much of the life history information regarding *A. cribrarius* results from work done in South America. *Achelous spinimanus* ranges from the coast of Virginia, through the south Atlantic and into the Gulf of Mexico. *Achelous gibbesii* ranges through the mid- and south-Atlantic regions of the US and into the Gulf of Mexico. It also reaches through Central America into the northern portions of South America.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Some *C. sapidus* inhabit oceanic waters as adults, but all undergo larval development in the ocean, relying on winds and ocean currents for distribution back to nearshore habitats before entering estuaries as megalopae (Epifanio, 1995). Recent changing climatic conditions could negatively influence many biological and physical factors that affect the survival and recruitment of larval crab (NEFSC, 2009). In the estuary, *C. sapidus* can be widely distributed across habitats from euryhaline to freshwater environments, depending on geographic location, season, and life stage (Williams, 1984). In South Carolina, small *C. sapidus* inhabit marsh-tidal creek habitats, mudflats, and oyster reefs (Mense & Wenner, 1989; Kingsley-Smith *et al.,* 2012) whereas larger *C. sapidus* move upriver in the warmer months (Archambault *et al.,* 1990; Childress, 2012). *Callinectes sapidus* feed opportunistically on a wide variety of live and dead food items but seem to prefer bivalve mollusks when available (Darnell, 1958; Hines *et al.,* 1980; Laughlin, 1982; Fitz & Weigert, 1991). Blue crabs are preyed on by many species, including sharks and sea turtles (Frazier, SCDNR, pers. comm.). Although tolerant of a wide range of conditions such as relatively low dissolved oxygen, drought, and high freshwater runoff, good water quality and undegraded estuarine habitats help to ensure the sustainability of the blue crab resource (Eldridge & Waltz, 1977; Engel & Thayer, 1998; Bell *et al.,* 2003; Bauer & Miller, 2010; Childress, 2012).

While *C. sapidus* and *C. similis* are known to co-occur, there may be differences in habitat preferences over small spatial scales. *Callinectes similis* has been documented to utilize more open water bay and estuarine waters as juveniles, whereas *C. sapidus* juveniles recruit to more shallow salt marsh systems in the Gulf of Mexico (Hsueh *et al.,* 1993). It is unknown if this habitat preference is retained in South Carolina.

CHALLENGES

As a heavily fished stock, *C. sapidus*—as is the case for most exploited species—is probably vulnerable to overharvesting, but that condition is difficult to document. Apparent population declines in the past have usually been followed by rapid recoveries (Sharov *et al.,* 2003). Efforts to cap the number of commercial licenses as a means of stabilizing fishing effort have been unsuccessful in South Carolina to date. Projected human population growth along the coast may be detrimental if development is not carefully planned to minimize runoff and non-point source pollution (Engel & Thayer, 1998). Increased water demands (Wilber, 1994) may alter estuarine salinity patterns. Educating the public and garnering support for lower impact development may

be the greatest challenge facing resource managers regarding blue crab and all species that utilize the estuaries. Derelict fishing gear in the environment can continue passively trapping portunid crabs in a process known as ghost fishing. There is currently no known estimate of the impacts of ghost fishing on portunid crabs as a collective group in South Carolina. Additionally, as climate changes, there is an expectation for the life history regimes of marine and estuarine organisms to shift. Many migratory and reproductive cues are environmental in nature, and therefore are susceptible to changing conditions. Furthermore, warming temperatures allow for the poleward expansion of marine organisms, which can create niche overlap and competition as species expand their ranges. There are several non-native portunid crabs in South Carolina, and it is unknown how their presence is affecting native portunids.

Predation by non-native blue catfish, *Ictalurus furcatus*, has been shown to be a source of mortality of portunid crabs, especially for juveniles that inhabit lower salinity waters (Fabrizio *et al.,* 2021). Other concerns include pathogens, such as viruses and parasites, that are known to infect and potentially impact populations of the Atlantic blue crab, and most likely other portunid crab species, including but not limited to: White spot syndrome virus (WSSV) (Powell *et al.,* 2015), *Callinectes sapidus* reovirus 1 (CsRV1) (Flowers *et al.,* 2018), and the dinoflagellate, *Hematodinium* sp. (Stentiford & Shields, 2005).

CONSERVATION ACCOMPLISHMENTS

Regulations on minimum size and prohibition of possession of egg-bearing females have ensured some protection of the *C. sapidus* stock in South Carolina. Protection of the Coastal Zone by legislation passed in the 1970s lessened the scale of destructive human activities such as dredging and filling of marshes and improved treatment of wastewater (Engel & Thayer, 1998). The protective stance and support of organized conservation groups such as the Coastal Conservation League and SC Wildlife Federation have promoted continued awareness of threats to the coastal environment in South Carolina. Genetic characterization of blue crab populations in SC suggests that the Charleston Harbor *C. sapidus* population is genetically 'healthy' (Cushman & Darden, 2017).

CONSERVATION RECOMMENDATIONS

- Investigate contemporary updates to our understanding of portunid crab life histories, given that much of the work to understand this is from decades ago. This is important in the context of climate change, anthropogenic impacts, and fishing pressures.
- Support efforts by SCDNR to manage the commercial blue crab fishery more actively by stabilizing effort and exploring short term closures or limits on harvest of female blue crab during times of low population abundance.
- Collect data, including survey information, to improve our understanding of the numbers of crabs removed from populations by the harvesting of blue crabs and the impacts of these practices on wild populations.
- Continue to support outreach and education and acquiring basic knowledge about the blue crab resource within an ecosystem context. Fishermen and interested members of the public should be involved in these efforts.
- Promote continuing monitoring and protection of critical habitats.

- Examine modeling techniques that have predictive value to assess how future human population growth and climate change will impact watersheds and blue crab stocks.
- Explore the reproductive biology of portunid crabs, given the short mating window following a female's terminal molt, and the possibility of sperm limitation
- Explore how changes in climate may be altering the movement and development patterns of portunid crabs in South Carolina.
- Empirically measure the impacts of derelict fishing gear on portunid crab populations.
- Establish reliable distributions and abundances of nonnative portunid species in South Carolina. This will help in understanding the impacts of nonnative species on native portunids.

http://www.dnr.sc.gov/marine/species/bluecrab.html,
http://www.dnr.sc.gov/marine/pub/seascience/bluecrab.html

MEASURES OF SUCCESS

As the above-mentioned action items are accomplished and yield valuable information, adaptive management procedures will be evaluated and implemented for this crab species.

Purple Marsh Crab

Sesarma reticulatum Say, 1817

Contributor: Andrew Tweel (SCDNR, 2024)

DESCRIPTION

Taxonomy and Basic Description

The purple marsh crab, *Sesarma reticulatum* Say, 1817 is a grapsid crab (family Grapsidae, shore or marsh crabs) characterized by scattered setae, a dark olive, black or purple carapace approximately 28 mm wide (Williams, 1984). This species is found in salt marshes, particularly the lower, muddier portions where it produces a burrow often found with a mud chimney (Ruppert & Fox, 1988).

Status

There are no population level estimates for this species, but it has been documented as playing a significant role in overall salt marsh ecology through the consumption of smooth cordgrass, *Spartina alterniflora* and the deposition of fecal pellets on the marsh surface (Day *et al.,* 1973; Williams, 1984). They also play a role in increasing the disturbance or turnover of salt marsh soils and decomposition processes.

POPULATION SIZE AND DISTRIBUTION

The purple marsh crab is found from Woods Hole, MA to Volusia County, FL, and in the Gulf of Mexico from Sarasota, FL to Calhoun County, TX. In South Carolina, *S. reticulatum* can be found in salt marshes, particularly the lower elevation, often muddier portions. The reported salinity preferences of this species range from 16 ppt to 20 ppt, but they are able to tolerate a much broader range.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Their habitat is the lower elevation portions of salt marshes, usually those that contain siltier sediments. In Georgia, this species has been found to be active when the marsh is flooded or during overcast conditions (Teal, 1959).

CHALLENGES

Recent research has highlighted the potential role that this species may play in shaping the morphology and evolution of salt marsh creeks in areas where they are highly abundant (Crotty *et al.,* 2020). Changes in sea level and inundation were reported to alter substrates and shift available habitat in favor of this species, which can trigger a cycle of excessive grazing, subsequent erosion, and altered channel morphology. Similarly, in high densities this species has

been associated with die off events or reduced productivity in southeastern US salt marshes (Angelini *et al.,* 2018).

CONSERVATION ACCOMPLISHMENTS

None known.

CONSERVATION RECOMMENDATIONS

Future research is needed to better understand how *S. reticulatum* may be affected by changes in sea level and inundation, and what impacts this might have on the greater salt marsh landscape and ecological cascades. These changes may also alter the cycling of nutrients and carbon through burrowing or decomposition processes (Wilson *et al.,* 2022). Conservation of salt marshes is critical toward preserving the landscape and ecology of the South Carolina coast, so a better understanding of predator-prey and other competitive relationships is important.

MEASURES OF SUCCESS

If measures of abundance and population demographics of *S. reticulatum* are conducted as part of regular monitoring efforts that are currently established to monitor macroinvertebrates associated with salt marsh habitats, this could be a cost-effective way to collect data to provide baseline information. If continued over a longer period, these data would be able to follow population trends, which will allow managers to make decisions regarding possible conservation measures for this species. The overall measure of success for *S. reticulatum* will be stable population trends along the entire coast, as part of the increased conservation and restoration of salt marsh habitat in South Carolina.

Ribbed Mussel

Geukensia demissa (Dillwyn, 1817)

Contributors: Loren Coen (2005, SCDNR, retired), Keith Walters (2005, Coastal Carolina University), Nancy Hadley (2013, SCDNR, retired) & Peter Kingsley-Smith (2013 & 2023, SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The ribbed mussel, *Geukensia demissa*, Dillwyn 1817 is a member of the bivalve molluscan family Mytilidae, previously included in the genera *Modiolus* and *Brachidontes*. It is relatively large, in coastal South Carolina growing to approximately 100 mm in length (see models in Julien *et al*., 2020a). The surface is grooved with obvious ribs from which its name is derived. It has a glossy brown-black shell, often with some yellow to a bleached white color on the exterior surface; the inner surface is generally white. It has no external siphon; rather it draws water loosely over its gills.

The ribbed mussel is distinguished from other South Carolina intertidal mussels by its oblong shape, parallel dorsal and ventral margins, very close exterior ridges, and the lack of teeth on the hinge. The other common mussels in South Carolina, *Brachidontes exustus* (scorched mussel) and *Ischadium recurvum* (hooked mussel), differ in several aspects. Both of these species reach sizes as adults of no more than 2.5cm to 5 cm (1-2”). Furthermore, the scorched mussel has a higher divergent angle from the umbo than the ribbed mussel, small cardinal teeth on the hinge, and its shell is thicker and stouter than that of the ribbed mussel.

Ribbed mussels are not hermaphroditic, and their sexes can be determined by the color of the mantle tissue. The mantle tissue in females tends to be a medium brown whereas the mantle tissue in males tends to be a yellowish-cream color. Reproduction usually occurs in spring and peaks by midsummer. Mussels are not known to spawn more than once in a season.

Status

The ribbed mussel is not a Federally-listed species; however, it is an ecologically important species in coastal estuaries in South Carolina that is susceptible to threats from harvesting pressure and other anthropogenic disturbances to habitat quality. Ribbed mussels do not seem to be declining in South Carolina; however, comparatively little is known about their populations here compared to the northeastern United States (except see recent studies by Julien *et al.,* 2019, 2020a,b). There are currently no fishery regulations through the South Carolina Department of Natural Resources that are species-specific to ribbed mussels; rather this species falls under the same regulations in terms of seasons, size limits, etc. that apply to other shellfish species, such as oysters (*Crassostrea virginica*). For example, there is no commercial harvest limit for the ribbed mussel in South Carolina and there are no best management practices for this species.

POPULATION SIZE AND DISTRIBUTION

The ribbed mussel inhabits salt marshes along the eastern coast of North America from the Gulf of St. Lawrence to Florida, forming dense aggregations in the marsh substrate (Bertness, 1984; Bertness & Grosholz, 1985). It also occurs in the Gulf of Mexico from Florida to the Yucatan. Although the actual population size of ribbed mussels is unknown for South Carolina, this species is assumed to be very abundant and forms rather dense colonies (Franz, 2001)

The relationship between shell height and age has recently been described by Julien *et al.* (2020a), with age determined through counting the number of external growth bands in the shell (described by Brousseau, 1984, Bertness & Grosholz, 1985). From this study, ribbed mussels were estimated to reach market size (76mm shell height) in approximately 3 years. Individuals with more than 10 growth bands were not uncommon and the oldest aged individual had 17 growth bands. Patch densities of ribbed mussels in South Carolina have been recorded as ranging from 352.3 ± 20.0 to 566.8 ± 41.0 individuals m^{-2} (mean ± S.E., Julien *et al.,* 2020a) or even as high as over 1,500 per m^2 (Coen *et al*., 1999; Luckenbach *et al*., 2005). Natural recruitment rates of ribbed mussels have been found to be low, especially following the removal of conspecifics from manipulated study plots (see Julien *et al.,* 2020a), supporting the premise that settlement is gregarious in this species (Bertness & Grosholz, 1985). Although growth rates decline at higher shore levels, this is offset by increased survival at higher elevations (Bertness, 1980; Bertness & Grosholz, 1985; Stiven & Gardner, 1992; Franz, 2001).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The ribbed mussel is an important ecosystem engineer in salt marshes along the eastern coast of North America from Canada to Florida (Alteri *et al.,* 2007, Angelini *et al.,* 2015, Bertness, 1984) where it is most commonly found associated with the smooth cordgrass, *Spartina alterniflora*, but may also occur in association with *Juncus roemarianus* (A. R. Julien, pers. obs.) as well as amongst intertidal oyster (*Crassostrea virginica*) reefs. Ribbed mussels increase the structural complexity of the habitat, both as living and dead animals (Kuenzler, 1961; Bertness, 1980; Jordan & Valiela, 1982; Bertness & Grosholz, 1985; Borrero, 1987; Borrero & Hilbish, 1988; Kemp *et al*., 1990; Stiven & Gardner, 1992; Franz, 1993, 1997). Ribbed mussels attach by byssal threads to any hard substrate like oyster shells and cordgrass stems and protrude above the surface. In South Carolina, one can typically find ribbed mussels embedded in and amongst salt marsh sediments attached by byssal threads to each other and/or to *Spartina* stalks. Unlike oysters, and like other mussel species, ribbed mussels have the ability to reattach if dislodged using their byssal threads, providing them with more opportunities to respond to disturbance. That said, the ability of ribbed mussels to repopulate at a local scale following simulated harvest and removal has been shown to be limited (Julien *et al.,* 2020a).

The ribbed mussel is a common filter feeder within a range of intertidal South Carolina intertidal habitats including marshes, pilings (Lent, 1969), and oyster reefs (Coen *et al*., 1999, 2004; Coen & Luckenbach, 2000; Luckenbach *et al*., 2005). Filter feeders improve water quality and affect nutrient cycling in estuarine habitats, especially with regard to the water-column microbiota community structure. Ribbed mussels are one of the few bivalves able to forage on small-sized bacterioplankton (Newell & Kambeck, 1995; Kreeger *et al.,* 1990), with most bivalves only consuming larger phytoplankton. At low tide, in general, the valves typically remain tightly closed to conserve water. Lent (1967, 1969), however, showed that ribbed mussels exposed at low tide are capable of respiring by "air-gaping."

The distribution of ribbed mussels poses a regional scale ecological question, as it appears to vary in relation to latitude. At northern latitudes, such as in the northeastern United States, ribbed mussels are most abundant at the edge of the marsh, forming a dense, continuous band (Bertness, 1984; Bertness & Grosholz, 1985). In the high marsh platform, which is characterized by short-form *Spartina alterniflora* (Valiela *et al.,* 1978), ribbed mussel abundance is low (Bertness & Grosholz, 1985). At southern latitudes, including the southeastern United States region, ribbed mussels are not found at the edge of the salt marsh in a continuous band; instead, ribbed mussels forms discrete, dense patches in the high marsh platform and near the mouths of tidal creeks (Kuenzler, 1961; Lent, 1969; Stiven & Gardner, 1992). The driving mechanisms responsible for these two distinct distribution patterns are unclear, although the difference has been attributed to variation in predation intensity (Nielsen & Franz, 1995).

Previous studies attempting to characterize the distribution of ribbed mussels have mostly focused on their relationship with biological variables, with several studies concluding that ribbed mussel distribution differs depending on salt marsh vegetation characteristics and location within the salt marsh. For example, Kuenzler (1961) noted that at a site on Sapelo Island, GA, ribbed mussels were most abundant near the mouths of creeks that supported tall-form *Spartina alterniflora* (size morphologies of *S. alterniflora* are described by Valiela *et al*., 1978). Kuenzler (1961) also observed lower abundances of ribbed mussels at higher elevations associated with short-form *S. alterniflora*. Other studies (*e.g.*, Bertness & Grosholz, 1985; Stiven & Gardner, 1992; Franz, 2001) have focused on the importance of salt marsh vegetation to the distribution of ribbed mussels, noting that they tend to occur in association with tall-form *S. alterniflora*. These studies only focused on small-scale factors that influence the distribution of ribbed mussels (*e.g.,* the importance of a microhabitat because of its biological characteristics), however, and would be difficult to apply to landscape-scale habitat characterization efforts. Furthermore, although the upper and lower salinity tolerances of ribbed mussels have been previously described (Wells, 1961; Lent, 1969), until recently no studies explicitly examined the relationship between ribbed mussel distribution and salinity, an important environmental variable for sessile marine bivalves (Remane, 1934; Deaton & Greenberg, 1986).

Recently, Julien *et al.* (2019) investigated the distribution of ribbed mussels in South Carolina salt marshes in relation to both elevation and salinity, with the goal of creating a tool that could be used to predict the distribution of ribbed mussel habitat throughout South Carolina. This study also established a methodology for determining the inundation period for ribbed mussels across a range of elevations, providing temporal insights into opportunities for filter feeding and exposure to tidally migrating predators. Using logistic regression modeling, Julien *et al.* (2019) found that

ribbed mussels were most likely to occur high in the intertidal zone (0.17 m below mean high water) and at an intermediate salinity of 18 ppt. Furthermore, this study determined the inundation period for ribbed mussel at sites in South Carolina to range from 45 minutes to 6 hours, averaging 3.5 hours per high tide, highlighting the physiologically challenging nature of their lifestyle.

In the southeastern United States, salt marshes and their associated tidal creeks serve as important nursery grounds for the early life history stages of several fish and crustacean species (Weinstein, 1979; Rountree & Able, 2007), with even the high marsh platform acting as a nursery ground during high tide (Kneib, 1984; Talbot & Able, 1984). In South Carolina salt marshes, mummichogs (*Fundulus heteroclitus*), daggerblade grass shrimp (*Palaemon pugio*) and blue crabs (*Callinectes sapidus*) are often the most abundant nektonic species (Kneib, 1984; 1997; LaSalle *et al.,* 1991) with these species, among others, moving onto the high-marsh platform with the incoming tide (Kneib & Wagner, 1994) as part of the transient nekton assemblage. Within the salt marsh landscape, the ribbed mussel is an example of a secondary foundation species, as it provides additional habitat within the range of smooth cordgrass in a hierarchical manner (Altieri *et al.,* 2007; Angelini *et al.,* 2015). Ribbed mussel aggregations provide physical structure, accrete sediments, and facilitate smooth cordgrass growth, thereby providing habitat for salt marsh invertebrates, such as fiddler crabs and marsh periwinkles (Angelini *et al.,* 2015).

The coexistence of smooth cordgrass and ribbed mussels has previously been shown to augment diversity more than the presence of smooth cordgrass alone in both Narragansett Bay, Rhode Island, USA (Altieri *et al*., 2010), as well as on Sapelo Island, Georgia, USA (Angelini *et al*., 2015). Areas of smooth cordgrass associated with high densities of ribbed mussels support greater invertebrate species abundance, richness, and species diversity than smooth cordgrass patches associated with low densities of ribbed mussels (Angelini *et al*., 2015). By modifying the pre-existing conditions and providing habitat for other species, foundation species such as the ribbed mussel increase the number of trophic interactions in a community (van der Zee *et al*., 2016). Consequently, ribbed mussels indirectly enhance landscape-scale ecosystem functions such as infiltration, which is influenced by burrowing invertebrates, and decomposition rates, which are influenced by smooth cordgrass productivity (Angelini *et al*., 2015; Bertness, 1984). Ribbed mussels and smooth cordgrass also play important roles in nutrient cycling, as their mutualistic relationship enhances landscape-scale salt marsh nitrogen removal (Bilkovic *et al*., 2017; Jordan & Valiela, 1982). Through these functions, ribbed mussels recognized as an ecosystem engineer (*sensu* Jones *et al*., 1997) and constitute an integral part of the salt marsh community.

Additionally, the role that ribbed mussels play in promoting nekton diversity was recently investigated by Julien *et al.* (2020b). While this study did not find significant differences in nekton abundance or diversity between plots with and without mussels, nekton community composition did differ between plot type, and season and tidal height both influenced nekton assemblage abundance and diversity. Interestingly, this study also revealed a pulse of juvenile (< 50 mm carapace width) blue crabs, *Callinectes sapidus* utilizing the high marsh platform during the fall season.

THREATS

Habitat loss and the pollution associated with coastal development are the main challenges to conserving ribbed mussel populations. Coastal salt marshes have declined in area over the last 200 years in the conterminous United States and are currently being lost at a higher rate than any other wetland category (Dahl, 2011). In South Carolina, USA, a recent shoreline assessment classified over 57% of coastal shorelines as erosional, with an average long-term marsh erosion rate of 0.34 m yr-1 (Jackson, 2017). The loss of salt marsh habitats is of particular concern as they represent some of the most biologically productive and ecologically valuable habitats in the coastal region (*e.g.*, Whittaker & Likens, 1973; Odum, 1979; Day *et al*., 1989; Levin *et al*., 2001; Peterson *et al*., 2007; Barbier *et al*., 2011). These marsh habitats are at risk of degradation and loss through synergistic relationships between sea level rise, increased storm frequency, coastal development, and shoreline hardening (Peterson *et al*., 2008a,b; Titus *et al*., 2009; Mattheus *et al*., 2010; Nicholls & Cazenave, 2010; Rahmstorf, 2010; Grinsted *et al*., 2013). Such losses of salt marsh habitat will comprise declines in abundances of ribbed mussels and losses of the ecosystem services that they provide.

Mussels have frequently been used for pollution assessment studies (O'Connor, 2002; Hellou & Law, 2003). "Mussel Watch" programs, in which mussels (typically *Mytilus* spp.) and oysters are used as valuable bioindicators of pollutant exposures and effects, have been used by the National Oceanic and Atmospheric Association (NOAA) in the United States and in a variety of countries throughout the world. Mussels are regarded as especially valuable bioindicator organisms because they readily accumulate pollutants in their tissues, and a number of valuable cellular biomarker approaches have been developed for characterizing the adverse effects of these contaminants on these organisms. Comparative studies with oysters have demonstrated some similarities in mussel bioaccumulation and biomarker responses, but these studies also suggest that marsh mussels may be more sensitive to pollutants. Therefore, marsh mussels may be particularly important as bioindicators of pollutants in marsh grass habitats where oysters are less common. Moreover, since *Mytilus* spp. do not occur in the southeastern U.S., *Geukensia demissa* may be a valuable alternative mussel species. Research conducted in South Carolina (*e.g*., Ringwood, 1999) and elsewhere (*e.g*., Ford *et al*., 2005) suggests that the ribbed mussel is an excellent subject to evaluate sediment contamination impacts. The results in South Carolina for the ribbed mussel were very similar to those observed previously by Ringwood *et al.* (1998a; 1998b; 1999a; 1999b) for *Crassostrea virginica*. Cellular 'biomarkers' appear to be extremely useful in assessing contaminant sublethal exposures under both field and laboratory conditions.

In South Carolina, driven by demand from restaurants and retail outlets in response to local interest in the human consumption of ribbed mussels, estimated commercial harvest of this species increased markedly from under 10,000 lbs before 2011 to a peak of more than 30,000 lbs between 2014 and 2016 (SCDNR Office of Fisheries Management, unpubl. data; Julien *et al.,* 2020a). This species is also occasionally harvested recreationally. The removal of ribbed mussels via harvesting raised concerns as to the potential for negative impacts on the ecological health and functioning of the salt marsh community in which it serves as a foundation species (*sensu* Dayton 1972). This concern prompted the study by Julien *et al.* (2020a) that investigated the demographics of ribbed mussels and the effects of simulated harvest on salt marsh health.

CONSERVATION ACCOMPLISHMENTS

The SCDNR Marine Resources Division in collaboration with multiple partners is actively involved in habitat enhancement efforts through the creation of intertidal oyster reefs, achieved through the provision of hard substrate for settlement and recruitment. It is likely that the provision of this substrate has also benefitted ribbed mussel populations. In addition, the Marine Resources Division is becoming increasingly active in the realm of salt marsh research and conservation at the landscape scale, which is likely to benefit ribbed mussels through an improved understanding of the need for salt marsh management and conservation.

CONSERVATION RECOMMENDATIONS

- Improve our basic understanding of ribbed mussel life history in South Carolina to include studies related physiological tolerances, growth rates, size-at-age relationships, predator-prey interactions, and reproductive phenology.
- Develop and apply habitat characterization models for ribbed mussel to predict their current and future statewide distributions for use as a conservation tool to support habitat conservation and sustainable harvest practices.
- Evaluate interactions between ribbed mussels and oyster reef population dynamics and the role of ribbed mussels in oyster reef development.
- Enhance/expand SCDNR habitat restoration and enhancement programs to consider benefits to ribbed mussels.
- Explore the feasibility of restoration efforts primarily focused on increasing ribbed mussel populations within the salt marsh landscape.
- Evaluate ribbed mussel contributions to the nutrient dynamics of salt marshes and the possible role of ribbed mussels in the restoration of marsh habitats.
- Develop a fisheries management plan for ribbed mussels and promote sustainable fisheries practices for ribbed mussel harvesting that serve to reduce the negative impacts on salt marsh health and that promote ribbed mussel recovery.
- Develop applications of ribbed mussels as a bioassay for determining pollution and as a potential indicator of the functional health of communities (*e.g.,* oyster reefs, salt marshes).
- Partner with local governments and the SC Department of Environmental Health and Control (SCDHEC) to deter development in sensitive areas where development will have negative effects on ribbed mussel populations.
- Implement and improve Best Management Practices (BMPs) in future urban and commercial developments to protect water quality.

MEASURES OF SUCCESS

By implementing the conservation recommendations listed above, the SCDNR will be able to encourage stable, or even increasing, populations of ribbed mussels in South Carolina. It is clear that more studies of the specific nature of ribbed mussels in our state our warranted and much basic information on the biology of this species remains lacking. Equivalent attention to the ecosystem services provided by ribbed mussels and its associations with smooth cordgrass as those appreciated for intertidal oyster reefs is arguably warranted.

Sea Walnut

Mnemiopsis leidyi Agassiz, 1865

Contributor: Daniel Sasson (SCDNR, 2023)

DESCRIPTION

Taxonomy and Basic Description

The sea walnut, *Mnemiopsis leidyi* Agassiz, 1865 (Phylum Ctenophora; Class Tentaculata; Order Lobata; Family Bolinidae) belongs to an order of ctenophores recognized by their pair of muscular lobes that project past the mouth. Along these lobes run eight ciliated comb rows. Small bumps sometimes seen on the lobes of *Mnemiopsis* are the basis for its other common name, the warty comb jelly.

Like most other ctenophores, *M. leidyi* is a simultaneous hermaphrodite with the ability to self-fertilize, although self-fertilization may come at a cost to embryonic viability (Sasson *et al.,* 2018). Spawning generally takes place at night and fertilization occurs externally. The number of eggs released is size dependent with larger *Mnemiopsis* releasing more eggs (Sasson & Ryan, 2016). They do not start spawning with regularity until reaching roughly 30 mm (Sasson & Ryan, 2016), but research has shown that they are capable of spawning at very small sizes (*e.g.,* 1 mm, Edgar *et al.,* 2022). *Mnemiopsis leidyi* can reach roughly 120 mm in length.

Mnemiopsis leidyi generally floats with water currents, although their ciliated comb rows can provide some directionality to their movement (Coonfield, 1934). Small and medium sized *M. leidyi* also have diel vertical migrations, perhaps to avoid predators or to follow the movement patterns of prey (Haraldsson *et al*., 2014). Lobate ctenophores generally feed on zooplankton, including fish eggs and larvae. To feed, beating cilia generate a current which pulls slow-swimming prey into oral tentacles covered in sticky colloblasts (Franc, 1978), which are then drawn into the mouth (Sutherland *et al.,* 2014). *Mnemiopsis leidyi* capture faster prey that would otherwise escape the current generated by altering their lobe positions in response to fluid disturbances made by the prey (Costello *et al.,* 1999).

Currently, all *Mnemiopsis* are considered a single species, but population genetic studies on this group suggest that *Mnemiopsis* above and below Cape Hatteras, NC are distinct either to the level of species or subspecies (Bayha *et al.,* 2015; Jaspers *et al.,* 2021). Given that the oldest description of *Mnemiopsis* was the species *gardeni* (L. Agassiz, 1860) from Charleston, SC (as compared to *leidyi* L. Agassiz, 1865 from Woods Hole, MA), it seems likely that eventually, the Charleston *Mnemiopsis* will either become *M. gardeni* or *M. gardeni* subspecies *gardeni*. There is also a chance that the genera will change (possibly to *Bolinopsis*, but there are other considerations based on precedence) since *Mnemiopsis* is paraphyletic within *Bolinopsis* (Christianson *et al.,* 2022).

While still in some dispute (*e.g.,* Redmond & McLysaght, 2021), the phylum Ctenophora is widely considered the sister species to all other animals (Dunn *et al.,* 2008; Whelan *et al.,* 2017, Schultz *et al.,* 2023). For this reason, ctenophores are often used as study organisms to understand early animal evolution (*e.g.,* Ryan *et al.,* 2013, Moroz *et al.,* 2014)

Status

Mnemiopsis leidyi is not currently included in federal lists of threatened or endangered species and there is no present-day direct human exploitation of this species in South Carolina. No targeted population assessments are conducted on this species, despite its ecological significance. Relatively little is known about the presence or ecological impacts of *Mnemiopsis* in South Carolina compared to areas where it has recently become established (see below).

POPULATION DISTRIBUTION AND SIZE

Mnemiopsis leidyi has been historically found in the western Atlantic Ocean ranging from New England to Argentina (GESAMP, 1997). It can be found in both offshore and inshore waters, including brackish estuaries.

In the 1980s, *M. leidyi* appeared in the Black Sea, likely brought over in the ballast water of ships, and has since been found in many European waters (Ghabooli *et al.,* 2011). In these regions, *M. leidyi* has been implicated in a reduction of zooplankton abundance (Roohi *et al*., 2008) and crashing fish stocks (Oguz *et al.,* 2008). Due to its potentially devastating effect on local ecosystems, *M. leidyi* is considered one of the 100 worst invasive species (Lowe *et al*., 2000).

HABITAT / NATURAL COMMUNITY REQUIREMENTS

Adult *M. leidyi* have wide tolerances to temperature and salinity (Haraldsson *et al.,* 2013), which allows them to thrive under many conditions, although reproduction may be reduced in lower salinity environments (Jaspers *et al.,* 2011). They are also tolerant of relatively low food environments and can continue spawning daily even after 12 days without food (Jaspers *et al.,* 2015). Their tolerance of wide-ranging conditions, high reproductive output, and ability to self-fertilize are likely key reasons why *M. leidyi* has been able to spread to, and become established in, areas outside of its native range.

CHALLENGES

Ctenophores are not used for any commercial purpose, but may be susceptible to changes in environmental conditions that lead to the degradation of their habitat, such as coastal development, pollutants and contaminants. This species may also be influenced by changes in environmental conditions associated with climate change-related shifts in temperature, pH and circulation patterns.

CONSERVATION ACCOMPLISHMENTS

Ctenophores in general have received little to no attention in terms of conservation efforts, likely due to a lack of demographic information. The species is currently not listed as either threatened or endangered at either the state or Federal level, which also explains the lack of targeted conservation efforts.

CONSERVATION RECOMMENDATIONS

Little is known about the abundance and ecological impacts of *Mnemiopsis leidyi* in South Carolina waters. As seen from areas where *M. leidyi* has recently become established, they can have profound impacts on zooplankton abundance and fish recruitment (Oguz *et al.,* 2008; Roohi *et al*., 2008). Quantifying the seasonal trends in abundance and the diet of *M. leidyi* would greatly expand our understanding of their role in the ecosystem of South Carolina.

The taxonomic classification of *M. leidyi* is currently in flux. Recent work suggests that those *Mnemiopsis* found north of Cape Hatteras are a separate species from those south of Cape Hatteras. Additional genetic sampling along the coast, especially in the Charleston area where *Mnemiopsis* was first described, would help to resolve this issue.

MEASUREMENT OF SUCCESS

A better understanding of the ecology, distribution, and taxonomic classification of *Mnemiopsis* in South Carolina would improve our ability to recognize changes in abundance patterns that might result from shifts in environmental conditions.

Shark eye
Neverita duplicata

Contributor: Peter Kingsley-Smith (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Neverita duplicata Say, 1822 (formerly *Natica duplicata* and *Polinices duplicatus*), common name the shark eye, or the lobed moonsnail, is a predatory marine gastropod mollusc in the family Naticidae, collectively referred to as the moon snails (Rosenberg, 2010). It is one of the most familiar animals of the southeastern coast, recognizable in both its postlarval form as well as from its characteristic circular egg collars (3”-4” in diameter) which can be found on sandy beaches at lower tidal elevations, and further up the beach when washed ashore after storms.

Hülsken *et al.* (2006) reported the existence of a second, very similar species with a smaller range of distribution that occupies part of the range inhabited by *N. duplicata*. This second species had previously been considered to be simply a form of *N. duplicata*, but is now recognized as *Neverita delessertiana*.

Reaching approximately 2” in height, the shell of *N. duplicata* is smooth, generally flattened and rounded with a low spire, such that the shell is generally much wider than it is high (Abbott, 1974). The operculum is corneous and flexible. The shell color ranges from slate gray to tan, with the base of the shell often whitish (Abbott, 1974). The shell aperture is large and the deep umbilicus extends up into the columella, but the umbilicus is partially plugged by a large brown growth of shell (Abbott, 1954; Ruppert & Fox, 1988).

Naticid gastropods are characterized by an extremely large and broad foot relative to the size of the shell. The foot is employed both in locomotion and in the capture, subjugation, and manipulation of prey. The anterior part of the powerful, muscular foot, referred to as the propodium, is used for burrowing and can act as a plough at the sediment surface. The snail is able to inflate its foot by drawing in seawater through a series of small posterior pores (Fretter & Graham, 1994) such that the expanded foot can have up to four times the volume of the retracted foot (Ruppert & Fox, 1988). The large foot permits rapid locomotion over soft substratum. Naticids possess a well-developed gill which is housed within a large and effectively isolated mantle cavity. During locomotion, the propodium is extended and reflected anteriorly over the shell, thereby regulating the pallial stream and preventing all but the smallest particles from entering the mantle cavity. Furthermore, an extension of the opercular lobe of the metapodium is raised over the posterior part of the shell, concealing the operculum, such that the foot is virtually hidden during locomotion.

During the process of prey capture naticids ‘pick up’ the prey using the propodium and secrete large quantities of mucus that reduces the likelihood of the prey escaping. Once captured, the

prey is transferred to the posterior region of the foot and towed beneath the sediment until the predator comes to rest. The prey is then brought forward such that the apex of the prey lies at the anterior end of the propodium ready for drilling (Fretter & Graham, 1994). Although foraging may occur near the sediment surface, an immobilized prey is usually dragged down into the substrate before drilling is initiated (*e.g.,* Kitchell, 1986; Kabat, 1990; Reyment, 1999; Kelley & Hansen, 2003). Shell penetration is achieved by alternation of chemical etching, as a result of chemical secretions from the accessory boring organ, and physical abrasion, thought the action of the radula (Ziegelmeier, 1954; Fretter & Graham, 1962; Carriker, 1981; Kabat, 1990), after which the proboscis is inserted through the hole for consumption of prey. Naticid drill holes are countersunk, truncated, spherical paraboloids, which is to say that the enlarged outer margin is bevelled or tapered (Benton, 1986).

Status

The status of this species in South Carolina is known as it is not the target of any standardized surveys, does not support a directed fishery, and is not listed on any recognized Federal or state conservation list.

POPULATION SIZE AND DISTRIBUTION

Neverita duplicata is distributed from Cape Ann, Massachusetts, to Florida and the Gulf States (Abbott, 1974). Hanks (1953) demonstrated that feeding in *N. duplicata* ceased at temperatures below 5°C, which likely plays a role in determining the distribution of this species. The size of the population of *N. duplicata* in South Carolina is unknown because this species is data deficient. While the general habitat association of *N. duplicata* in the region is known, details of its distribution in South Carolina are lacking.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Neverita duplicata is typically found on silty sand beaches along protected stretches of coast and spends much of its time beneath the sand in search of its typical molluscan prey. Naticid gastropods are regular members of infaunal invertebrate communities across a broad range of latitudes (Taylor & Taylor, 1977) and are specialist predators of shelled prey, most commonly bivalve species. The diets of naticids comprise over 80 families of gastropods and bivalves, mainly restricted to those taxa inhabiting soft substrata, in particular *Donax*, *Tellina*, *Macoma*, and *Mactra*, but also *Mya*, *Abra*, *Spisula*, *Chamelea*, and *Nucula* (Piéron, 1933; Ziegelmeier, 1954; Fretter & Graham, 1994).

Naticid gastropods have been significant predators of benthic marine molluscs since the Cretaceous period (Sohl, 1969), with evidence of their consumptive behavior in nearshore habitats remaining in the form of stereotypic and characteristics countersunk boreholes in left behind in the shells of their molluscan prey (*e.g.,* Guerrero & Reyment 1988; Kabat, 1990; Kelley, 1991; Dietl & Alexander, 1997; Kelley & Hansen, 2003; Kingsley-Smith et al., 2003; Dietl & Kelley, 2006; Harper, 2006; Cintra-Buenrostro, 2012). Along northwest Atlantic coastlines, naticids consume a broad diversity of molluscan fauna, including commercially-important species (*e.g.,* Dietl & Alexander, 1995; Clements *et al.,* 2013), such as the surfclam

Spisula solidissima, with consequent effects on the spatial patterns and abundances of their prey (*e.g.,* Wiltse, 1980).
Although many naticids have broad diets (*e.g.,* Edwards, 1974; Edwards & Huebner, 1977; Ansell, 1983; Clements *et al.,* 2013), many are also capable of selective predation with respect to prey species, prey size, prey shell thickness, and borehole location. In such cases, larger predators tend to feed on larger prey items (*e.g.,* Rodrigues *et al.,* 1987; Kingsley-Smith *et al.,* 2003; Chiba & Sato, 2012), with the correlation coefficient of the relationship between predator size and prey size representing the strength of their selectivity (Dietl & Alexander, 1997). Interspecific prey selectivity has also been observed in naticid species associated with selection of prey species that, for a certain size class of prey and predator, offer a better energetic reward per unit handling time (*e.g.,* Kitchell et al., 1981; Kelley, 1991; Dietl & Alexander, 1995, 1997; Kelley & Hansen, 1996). Kitchell *et al.* (1981) reported a consistent rate of drilling in *N. duplicata* of 0.0223 mm hr^{-1}. Kitchell *et al.* (1986) found that *N. duplicata* would not feed on opened bivalves-only live, closed prey items were chosen. This suggests that the stereotypy of prey choice restricts naticids to fresh prey and rules out scavenging or carrion-feeding.

Members of the family Naticidae have traditionally been considered to be predators that drill distinctive, circular holes in the shells of their bivalve and gastropod prey to gain access to the soft tissues inside (Carriker, 1981; Kitchell *et al*., 1981). Laboratory experiments confirm that moon snails drill using a combination of radular scraping and the application of weak acid produced by an accessory boring organ (Kabat, 1990), and consume all or most prey tissue (Carriker, 1981; De Angelis *et al*., 1985; Kitchell *et al.,* 1986; Visaggi *et al*., 2013). Recent stable isotopic analyses—a powerful tool for determining dietary sources and complex trophic interactions (Post, 2002; Layman *et al*., 2012)—yielded realized trophic positions for *Neverita duplicata* between 2.3 and 2.5 in Long Island Sound (Casey *et al.,* 2014). The lower than expected trophic positions reported by Casey *et al.* (2014) resulted from a combination of unexpectedly high carbon signatures and lower than expected nitrogen signatures (Casey & Post, 2011; Casey *et al.,* 2014). The high C signatures indicate that *N. duplicata* relies heavily on littoral carbon sources *i.e.,* those that grow along the surface of the seashore (Casey *et al*., 2016).

CHALLENGES

The spatial distribution appears to be closely associated with silty sandy beaches along protected stretches of shorelines, such that alterations and disturbances to such habitats are likely to be a significant challenge to this species. Processes that alter the grain size and morphology (*e.g.,* installations of piers and land-based shoreline structures, beach renourishment activities) of sandy beaches where *N. duplicata* occurs are therefore likely represent threats to this species. This species is typically found in high salinity habitats, and not in brackish or estuarine habitats, such that alterations to the salinity of areas where this species occur are likely to have negative impacts on *N. duplicata*. Freshwater discharges may influence the distribution, abundance, and life history traits of this species, raising the possibility that freshwater discharges from "swashes" in South Carolina could be a potential cause of disturbance to *N. duplicata*. This species may also be negatively affected by coastal storms through physical disturbance, such that the increased frequency of tropical storms and hurricanes predicted under future scenarios of anthropogenically-driven climate change could be an additional challenge to this species.

CONSERVATION ACCOMPLISHMENTS

Neverita duplicata has received little or no attention in terms of past conservation efforts, likely due to the data deficient nature of this species to indicate that its number have been in decline, either as a result of natural or anthropogenic factors.

CONSERVATION RECOMMENDATIONS

- Periodically conduct assessments of beach invertebrate communities to determine their condition and better understand their temporal and spatial dynamics.
- Work with coastal municipalities and communities to reduce future impacts of development on sandy beach environments.
- Work with appropriate state, local, and non-governmental agencies to discourage development on beachfront properties.
- Educate the public as to the importance of sandy beach habitats and about some of the key fauna that rely on these coastal habitats.
- Encourage planned development projects in coastal zones to reduce associated impacts of development on the long-term health of sandy beach habitats in South Carolina.
- Continue to investigate and document the effects of rising sea levels and global warming on beach habitats.
- Discourage the building or repair of seas walls and groins on South Carolina's beaches to allow more natural movement of sand and, ultimately, more natural beach renourishment.

MEASURES OF SUCCESS

A better understanding of the spatial distribution and baseline life history of *N. duplicata* would be first order measures of conservation success. Such an understanding would enable the impacts of disturbances to be conceptualized but also provide protection to critical habitats, including at key points in their life history. An improved understanding of the trophic interactions between this naticid gastropod species and the molluscan prey community of sandy beach habitats will help to understand the role of this predator within such ecosystems in coastal South Carolina habitats, including its potential impacts on commercially-important and conservation priority bivalve species.

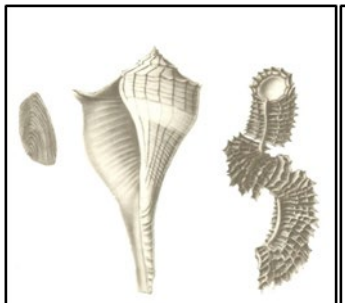
Knobbed Whelk *Busycon carica*

DESCRIPTION

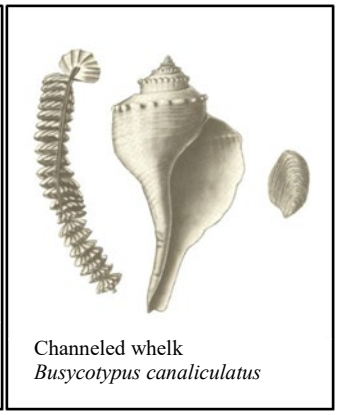
Taxonomy and Basic Description

The knobbed whelk, *Busycon carica*, is the most common whelk in South Carolina, but three other species are found in State waters in the following order of abundance: the channeled whelk (*Busycotypus canaliculatus*); the lightning whelk (*Sinistrofulgur perversum*); and the pear whelk (*Fulguropsis spirata*). The only whelk in SC found in commercial quantities is the knobbed whelk and therefore it is the best studied.



First described by Gmelin in 1791, the knobbed whelk, *Busycon carica,* is a member of the family Melongenidae. Whelks have flourished off of the South Carolina coast in the Atlantic for over 30 million years. Adult knobbed whelks are usually 5-9” in length and are characterized by low knobs on the shoulder of the whorl with the aperture on the right side. Aperture coloration ranges from light orange-yellow to brick red. The knobbed whelk is the state shell of both New Jersey and Georgia.

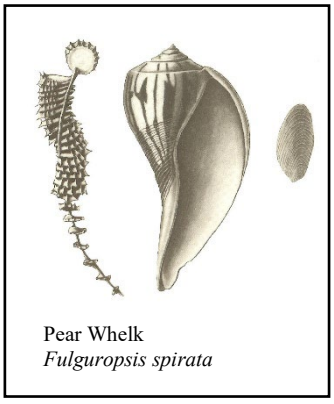
The structure and coloration of knobbed whelk shells vary greatly, not only over their geographical range, but also within a locality. It is not unusual to find whelks on South Carolina beaches with different knob lengths, knob directions, and aperture colors. Whelks grow by extending the shell around a central axis, producing turns or whorls as they evolve. The final whorl—and usually the largest—is the body whorl that terminates, providing the aperture into which the snail can withdraw. Whelks also have a separate hard, horny plate, called an operculum, which acts like a trap door when the snail withdraws into the shell. Sometimes called a “shoe,” the operculum is attached to the top of the foot and is seldom found with empty whelk shells (Magalhaes, 1948; Eversole & Anderson, 1985).



Knobbed whelks in South Carolina lay egg strings twice a year, usually from September through October and April through May. Egg strings start to appear at times when the water temperature approximates 20°C (68°F). Of the two egg-laying periods, fall appears to be the most productive. It is not known if an individual female whelk contributes to both of these egg-laying peaks or if a

female lays more than one string per season. Good estimates of the average number of eggs per capsule (34 to 35) and capsules per string (100 to 120) are available for this species. Spent egg strings often wash up on beaches and consist of a series of flattened capsules attached at one end to a tough cord or string-like structure. Some egg cases reach a length of over 0.3 m (1ft.) and contain up to 160 capsules. In all four whelk species, eggs complete their development within the egg capsule and, after hatching, small juvenile snails emerge through a predesigned exit. The first capsules in the string usually do not contain eggs and are buried in the ocean floor as an anchor. Knobbed whelk egg capsules are coin-shaped, 20 mm to 30 mm (0.8-1.2 in.) in diameter and are 3 mm to 6 mm (0.1-0.2 in.) thick with crenulations around the edges. Eggs develop slowly, hatching in about 3 to 13 months. Egg cases that wash up on beaches are usually empty, with open holes providing evidence of successful hatchings (Magalhaes, 1948; Eversole & Anderson, 1985).

If one finds a large knobbed whelk on the beach, chances are good it is a female. Male knobbed whelks rarely reach the large sizes of their opposite sex. Normally, female knobbed whelks have larger shells, weigh more, and possess a larger foot. Whelks are thought to be protandric hermaphrodites; this means that they start out as males when young, and then change into females as they grow older. This phenomenon may lead to a preponderance of females among the older and larger-sized individuals in the population (Eversole & Anderson, 1985).



Lightning Whelk
Sinistrofulgur perversum

Channeled whelk
Busycotypus canaliculatus

Channeled whelks have a much thinner shell than knobbed whelks and may be covered with a fine hairy periostracum. The spire is characterized by flat shoulders with knobs that are reduced to fine beads.

Lightning whelks can reach a length of 16”, making them the largest whelk in South Carolina. It is, however, rare to see a lightning whelk in inshore waters. Chances increase in the fall when mature individuals may migrate inshore to breed. A lightning whelk is distinguished from the other whelks in South Carolina by the counter-clockwise coiling of the shell, giving it a “left-handed” shell.

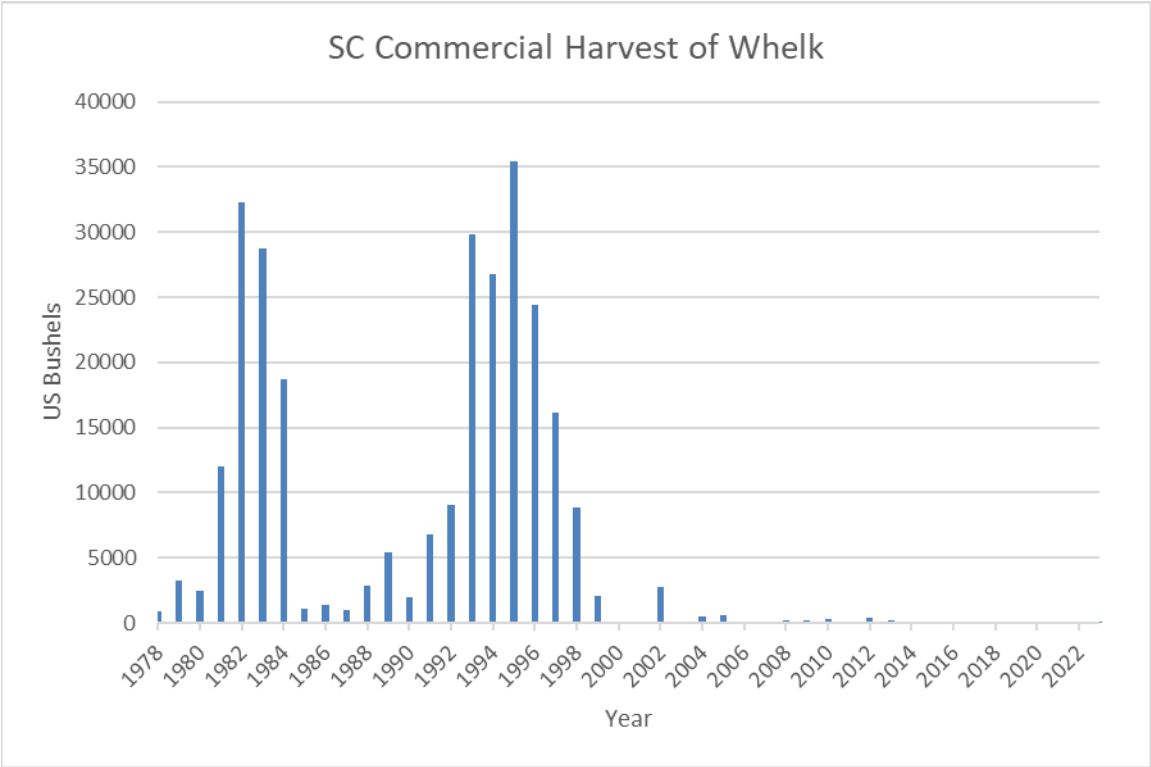
Pear Whelk
Fulguropsis spirata

Pear whelks are smaller than the other species, seldom exceeding 6”. The species lacks knobs, beads, and periostracum and has a large flaring aperture. It is found in high salinity, subtidal areas and is nocturnal so live specimens are seldom seen in South Carolina, although shells may be found along the southern coastline.

Whelks are carnivorous gastropods, not to be confused with filter feeding conchs, such as the queen conch (*Strombus gigas*), found in the waters of southern Florida and the Caribbean.

Whelks feed by tearing off strips of tissue with their file-like radula. Knobbed whelks and lightning whelks feed on bivalves such as hard clams (*Mercenaria* spp.), oysters (*Crassostrea virginica*), and incongruous arks (*Anadara brasiliana*). These heavy whelks use the lip of their shell to chip and pry the valves of their prey apart, holding it with its foot so that the ventral edges of the prey valves are under the outer lip of the whelk shell. Slow chipping continues until an opening is generated that allows the whelk to wedge its shell between the prey valves and then enter its proboscis to begin feeding. Since the feeding process results in damage to the shell, limited growth sometimes occurs in adults as energy is used to repair their shells (Magalhaes, 1948; Carriker, 1951).

The thinner-shelled pear and channeled whelks feed on incompletely closed bivalves (*e.g.* razor clams) or wait for prey to open its valves and use the lip of their own shell as a wedge. Pear whelks also feed on mobile gastropods which they outrun and trap in their large siphonal canal.



Status

The knobbed whelk is a common species of the shallow shelf ecosystem of the South Carolina coast. The prevalence of knobbed whelks in this habitat makes it an excellent indicator of the health of this ecosystem. Many people enjoy collecting whelk shells at the beach. Aside from its recreational and ecological value, the knobbed whelk is targeted in the offshore whelk trawl fishery in South Carolina. Although this species is harvested, there is limited information about population trends or how whelk populations recover from commercial harvests.

The commercial whelk trawl fishery off the South Carolina coast evolved in 1977-1978 as an alternative industry to provide cash flow during the periodic closure of the shrimp season. During the early 1980s, knobbed whelks were shipped alive to processing facilities in Mt. Pleasant and near Beaufort, South Carolina and cooked under pressure for approximately 20 minutes to break down the viscera that attaches the animal to its shell. Meats were extracted from the shell and transported on ice to New England or blast frozen in Savannah, Georgia for markets in the Far East. Whelk meats that arrived in New England were usually processed as canned scungilli (Anderson *et al.,* 1985).

Trawling occurs from 0.8 km to 4.8 km (0.5 to 3 mi.) offshore. Peak collections occur in the spring as the water temperature approaches 14°C (57°F); this is when whelks begin moving over the sediment surface after a dormant period of burial. Of the whelks collected in this trawl fishery, knobbed whelks average approximately 90% of the catch with the remainder being channeled whelks. In recent years, no more than three commercial fishermen have participated in the whelk trawl fishery with some years not having any participants. Peak whelk harvests occurred in 1982 and 1995 with landings of over 30,000 US bushels. This was followed by two years of declining catches and four consecutive years (1985-1988) of production below 3,000 US bushels as the fishery collapsed. Currently, whelk harvest in State waters is limited to a total of 13,000 US bushels per year (SCDNR Office of Fisheries Management, 2003), but harvests have not reached that level since 1997. Since 1998, annual harvests have been lower than 10,000 bushels, whereas the average annual harvest for 2013-2023 was only 43 bushels. The last two years of reported commercial harvest through the whelk trawl fishery were 2005 and 2010.

The cyclical nature of the offshore fishery suggests that overfishing is followed by fishery collapse and slow recovery. The offshore whelk fishery will likely remain cyclical based on market demand, cost of processing the whelk, and the capacity of fishermen to locate aggregations of whelk populations in offshore coastal waters. South Carolina has a highly regulated, short exploitation window for whelk (usually mid-February to mid-April) that is further limited by fishing gear restrictions, weather conditions, minimum whelk harvest size, and marketing opportunities.

South Carolina manages the whelk trawling fishery through the SC Whelk Fishery Management Plan. Although state law provides for a minimum size of 4" shell length (hand collection), the trawl fishery minimum size is currently 4.5". The Plan restricts trawling to early spring, with exact dates determined by the closing of shrimp trawling season and water temperature, and fishermen are required to report catches daily so that the fishery can be closed when the harvest approaches 13,000 bushels, which is considered to be the maximum sustainable yield.

POPULATION SIZE AND DISTRIBUTION

Knobbed whelks are found in US East Coast waters from the south shore of Cape Cod, Massachusetts to Cape Canaveral, Florida, with greater numbers occurring in more southern latitudes (Abbott, 1974). There is no estimate of the whelk population size or distribution in South Carolina. All existing data are fishery-dependent.

Channeled whelks have a similar distribution but are more common in northern latitudes.

Lightning whelks range from New Jersey to Florida and into the Gulf of Mexico but are more common in the southern portion of the range. Pear whelks are found from North Carolina to Mississippi and are more common in Florida and Georgia than in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The knobbed whelk lives in tidal estuarine waters and offshore in depths of up to 150 ft, although they are more commonly found in shallow shelf waters. In estuaries, knobbed whelks sometimes congregate on oyster reefs and clam beds as they feed on these species, along with other marine bivalves, such that these are key habitats for these gastropods (Magalhaes, 1948). Mating and spawning occurs in estuaries and offshore where egg cases are anchored to the bottom. Higher abundances of whelk in intertidal habitats in spring and fall have been assumed to reflect migrations to and from subtidal waters; however, Shalack *et al.* (2011b) suggest that intertidal populations probably remain localized year-round and are simply less visible in summer and winter when harsh intertidal conditions limit their ability to forage at low tide.

Results from mark-recapture studies indicate that whelks are very slow growing and exhibit little long-shore movement, migrating to and from estuaries only in the immediate area of their genesis (Anderson *et al.,* 1985; Eversole *et al.,* 2008). Similar results have been found in Georgia (Walker *et al.,* 2008) where male whelks have been shown to reach sexual maturity at 4 years old and 3.5", while females did not reach maturity until 3.9" and 6 years of age (Power *et al.,* 2009).

CHALLENGES

Currently, low levels of commercial harvest of whelks (predominately knobbed whelks but probably also channeled whelks) have been collected as by-catch in crab pots. Inshore populations have not been studied in South Carolina, but data from Georgia (Shalack *et al*. 2011a,b) suggest that inshore populations may be easily overfished. The SC Whelk Fishery Management Plan does not regulate the inshore fishery. Although this by-catch has made up most of the annual whelk harvest, it is a relatively modest total (< 50 bushels per year). If a targeted whelk fishery were to emerge, landings might increase substantially and represent a risk to inshore populations. Also, if whelk pots are utilized, these are likely to target channeled whelks more than knobbed whelks. Our knowledge of channeled whelk populations is less than that for knobbed whelk.

To provide whelks the opportunity to reach sexual maturity and spawn before entering the fishery, SCDNR requires a minimum size of 4.5" in shell length (apex to end of siphonal canal) for whelk harvest by trawl (hand harvest minimum size is 4:); however, as the siphonal canal frequently breaks during normal feeding, the minimum shell length may not always be indicative of sexual maturity. Furthermore, data from Georgia suggest that females have only recently reached sexual maturity at 4" (Walker *et al.,* 2008). Data from both South Carolina and Georgia suggest that this size limit will result in the selective harvest of females (Walker *et al.,* 2008; Eversole *et al.,* 2008).

Other anthropogenic activities that may negatively impact whelk populations include oil spills, beach renourishment, and dredging. Oil spills, depending upon their severity, could inhibit the

feeding and movement out of the affected area by whelk. Whelks can be entrained in the dredge cutter during beach renourishment, where sand is pumped from offshore or directly from a nearby tidal creek onto the front beach, causing mortality. Pumping substrate for projects such as maintenance dredging in South Carolina harbors or the Atlantic Intracoastal Waterway can also cause mortality in a manner similar to that described above (W. D. Anderson, pers. obs.).

Whelks are major predators on oysters and clams such that shellfish growers actively remove and destroy whelks preying on their culture grounds. While the presence of large numbers of whelks in these areas suggests an abundant population, the practice of destroying large quantities of these organisms could become problematic for the larger population.

CONSERVATION ACCOMPLISHMENTS

Since 1983, SCDNR has had regulatory authority over commercial whelk fisheries to set lawful fishing areas, minimum size requirements, net mesh size, and the opening / closing dates for the offshore whelk trawl fishery. Currently, whelk harvesting in state waters by trawl is limited to a total of 13,000 US bushels per year. The complete closure of inshore trawling areas in 1986 has conserved the resource by reducing incidental whelk by-catch during shrimp harvest. A management plan for South Carolina's offshore whelk trawl fishery was developed in 1999 to provide for a more balanced, less cyclical fishery. There has been virtually no fishery since the plan was enacted, although it is unclear whether this is due to a lack of fishing effort or reduced catch per unit of effort (CPUE). The management plan specifies closing the whelk season when water temperature reaches 20°C (68°F) to prevent trawling when sea turtles are present.

CONSERVATION RECOMMENDATIONS

- Develop reliable aging techniques for knobbed whelk.
- Determine sex specific growth rates for knobbed whelk.
- Further study the population dynamics of inshore whelk (both knobbed whelk and channeled whelk).
- Develop methods for and evaluate long-term population trends in both inshore and offshore populations of knobbed whelk.
- Evaluate the potential effects of an inshore fishery on whelk populations and determine the need for an inshore whelk fishery management plan.
- Utilize and continue to update the SCDNR Offshore Whelk Trawl Fishery Management Plan.
- Investigate the roles that knobbed whelk play in benthic communities, particularly as they pertain to oyster and clam populations.

MEASURES OF SUCCESS

There is currently a lack of biological information needed to effectively manage the whelk fishery for sustainability, particularly with regards to a growing inshore fishery. Development of

this knowledge base would be a measure of success. Consistent, less cyclical, whelk harvests in the offshore fishery and sustainable harvests in an inshore fishery would also be indicators of success.

GENERAL TURTLE DIVERSITY INTRODUCTION

The Southeastern United States includes one of the world's richest regions for freshwater turtle diversity. Freshwater turtles are under increasing levels of threat around the world. Two-thirds of the world's turtle species are listed as threatened by the IUCN, and many of the remaining third have not been evaluated (Turtle Conservation Fund 2002). Human exploitation of turtles has resulted in population declines, local extirpations, and even extinction of some species (Thorbjarnarson et al. 2000).

DESCRIPTION
Taxonomy and Basic Description

The yellow-bellied slider, eastern river cooter, coastal plain cooter, eastern chicken turtle, eastern painted turtle and spotted turtle are members of the family Emydidae, the semi-aquatic pond turtles (Ernst and Barbour 1989). These species all have hardened carapace (top) and plastron (bottom) shells.

The yellow-bellied slider is large, reaching lengths from 12.5 to 20.3 cm (4.9 to 7.9 in.). The maximum length for the yellow-bellied slider is approximately 29 cm (11.4 in.). Adults are sexually dimorphic; females reach greater lengths and overall body size than males (Ernst and Barbour 1998). Adults are typically dark with vertical yellow markings on their carapace. The most conspicuous marking is the yellow blotch on the side of the head just behind the eye (Conant and Collins 1991; Martof et al. 1980). The plastron of these turtles is yellow with round, dark markings along its edge. Older adult yellow-bellied sliders can become very dark, obscuring many of their distinguishing marks.

Photo by Andrew Grosse

The eastern river cooter and coastal plain cooter are both large turtles that can reach lengths between 23 and 33 cm (9 to 13 in.); approximately 39 cm (15.3 in.). Adults of both species have dark carapaces with yellow markings; however, markings on the coastal plain cooter tend to be

Photo by Andrew Grosse; *Eastern River Cooter (left) Coastal Plain Cooter (Right)*

vertical stripes while the eastern river cooter as a net-like pattern. The plastron of the coastal plain cooter is typically plain yellow (Conant and Collins 1991; Martof et al. 1980). The eastern river cooter has dark markings on its plastron. Both cooters have yellow stripes along the sides of their heads. These species are closely related and some taxonomists believe they might actually be the same species (Seidel 1994). They are typically found in different habitat types, but some overlap does occur and they may hybridize readily in these areas, producing individuals that share traits of both species.

The eastern chicken turtle is small to moderate in size. This turtle reaches lengths from 10 to 15 cm (3.9 to 5.9 in.); maximum length is approximately 25 cm (9.8 in.). This species has a dark black to brown carapace with a light, net-like pattern and a very long, striped neck (Conant and Collins 1991; Martof et al. 1980). The plastron is typically plain yellow, and patterning on the bridge varies among individuals. The bridge may have a black bar, one or two spots, or no markings at all. Very strong, vertical striping is present on the rear legs.

Photo by Andrew Grosse

The carapace is longer than it is wide and is widest toward the rear, appearing somewhat pear-shaped from above. The edges of all marginal scutes are smooth. The species differs from most other North American turtles because it has both a fall and spring nesting season as well as a long incubation period.

The eastern painted turtle is a medium-sized turtle, typically ranging in adult size from 11.5-15.2 cm (4.5-6 in.) (Conant and Collins 1991). The record size for an adult is 19.5 cm or just over 7 in. The large scutes of its smooth carapace are arranged in straight lines across the back, making it unique in that regard (Conant and Collins 1991). Eastern painted turtles are brightly marked with red on the marginal scutes, a yellow plastron, and red stripes on the head and neck. The adults are sexually dimorphic with males exhibiting very long nails on the front feet and thicker tails (Conant and Collins 1991). This turtle is found most often in shallow waters in the Piedmont of South Carolina though some do exist further south in Pee Dee River Drainage.

Photo by Andrew Grosse

The spotted turtle is a small turtle, reaching lengths of only 9 to 11 cm (3.5 to 4.3 in.); maximum size is approximately 12 cm (4.7 inches) (Conant and Collins 1991). The carapace is typically black in color sprinkled with numerous orange-yellow spots. However, the density and location of spots on the carapace vary and spotless individuals have been observed. Typically, hatchlings and juveniles have a single spot per scute. The head and neck of this species also has orange-yellow blotches. This species has no hinges on the plastron but typically the plastron is a red/orange or cream color with black blotches.

Photo by Andrew Grosse

The Florida softshell turtle and the Gulf coast spiny softshell turtle are both members of the Family Trionychidae (Ernst and Barbour 1989). Members of this family are semi-aquatic and have cartilaginous shells rather than hardened shells like other turtles and tortoises. The cartilaginous "shell" of these turtles covers a bony shell in much the same way the scutes of other turtles and tortoises cover a bony shell. Softshell turtles, in general, have very flattened, pancake-like shells.

Photo by Andrew Grosse

The Florida softshell turtle is a large species, reaching lengths between 28 and 62 cm (11 to 24 in.); females are significantly larger than males (Conant and Collins 1991; Martof et al. 1980). The shell of this species is typically dark brown to dark green and generally uniform in color. The Florida softshell has an oval-shaped shell with numerous bumps on the carapace just behind the head and neck.

The Gulf coast spiny softshell turtle is also a large species, reaching lengths between 18 and 45 cm (7 to 17.7 in.) (Conant and Collins 1991; Martof et al. 1980). Females of this species are significantly larger than males. The spiny softshell turtle has a more rounded shell than the Florida softshell, and there are usually two or more dark, broken lines that parallel the curve of the shell at its rear. The carapace of this species also has numerous small blotches or circular marks. The spiny softshell has two stripes along its neck. The Gulf coast spiny softshell has few to many small “spines” on the carapace just behind the head and neck. Both species have extremely long necks and elongated nostrils.

Photo by Andrew Grosse

The snapping turtle is a member of the Family Chelydridae which includes the snapping and alligator snapping turtles. Members of this family are semi-aquatic and are only found in North America. The snapping turtle is large, reaching lengths of 20 to 36 cm (7.8 to 14 in.). The maximum length for this species is approximately 50 cm (19.6 in.) (Conant and Collins 1991; Martof et al. 1980). This species has a "prehistoric" appearance because its long tail looks "saw-toothed" and its dark brown carapace has a jagged edge. The plastron of this species is greatly reduced and white. The head of the snapping turtle is very large and includes a sharp beak-like snout.

Photo by Andrew Grosse

Striped mud, eastern mud and eastern musk turtles are all members of the Family Kinosternidae (Ernst and Barbour 1989). These turtles are small (2-5 inches) semi-aquatic turtles with a hard carapace and plastron, though the plastron for all these species has varying levels of flexibility. While these species can and do swim, they are typically found walking the bottom of slow or non-moving aquatic habitats.

The striped mud turtle was first documented to occur in South Carolina in the late 1960s. Since that time, additional surveys have confirmed the occurrence of the species in this state and revealed that it is more widespread than previously believed. In the heart of its range (Florida and Georgia), the striped mud turtle has 3 stripes on its carapace and stripes on the side of its head. In South Carolina many individuals of this species lack the carapacial and head stripes, making it easy to confuse them with the more common Eastern mud turtle. Based on museum searches (Lamb and Lovich 1990), this species occurs throughout the Coastal Plain of South Carolina and may be relatively common. However, it seems to be most common in the floodplain swamps of rivers.

Photo by Parker Gibbons

Photo by Andrew Grosse

The eastern mud turtles are a small turtle (2-5 in.) found through most of SC. The carapace is dark in color and plastron is usually yellow or orange with two hinges allowing the turtle to close its shell. The head is usually mottled with yellow with no defined stripes like striped mud and eastern musk turtles.

The eastern musk turtle is a small species (2-5 in.) found throughout SC. The carapace is dark in color and usually covered in algal growth. The plastron has a slight, single hinge and is reduced exposing much of the turtle's soft underbelly. The head has a pair of solid yellow stripes above and below the eye.

Photo by Andrew Grosse

Status

Of this group, only the spotted turtle is listed as a species in Need of Management in South Carolina. The spotted turtle was listed as a species of concern until 2001 when its status was changed to Species in Need of Management (threatened). This change in status was based on the growing popularity and price of the spotted turtle in the pet trade and the fact that most of South Carolina's neighboring states already protected this species. Increasing the protection of this species in South Carolina helped strengthen protections for spotted turtles in South Carolina and the SE US. The South Carolina Department of Natural Resources ranks this species as vulnerable, at moderate risk of extirpation (S3) and it is ranked globally as secure (G5) (NatureServe 2023). Additionally, spotted turtles are listed as Endangered by the International Union for Conservation of Nature (IUCN; van Dijk, 2011), and are currently being evaluated for listing by the United States Fish and Wildlife Service.

Each of the other turtle species are currently considered relatively common to abundant in South Carolina. However, all native turtles in South Carolina continue to face increased threat of illegal collection to meet the growing domestic and international demand for food and pets. These species all occur in freshwater habitats in this state and are susceptible to over harvest.

Freshwater turtle populations cannot withstand the level of harvest to which they have been subjected to in South Carolina. Many of the "target" species are long-lived animals that may not reach sexual maturity until they are 15 years old. Further, these turtles exhibit low survivorship in both the egg and juvenile life stages. It could be possible for one trapper to eliminate a population of turtles at a given site within a matter of months.

Turtle Life Histories

Endangerment of many tortoise and freshwater turtles worldwide is directly related to their life history strategies. Turtles are long-lived organisms that can take years to mature; in some species,

sexual maturity is not reached until 20 years of age. Turtle life history traits sharply contrast with those of North American wildlife game species. Rabbits, squirrels, and white-tailed deer can reproduce at 6 to 12 months of age and may only live to be 2 or 3 years old. Even earlier maturing turtle species become reproductive later than do many shorter-lived birds and mammals: diamondback terrapins (*Malaclemys terrapin*) mature at age 6 (Lovich and Gibbons 1990), Florida cooters (*Pseudemys c. floridana*) at age 6 to 7 (Gibbons and Coker 1977), yellow-bellied slider (*T. scripta*) females at age 8 (Gibbons et al. 1981), and chicken turtles (*Deirochelys reticularia*) at 5 to 6 years of age (Buhlmann et al 2009). Thus, turtles grow slowly, mature later in life, and survive for many years. Consequently, management strategies for turtles should be very different from historical wildlife management approaches for most game species.

When turtles reach sexual maturity, they have a low annual fecundity. In general, few hatchling turtles survive; those that do must harvest resources, grow, and survive for years before they become adults. Thus, adult turtles must have high annual survivorship to maintain stable populations (Congdon et al. 1993, 1994). In some species, older females have higher survivorship and produce more offspring than do younger individuals (Gibbons 1990). Many animals eat turtle eggs, hatchlings, and juveniles, but adults of many turtle species have few natural enemies except humans (Gibbons 1990). Commercial harvests remove large numbers of adult turtles which are the most important individuals for population stability and persistence.

POPULATION SIZE AND DISTRIBUTION

Accurate population estimates do not exist for any of these species. The spotted turtle is not an abundant species in South Carolina, but it can be found in high densities in appropriate intact, contiguous habitat throughout the Coastal Plain. While data exists throughout the state, many of the elemental occurrences in the heritage database are of individuals moving through the landscape or crossing roads and almost no population level data has been compiled. However, this species is known to occur on several tracts of public land in South Carolina. Most of the remaining species are considered relatively common to abundant in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

All of the members of this group inhabit some type of freshwater and/or wetland system in South Carolina. The spotted turtle is a semi-aquatic species that inhabits a variety of wetland types including small, isolated wetlands, small streams, swamps, flooded forests and other shallow bodies of water (Conant and Collins 1991; Martof et al. 1980; Ernst and Barbour 1989). Spotted turtles are most active during early spring when they can occasionally be observed basking on logs and other objects. Individuals can wander some distance from wetlands when moving between isolated habitat patches, searching for mates, or during nesting movements. This species is difficult to find during the summer months and may undergo a period of summer dormancy (aestivation) in some areas (Litzgus and Mousseau, 2004).

Some species, such as the Gulf coast spiny softshell turtle and the river cooter, are restricted to reservoirs resulting from impounded rivers as well as the rivers themselves. The yellow-bellied slider, coastal plain cooter, mud and musk turtles and eastern painted turtle are most commonly associated with ponds, small lakes, and other non-flowing wetlands. The chicken turtle inhabits seasonally fluctuating, fish-free isolated wetlands. The Florida softshell turtle and the snapping turtle occur in ponds, lakes, and other wetland types.

Chicken turtles (and spotted turtles) also use surrounding upland habitats for refugia during periods when wetlands are dry (Buhlmann et al 2009). These turtles, predominantly juveniles and males but also several females, can spend September through March wintering 50 to 250 m (164 to 820 ft.) from a Carolina bay in South Carolina (Buhlmann and Gibbons 2001). Most often, chicken turtles chose an older live oak-pine forest for wintering habitat; fewer choose clearcut areas. Even the most stringent wetland protection laws do not protect more than 30 m (100 ft.) of adjacent uplands (Burke and Gibbons 1995).

In contrast to the Florida softshell, Gulf coast spiny softshell turtles live in riverine habitats where they often bask on sandbars and bury in clean sand in river bottoms.

CHALLENGES

Due to their life history characteristics, the primary challenge facing turtle populations in South Carolina is the intentional or unintentional, loss or removal of adults. Studies have shown that the loss of only a few individuals per year can result in drastic population declines or complete extirpation of turtle populations (Howell and Seigel 2019).

Alterations to freshwater habitats can result in impacts to all these species but especially eastern chicken turtles and spotted turtles. These alterations include draining and filling isolated wetlands. Additionally, a substantial increase in coastal plain development has resulted in increased wetland impacts, especially to non-jurisdictional freshwater wetlands that have little to no protection. These projects continue to clear-cut forests to edges of wetlands or leave insufficient buffers that eliminate the dry season habitat required by chicken turtles. Narrow buffers of forest habitat left to protect water quality are currently insufficient to provide the upland habitat component needed by chicken turtles. Water quality degradation in these wetlands can also adversely affect these turtles. Eastern chicken turtle populations appear most robust where clusters of seasonal wetlands exist in proximity in an unfragmented landscape. Roads that pass near seasonal wetlands contribute to eastern chicken turtle and spotted turtle population declines through automobile mortality; this mortality results when turtles are moving to nesting areas or upland forests during the dry period.

The primary threats facing the spotted turtle are collection for the illegal wildlife trade and habitat loss or alteration. Due to their colorful pattern and small size, spotted turtles remain highly collectible and can bring a large profit to illegal collectors. A skilled poacher can successfully capture spotted turtles at a rate that is not sustainable because populations depend on high adult survival for long-term stability, resulting in severe population declines or localized extirpation. Draining and filling isolated and/or forested wetlands, a preferred habitat of the spotted turtles, has reduced the number of populations and continues to impact this species. Small shallow ponds, Carolina bays, and other related wetlands receive little to no protection under the Clean Water Act and in many cases are drained and altered.

The loss of wetlands has likely reduced suitable habitat for coastal plain cooters. Mortality also occurs as roads and highways further fragment and isolate wetland habitats.

Population stability of yellow-bellied sliders is threatened by hybridization with red-eared sliders (*Trachemys scripta elegans*), a related subspecies from the Mississippi Valley. Red-eared sliders were sold in South Carolina pet stores for many years and continue to be sold through other venues such as flea markets and exotic animal trade shows. This non-native species is often released in South Carolina by well-meaning, but ill-informed people and can survive in our state. The primary issue here is one of genetic integrity as established red-eared sliders interbreed with yellow-bellied sliders, shifting the genetics of these local populations.

Florida softshell and Gulf coast spiny softshell turtles are often captured incidentally on hook and line and are either killed to retrieve the tackle, or later die due to complications from the ingested hook. Road mortality may be a factor as Florida softshells frequently move overland between lakes and wetlands.

Pollution of rivers and streams may adversely affect Gulf coast spiny softshell turtles at greater rates relative to hard-shelled turtles due to the permeability of the skin and shell. Sandbars used for nesting are also favorite sites for recreational boaters and campers during the summer months.

Whether the human use of the sandbars directly and significantly affects nesting and hatching success is unknown; however, raccoon predation likely increases where camping refuse is also found. Fire ants have been observed to colonize river sandbar habitats and likely affect hatchling survival (Buhlmann and Coffman 2001).

Alteration of rivers, through damming and dredging, adversely affects river fauna. Dams increase normal summer low flows and thus scour aquatic weed beds (Petts 1984); these abnormal flows may affect hatchling survival. Bottom-release dams reduce river water temperatures and may adversely affect river cooters. Reservoirs may also allow for hybridization between river cooters and Florida cooters as their habitats coincide.

Establishment of nonnative fire ants in the Southeastern US has had an adverse impact on freshwater turtles as they will predate nests and newly hatched turtles. These ants especially affect those species in which the hatchlings exhibit delayed emergence and have evolved to remain in the nest because it provided a safe refuge. Other nonnative species that likely negatively impact turtles and their nests include wild hogs and armadillos.

CONSERVATION ACCOMPLISHMENTS

The spotted turtle was listed as a species in need of management in 2001. As such, a set of regulations was adopted that controlled the take and possession of spotted turtles in South Carolina. Effective July 1, 2002, anyone that possessed spotted turtles in South Carolina was required to apply for a free possession permit prior to September 30, 2002. This regulation change limited wild-caught spotted turtles to nine individuals and anyone exceeding that was allowed to apply for a permit to retain all legally acquired turtles prior to the regulation change by September 30, 2002. Over the years following this regulation change, it was clear that permitted individuals had found a loophole and were taking advantage of it to illegally collect and export spotted turtles for profit. As such, in 2019, regulations pertaining to all native reptiles and amphibians were updated, adding protections for all native species from commercial exploitation. A major component of these regulation changes were increased protections for turtles, which prohibited export, transfer of possession, and added possession limits for individual species as well as in aggregate. For spotted turtles specifically, possession of spotted turtles without a permit was still prohibited and current permit holders with a legally acquired collection of spotted turtles were given an opportunity to apply for the new permit within 90 days of the new regulations. Additional changes included, no new turtles could be acquired, no unmarked turtles could be acquired, no reproduction allowed, all individuals permitted must be notched uniquely (with a SCDNR issued code that is unique to every permitted turtle) and photographed annually. Failure to do so results in denial of permit applications/renewals. Notching and annual permit renewals with photographs have addressed the identified loophole. Additionally, new possession permits for spotted turtles are only considered for education and research and justification must be provided.

As the new regulations and permitting requirements were put in place, SCDNR herpetology staff created a Freshwater Turtle and Tortoise identification guide for all South Carolina native turtles and tortoises, which included natural history, how to ID (with photos), and all the new regulations as they pertained to each species. This ID guide was specifically created as a tool for SCDNR Law Enforcement Officers to help assist with identification of native species and the corresponding regulations. Additional collaboration with our chiefs, permitting biologist, law enforcement, and herpetology staff has continued to foster healthy relationships and enforce the new regulations, resulting in greater compliance.

Since the last revision in 2015, we (SCDNR) have added a significant number of new records to the heritage database identifying new populations or areas of interest for many of our native turtles. In 2019, a US Fish and Wildlife Service grant funded The Orianne Society to survey multiple locations throughout SC, to identify presence of spotted turtles at new locations. This survey data was combined with data collected under a Competitive State Wildlife Grant in states across the eastern US and included in the recently published Status Assessment and Conservation Plan for the Spotted Turtle in the Eastern United States (Willey et al. 2022). Beginning in 2020, the Amphibian and Reptile Conservancy initiated an effort to identify important spotted turtle locations. Using telemetry and intensive trapping methodology, they have been successful identifying multiple new locations and population hotspots for this species, as well as gaining a better understanding of spotted turtle behavior and habitat use. In 2022, SCDNR began revisiting population previously studied in the late 1990's to the early 2000's (also surveyed by The Orianne Society in 2019). During the initial study, many individuals were uniquely marked, and some tracked using radio telemetry. Surveys by SCDNR in 2022 and 2023 identified three individual females that were originally marked in 1999 and 2000. Two of these individuals were adults when they were originally captured. Spotted turtles mature between 8-12 years of age, suggesting a minimum age of 30 years old, further supporting the importance of long-term habitat and population protection.

Surveys conducted by the Amphibian and Reptile Conservancy since 2015 in the Francis Marion National Forest have added a significant number of element occurrence records to the South Carolina Heritage Database for several species of this guild. These data have helped inform the status and distribution of several species in the Francis Marion National Forest, including chicken turtles, striped mud turtles and spotted turtles.

Recently, another Competitive State Wildlife Grant was funded to identify presence of spotted turtles in new locations and more intensively survey known populations to learn more about their life history, population viability, and habitat needs in South Carolina. This project is set to begin in January 2024 and continue through 2026. Data resulting from these surveys will continue to help SCDNR make more informed management decisions for spotted turtles in South Carolina.

CONSERVATION RECOMMENDATIONS

- Include the importance of protecting all freshwater turtles and their habitat in general in education materials.
- Consider habitat needs of freshwater turtles in river dredging and dam construction projects.
- Consider all spotted turtle habitat needs when managing Carolina bays and floodplain ecosystems.
- Work with partners on public and private lands to protect spotted turtle habitat and manage appropriately.
- Work with law enforcement to enforce regulations that protect native turtle populations.
- Identify locations of viable spotted turtle populations by conducting early spring surveys when basking turtles are easily seen.
- Continue research and surveys at known spotted turtle populations to learn more about the life history of this species in South Carolina.
- Monitor known spotted turtle sites and populations.
- Conduct research to better understand how relocation effects freshwater turtle species

- Determine locations of viable river cooter populations. Surveys can be conducted via basking surveys during the spring and early summer months. These surveys can form the baseline for long-term monitoring.
- Conduct research that determines effects of dams and reservoirs on the exclusively riverine river cooter.
- Conduct research to determine the ecological habitat niche overlap between Florida cooters and river cooters.
- Determine locations of viable Florida cooter populations.
- Include chicken turtles in protection plans for coastal plain wetlands.
- Consider chicken turtle habitat needs when managing Carolina bays and similar wetland ecosystems.
- Determine locations of viable chicken turtle populations and monitor those populations. Priority survey sites should be located in the vicinity of Carolina Bay clusters.
- Assess the probable impacts of fire ants on freshwater turtles, particularly on chicken turtles, which spend a greater amount of time in the ground as developing eggs, overwintering hatchlings, and terrestrially aestivating adults.
- Survey for Florida softshell turtles and identify possible sites for protection based on results of surveys.
- Consider Gulf coast spiny softshell turtle habitat needs in river dredging and dam construction projects.
- Monitor known spiny softshell turtle sites for water quality changes and determine whether changes in water quality adversely affect this species.
- Determine striped mud turtle distribution, locations of viable populations and collect data on its life history and demography in South Carolina.
- Monitor and conduct research on the impacts of nonnative species on freshwater turtles.
- Monitor changes in the demand for turtles and turtle products and the effectiveness of the new law.
- Work with the South Carolina Department of Transportation (SCDOT) and other partners to design wildlife crossings to reduce road mortality of reptiles and amphibians.
- Evaluate the impacts of disease on this guild.

MEASURES OF SUCCESS

As results from current research and surveys or future efforts are identified and analyzed, projects will be initiated to address specific needs that arise from these results. Stable or growing native turtle populations on protected lands will be considered a measure of success. Data from surveys and other research will be used to continue to determine the best means of conserving these species in South Carolina through habitat and species management and regulatory means.

Reviewed and Edited (2012): Stephen H. Bennett (SCDNR) and Will Dillman (SCDNR)
Reviewed and Edited (2024): Andrew Grosse (SCDNR)

The following snakes are a part of the aquatic snakes guild due to their dependence on aquatic environments. These vary from large lakes and ponds to isolated ephemeral wetlands. Most of these species have been under surveyed due to their cryptic nature and difficulty to capture or have a limited distribution in South Carolina. As such, all species are listed as data deficient except the Florida Green Watersnake which is a high priority species in the State Wildlife Action Plan.

DESCRIPTION

Taxonomy and basic description

Photo by J.D. Willson

The Carolina swampsnake is the smallest snake in this guild reaching lengths of only about 56 cm (22 in). Carolina swampsnakes have a dark, typically black background with iridescent scales and a red or orange belly. Females are longer and heavier than males but males have longer tails (Camper 2019).

The Florida green watersnake is a large to moderately sized snake that reaches lengths of between 76 to 140 cm (30-55 in.) with a maximum length of approximately 188 cm (74 in; Conant and Collins 1991). It is a heavy bodied snake with a row of subocular scales under each eye and pale, creamy unmarked belly. Florida green watersnakes have keeled scales and typically range from green to brown with short, wavy, bands or crossbars and small black spots (Camper 2019). Surveys at the Savannah River Site showed females are generally larger than males. Females averaged 83 cm (33 in) and males averaged 59 cm (23 in; Gibbons and Semlitsch, 1991).

Photo by Andrew Grosse

Photo by Parker Gibbons

The glossy swampsnake is a small snake with a light brown to olive green appearance. It can reach length of only about 80 cm (31 in). The belly is pale yellow or cream colored with two rows of dark “half moon” shaped markings on each scale. Females tend to larger and thicker than males overall but the males have longer and thicker tails than females (Camper 2019).

The queen snake is a small snake reaching up to about 92 cm (36 in). Queen snakes typically have a dark background color though can be light brown to olive-green in color. Their belly is pale in color but has four dark stripes that run the length of the body, though can fuse together as they near the tail. Females will grow larger and thicker than males but males have thicker and longer tails (Camper 2019).

Photo by Todd Pierson

Photo by Parker Gibbons

The rainbow snake can grow up to 1.7 m (66.5 in). Similar to red-bellied mud snakes, rainbow snakes have an iridescent dark skin with smooth scales however they have three red dorsal stripes. The belly is red with two or three rows of dark spots (Camper 2019). Females are larger and longer than males but have shorter tails.

The red-bellied mudsnake is a large snake that can reach length of up to 2 m (78 in.). They have dark iridescent skin with smooth scales and red ventral and lateral markings (Camper 2019). The belly has alternating red and black bars that extend onto the sides of the snake. Females tend to be larger and relatively longer than males but have shorter tails (Camper 2019).

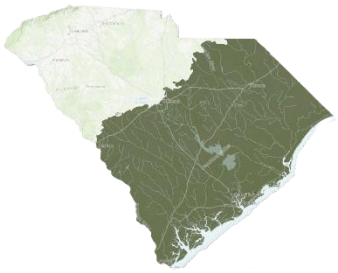
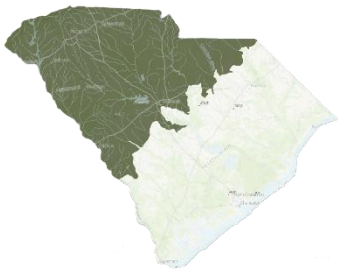
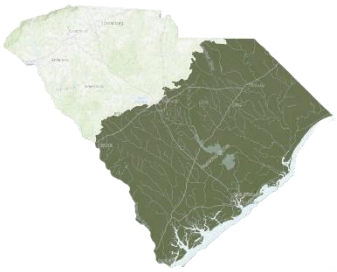
Status



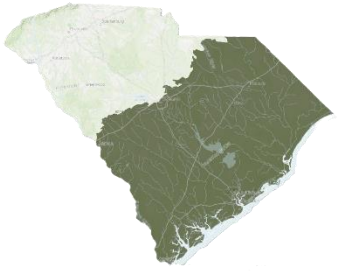
The Carolina Swampsnake is listed as vulnerable in South Carolina (S3) and apparently secure as a subspecies (T4). The Florida green water snake is listed as a Species of Concern in South Carolina and has a rank of S2/G5. The Glossy Swampsnake is listed as vulnerable in South Carolina (S3) and secure globally (G5). The queen snake is listed as apparently secure in South Carolina (S4) and secure globally (G5). The Rainbow snake is listed as listed as vulnerable in South Carolina (S3) and apparently secure globally (G4). The red-bellied mudsnake is listed as apparently secure in South Carolina (S4) and secure globally (G5; NatureServe 2024).



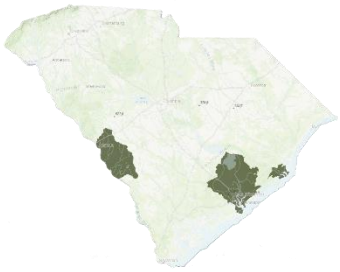
POPULATION SIZE AND DISTRIBUTION



Little data exists concerning the population biology of each of these species in South Carolina. While some of these species have several records throughout the coastal plain of South Carolina, element occurrence data represent a single observation and no thorough population studies have been done. Other than queen snakes, which occur primarily above the fall line, these species largely occur in the coastal plain of South Carolina, with some having more extensive distributions than others depending on their preferred habitat.



The Florida green watersnake is known from the Savannah River Site in Aiken, as well as Barnwell, Charleston and Berkeley Counties. There are also reports of this species from old rice fields in Georgetown County. There are no records from the counties between these two South Carolina population areas. The South Carolina population of the Florida green watersnake are disjunct from the primary range of this species, which is extreme South Georgia and Florida, by over 300 kilometers (200 miles).



Red-Bellied Mudsnake

Rainbow Snake

Queen Snake

Carolina Swampsnake

Glossy Swampsnake

Florida Green Watersnake

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Carolina swampsnake, glossy swampsnake and red-bellied mudsnake are semi-aquatic species that inhabit a variety of wetland types. These species are typically associated with wetlands that have abundant aquatic vegetation, including water lilies and other emergent species. Some of these habitats include Carolina bays, isolated wetlands, cypress swamps and slow moving streams and rivers. In South Carolina the Florida green watersnake has been reported from such wetland types as Carolina bays, lakes, rivers, old rice fields, and reserves. Sites where the Florida green watersnake has been typically reported have open water with little or no canopy of trees and an abundance of "pad plants" such as water lily, cow lily, lotus, and water shield. The queen snake is typically found in the piedmont and mountains around streams, creeks and rivers. The rainbow snake is found in the coastal plain of South Carolina and is more commonly found in blackwater streams, creeks and rivers, but has also been found using cypress swamps and occasionally, isolated wetlands and Carolina bays.

CHALLENGES

All of these species are dependent on aquatic systems for persistence. Habitat degradation, habitat loss, pollution and disease are the most common challenges for species persistence. Snake Fungal Disease (*Ophidiomyces ophidiicola)* has been documented on most species of this guild. Preliminary results from a study conducted by Viriginia Tech showed high prevalence of *Ophidiomyces ophidiicola*, on rainbow snakes and anecdotal data suggests rainbow snakes may be more susceptible and/or more negatively impacted than other species of this guild. Unfortunately, due to their cryptic nature, surveillance of the impacts of *Ophidiomyces ophidiicola* on this guild is challenging but remains an area that warrants further investigation.

Species such as the Florida green watersnake and Carolina swampsnake, have been shown to be poor overland dispersers and less drought tolerant than other snake species and may not easily become re-established if extirpated from wetlands due to ditching, draining, or drought (Seigel et al.1995, Winne et al. 2001).

CONSERVATION ACCOMPLISHMENTS

In 2019, the SCDNR passed new regulations that added significant protections for all reptiles and amphibians native to South Carolina. Specifically, as it pertains to these species, no native species can be exported from SC and transfer of possession (buy, sell, trade, etc.) is prohibited.

A State Wildlife Grant was funded from 2021-2026 to focus efforts on expanding the known distribution of Florida green watersnakes and Carolina swampsnakes. While the 2015 version of the State wildlife Action Plan only listed these two species, targeted surveys for them are conducted in the same habitats as the other species listed in the aquatic snakes guild. The only exception is the queen snake which occurs north of the fall line. This survey effort was an opportunity to add new EO records for several species. While these surveys are ongoing, several new EO records have already been added, on new properties, to our heritage database. These include: Eleven (11) new records of Carolina swampsnakes on two (2) different SCDNR properties, 24 new records for rainbow snakes on seven different properties, five (5) new records for glossy swampsnakes on two (2) different properties and three (3) new records for red-bellied mudsnakes on three (3) different properties. For Florida green watersnakes, surveys conducted on the Savannah River Site in 2019 successfully captured 10 individuals. Additionally, recent surveys, as part of the above State Wildlife Grant, conducted in 2021-2025 captured adults at four new locations expanding the range and number of properties where this species is known to occur. All data collected during all surveys have been compiled and included in the SCDNR Heritage Database.

CONSERVATION RECOMMENDATIONS

- Conduct surveys for these species on public and private properties—with appropriate permission—within the range of this species to identify new properties and watersheds/wetlands/river systems where these species occur to better understand abundance and distribution in South Carolina.
- Conduct life history research on these species, at selected sites, to determine habitat and management requirements.
- Monitor and conduct research on the impacts of nonnative species on this guild.
- Work with the South Carolina Department of Transportation (SCDOT) and other partners to design wildlife crossings to reduce road mortality of reptiles and amphibians.
- Evaluate the impacts of disease on this guild.

MEASURES OF SUCCESS

As results from current research and surveys or future efforts are identified and analyzed, projects will

be initiated to address specific needs that arise from these results. Identifying specific population parameters for these species would be beneficial for future management.

GUILD DESCRIPTION

This grouping includes several amphibian and reptile species that are not necessarily related in terms of their life histories or habitat requirements. These species are restricted to or primarily occur in the Blue Ridge Physiographic Province (Southern Appalachian Ecoregion) and upper piedmont (foothills) of South Carolina; some are peripheral to our state. Several members of this group are, in fact, quite common in the core of their geographic ranges to the north of South Carolina. Several large public lands are located within the ranges of these species and those land managers will be responsible for management of these species. These land holdings include Sumter National Forest and the Jocassee Gorges Wildlife Management Area as well as several South Carolina State Parks. Thus, presenting these species together as a "guild" may help land managers develop a holistic, multiple species conservation plan and minimize management conflicts that may occur if the species are treated separately.

The Southern Appalachian Ecoregion (Blue Ridge Province) and upper piedmont of South Carolina support a diverse and rich herpetofaunal assemblage. Many species found in this region occur nowhere else in South Carolina with most of their geographic range lying to the north of the State. While several of the species represented in this grouping are relatively common outside of South Carolina, some, such as the bog turtle, are not. Other species, such as the green salamander and coal skink have disjunct ranges and are of conservation concern in other portions of their range.

Although most of these species are peripheral to South Carolina, we can make a case for their conservation in our state based on the overall rarity of some and the consideration that most species are most vulnerable at the edge of their geographic range. In addition, the edge of a species' range is often where it experiences the greatest possibility for some evolutionary change, making these populations of potential interest to evolutionary biologists as well as conservation biologists.

BOG TURTLE

DESCRIPTION

Photo by Todd Pierson

The bog turtle is a small, semi-aquatic turtle that can reach 7.5 to 9 cm (2.9 to 3.5 in.) in length; maximum is approximately 11 cm (4.3 inches). Bog turtle shells are typically dark brown with light yellow or red centers on the large scutes. The bog turtle has a distinctive orange or yellow blotch on the head located just behind the eye (Conant and Collins 1991).

Status

The bog turtle is currently listed as threatened in South Carolina with a state rank of S1, critically imperiled, and a global rank of G2, imperiled (NatureServe 2024). In the Southern Appalachians, bog turtles are listed as federally threatened, due to similarity of appearance to the northern populations. This species was discovered in South Carolina in the 1980s.

POPULATION SIZE AND DISTRIBUTION

The bog turtle was first documented in South Carolina in 1988 (SC Heritage Trust Program). To date no populations of bog turtles have been documented. In South Carolina, the bog turtle is not a truly mountain species. The occurrence records we have indicate they occur primarily in the foothills region of the state.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The bog turtle is typically found in streamside bogs, fens, seeps, beaver ponds and other wetlands. In South Carolina, the few specimens found have been discovered in streamside bogs or crossing roads adjacent to streams or beaver ponds. Bog turtle wetlands are generally characterized by wet meadow habitats described as open canopies with spring-fed water and deep silts (Palmer and Braswell 1995). In South Carolina, this habitat type is generally found in the upper piedmont and foothills in association with small streams, seeps, springs and rivers.

CHALLENGES

The wet meadow habitats in which bog turtles are found are typically associated with farming activities or in some cases beaver activity. As farming has declined, the wet meadow bogs have undergone natural succession to red maple swamps (Buhlmann et al. 1997; Herman and Tryon 1997). As succession occurs, the previously open canopy of a bog closes, limiting light to the ground layer. Canopy closure results in changes to the vegetative composition and the physical structure of the bog, resulting in degraded habitat for bog turtles. Over time, the loss of the vegetative composition and structure of the bog systems results in declines in survival, lack of

reproduction and overall population declines for this species. Bog turtles grow slowly, have delayed sexual maturity (4-10 years of age), low annual fecundity (~3 eggs) and require high survivorship of adults for populations to persist. Direct mortality of adults from road mortality, subsidized predators and illegal collection can have detrimental impacts to bog turtle populations and lead to population declines or extirpation.

EASTERN MILK SNAKE

DESCRIPTION

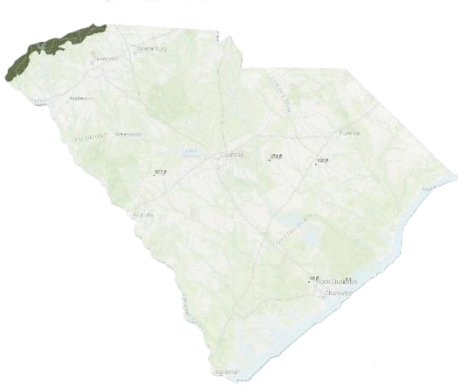

Photo by Todd Pierson

The eastern milk snake is a slender, strongly blotched snake that reaches lengths of 61 to 90 cm (24 to 35 in.); the maximum length is approximately 132 cm (52 in.) (Conant and Collins 1991; Martof et al. 1980). Milk snakes typically possess reddish-brown blotches or saddles that run the length of the snake's body. In South Carolina, though the exact delineation of their distribution is unclear, milksnakes are only found in the upstate. Previous studies suggested that milk snakes in South Carolina may be an "intergrade" between the eastern milk snake and the scarlet kingsnake. However, more recent genetic studies suggest that eastern milks snakes are a separate species from the more common and widespread scarlet kingsnake (Pyron and Burbrink 2009, Ruane et al. 2014 and Chambers and Hillis 2020). Additionally, Crother et al. 2017 list each as separate species.

Status

The South Carolina Department of Natural Resources (SCDNR) Heritage Trust Program assigns a state rank of S2 to the population of the eastern milk snake, classifying it as imperiled because of rarity and restricted range in South Carolina. The global rank of the species is secure (G5; NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Specimens of the eastern milk snake have been recorded from the several areas of the Blue Ridge region of South Carolina. Many of the element occurrence records in the Heritage Database are from protected National Forests, State Forests, State Parks and SCDNR state owned properties. Unfortunately, not many records exist in South Carolina and what is available does not provide information on population status and full distribution of this species in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Little is known about the specific habitat requirements of the milk snake. Specimens have been found in mountain valleys, along streams, and in rocky areas. This species is likely to be fossorial much of the year and can be found occasionally under cover objects such as rocks and fallen woody debris (Conant and Collins 1991).

CHALLENGES

Lack of data on the abundance and distribution of the milk snake in South Carolina makes conservation planning for this species problematic. Additionally, milk snakes are highly collectible in the pet trade and illegal collection can have negative impacts on populations.

TIMBER RATTLESNAKE – *Mountain population*

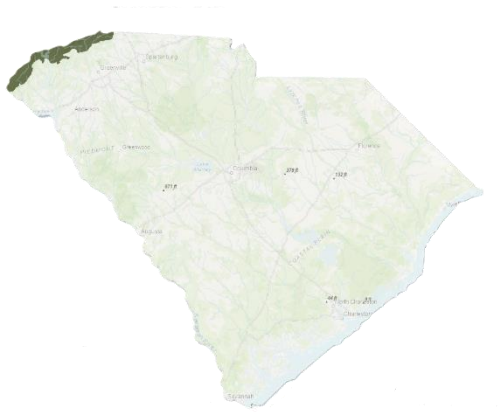
DESCRIPTION

The timber rattlesnake is a large bodied snake that can reach lengths between 90 and 152 cm (35 to 60 in.); maximum length is approximately 189 cm (74 in.) (Conant and Collins 1991; Martof et al. 1980). There are 2 forms, or phases, of the timber rattlesnake found in South Carolina: the coastal plain form, known colloquially as the canebrake rattlesnake, and the mountain form known as the timber rattlesnake. These 2 forms were formerly recognized as subspecies of the timber rattlesnake, but recent research has determined that no genetic evidence supports this classification (Pisani et al 1972). Despite the genetic similarity, there are morphological and ecological differences between the 2 forms (Brown and Ernst 1986).

Photo by Kiley Haberman

The canebrake rattlesnake is typically a tan to flesh-colored snake with black chevrons crossing the body and a dark red lateral stripe running the length of the body along the spine. A dark stripe runs diagonally through the eye (Conant and Collins 1991).

Two color phases are known for the timber rattlesnake. In the first color phase, the body is yellow; in the second color phase, the animal is almost solid black. In both phases, dark chevrons cross the body, and the dorsal stripe, if evident, is not red. This form does not typically have an eye stripe (Conant and Collins 1991).



Status

The timber rattlesnake (both the Mountain and Coastal Plain forms) is listed as a species of concern by the South Carolina Heritage Program and although it is considered a single species, is

ranked separately by form/location in the state. Snakes found in the blue ridge region are referred to as Timber Rattlesnakes and are ranked as imperiled (S2) in South Carolina, while snakes found further south are ranked as apparently secure (S4) in South Carolina, with a ranking of apparently secure (G4) globally (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

To date no exhaustive population study exists for the timber rattlesnake and the canebrake rattlesnake in South Carolina, however, although rattlesnakes are widespread in South Carolina, they are most common in the Coastal Plain and Blue Ridge and tend to be uncommon or absent in much of the intervening Piedmont. In Upstate South Carolina, the distribution of the timber rattlesnake is not fully known. Timber rattlesnake specimens from the foothills and upper piedmont more closely resemble the canebrake form of this species. The distribution of the mountain form of the timber rattlesnake is not known, but it is assumed that this form is isolated to areas of higher elevation in our state.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The mountain form of the timber rattlesnake is generally associated with dry, south-facing slopes at relatively high elevations. In these areas, the timber rattlesnake uses communal den sites in rock outcrops, particularly those with an open south face exposed to the sun. Timber rattlesnakes spend the winter months in these dens; pregnant females give birth to their young in the fall. During the warmer months, timber rattlesnakes may be found in several mountain habitats. This species is an ambush predator, feeding primarily on squirrels and other large rodents (Palmer and Braswell 1995).

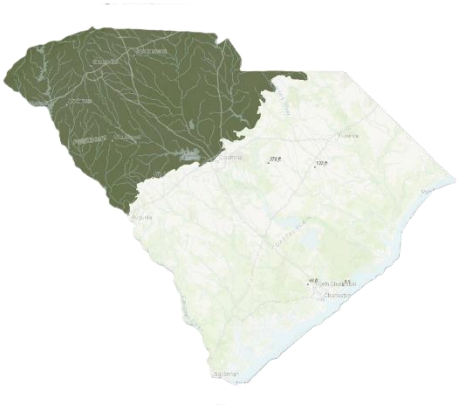
CHALLENGES

Humans often fear rattlesnakes, so snake/human interactions often end with the death of the snake. Populations may be threatened by urban development as the timber rattlesnake's habitat becomes more fragmented. Additional development is also likely to result in increased road mortality. Emerging diseases, including snake fungal disease is known to have significant impacts on other rattlesnakes. Finally, illegal collection for the pet and venom trade can have profound negative impacts on populations since collectors target overwintering and birthing habitats where several snakes can be collected at one time.

NORTHERN PINESNAKE

DESCRIPTION

Photo by Bryan Hudson



Northern pinesnakes are large, snakes that average 48-66 inches (122-168 cm). Northern pinesnakes tend to be a white, cream or yellow color with distinct, dark, square blotches on the sides and back. Typically, the blotches become more distinct closer to the tail. The belly is generally white with some dark spotting on the edges. Compared to other large snakes, pinesnakes have a smaller head and more of a pointy snout. Additionally, they have four prefrontal scales.

Status

The Northern pinesnake is ranked as imperiled (S2) in SC but apparently secure globally (G4, NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

There are two subspecies of pinesnakes in South Carolina the Northern (*P. m. melanoleucus*) and the Florida pinesnake (*P. m. mugitus*). It was once thought that both subspecies overlapped in South Carolina, creating a hybridization zone somewhere in the coastal plain. However, a recent genetic study suggests that northern pinesnakes may only be found in the upstate and mountains of South Carolina while the Florida pinesnake subspecies, is found further south throughout the coastal plain (Apodaca et al. 2021). To date, no exhaustive population study for the northern pine snakes exists in South Carolina and there are only four occurrence records in Oconee and Greenville counties.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Pinesnake habitat is generally characterized as xeric, pine-dominated or pine-oak (50 to 80% pine) woodland with an open canopy and open understory of herbaceous vegetation established on sandy soils. In the coastal plain, longleaf pine sandhills appear to represent critical habitat over much of the southeastern United States. In the mountains, pinesnakes are found along the edges of open fields and dry mountain ridges.

CHALLENGES

The primary threat to northern pine snakes is likely habitat loss and degradation although illegal collection and human persecution likely have a negative impact on this species. Larger snakes are particularly vulnerable to habitat fragmentation. Pine snakes, are long-lived animals with large home ranges, whose life histories are not suitable for either harvest or additive mortality. Maintaining viable populations becomes more difficult when additive mortality from automobiles is factored into the equation.

COAL SKINK

DESCRIPTION

Photo by Todd Pierson

The coal skink is a small lizard that reaches lengths of 12 to 17 cm (4.7 to 6.6 in.). This skink has four dorsal lines with the light stripes extending onto the tail. A thick, dark stripe lies between the two light stripes on either side of the body. The body color is bronze to brown, sometimes with dark brown spots, dashes, or lines (Palmer and Braswell 1995). There are no light lines on the head in this species. The heads of males occasionally turn light red during mating season (Conant and Collins 1991; Martof et al. 1980).

Status

The coal skink is listed as endangered in South Carolina with ranking of critically imperiled (S1) in SC but secure globally (G5, NatureServe 2024). This species is split into two subspecies (northern and southern) however, it is unclear which subspecies occurs in South Carolina, especially since the coal skink has only been found at one site, Sassafras Mountain, in South Carolina. This skink is an enigmatic species; it is rarely seen and is never seen in large numbers (Palmer and Braswell 1995)

POPULATION SIZE AND DISTRIBUTION

To date, no exhaustive population study for the coal skink exists in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The coal skink occurs near small, forested streams. They are found in mesic environments under stones, logs and other sheltering debris (Palmer and Braswell 1995). Little is known about its habitat preferences in South Carolina. In the Appalachians, this species occurs most frequently in forests formerly dominated by chestnut, chestnut oak and yellow poplar (Braswell 1977).

CHALLENGES

Lack of data on the distribution of the coal skink in South Carolina makes conservation planning for this species problematic.

SEEPAGE SALAMANDER

DESCRIPTION

Photo by Todd Pierson

The seepage salamander belongs to the dusky salamander group. This salamander is small; it typically only reaches lengths from 4.4 to 5.7 cm (1.7 to 2.2 in.) and is very slender. Seepage salamanders typically have a wide dorsal stripe that varies in color from tan to yellow. Some individuals have a dorsal strip that terminates in a "Y" behind the head. The sides of the salamander are dark while the underbelly is pale (Conant and Collins 1991; Martof et al. 1980).

Status

The seepage salamander has only been found in the Sumter National Forest in Oconee County (Petranka 1998). The seepage salamander is ranked S2, Imperiled, in South Carolina, and has a global ranking of G3, vulnerable (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

To date, no exhaustive population study for the seepage salamander exists in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The seepage salamander is associated with small streams and wetlands where it may be found beneath leaf litter and debris, especially in seepage areas. The South Carolina population is disjunct from the main geographic range of this species (Petranka 1998).

CHALLENGES

Lack of data on the distribution of the seepage salamander in South Carolina makes conservation planning for this species problematic.

SHOVEL-NOSED SALAMANDER

DESCRIPTION

Photo by Todd Pierson

The shovel-nosed salamander is a totally aquatic relative of dusky salamanders. This species can reach lengths of 9 to 12.5 cm (3.5 to 4.9 in.) with a maximum length of approximately 14 cm (5.5 in.). The shovel-nosed salamander is variable in coloration, ranging from gray-brown to yellow. Typically, a paired row of lightly colored spots is found on the back (Conant and Collins 1991; Martof et al. 1980). The tail of the shovel-nosed salamander is compressed laterally, an adaptation to its aquatic lifestyle.

Status

The shovel-nose salamander is ranked vulnerable (S2) in the State of South Carolina and apparently secure (G4) globally (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

To date no exhaustive population study for the shovel-nose salamander exists in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The shovel-nosed salamander is a stream dweller, found in fast-flowing, rocky streams. The salamander is typically found under rocks, mostly in second and third order steams below elevations of 1,220 m (below 4,000 ft.) (Petranka 1998).

CHALLENGES

Lack of data on the distribution of the shovel-nosed salamander in South Carolina makes conservation planning for this species problematic.

GREEN SALAMANDER

DESCRIPTION

Photo by Todd Pierson

The green salamander is the only arboreal salamander in South Carolina. This species can reach lengths of between 8 and 12 cm (3.1 to 4.7 in.) with a maximum length of approximately 14 cm (5.5 in.). Green salamanders are perfectly adapted for life in and around rocky habitat. They are dorsoventrally flattened to fit in small rock crevices, has toe pads, much like those of a treefrog, to help it climb trees and rocky cliffs, and is green and black with a pattern that resembles the lichens and mosses found growing on rocks in the green salamander's habitat (Conant and Collins 1991; Martof et al. 1980).

Status

The green salamander is ranked critically imperiled (S1) in South Carolina and vulnerable (G3) globally and is listed as a Species of Concern. (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Systematic and opportunistic surveys for green salamanders suggest their distribution in South Carolina is restricted to the blue ridge and some portions of the upper piedmont regions of the state.

From 2016-2019 a Competitive State Wildlife Grant (CSWG) project was funded for several Southeastern states to better understand the green salamander populations in their states. In South Carolina, Clemson University staff and students surveyed over 60 historic sites to document presence/absence. Results of those surveys indicated that green salamanders were present at about half of the sites surveyed. Additionally, a follow up project (2020-2022 State Wildlife Grant SWG), was funded for Clemson University to further investigate information gleaned from the previous CSWG. Photo capture-mark-recapture surveys at eleven sites produced abundance estimates between 3 and 27 individuals with high survival estimates.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The green salamander is occasionally found in the same rocky areas that are used by the timber rattlesnake. This species is a "cliff dweller," residing in moist, but not wet, rocky sites with abundant crevices. Green salamanders are also found using arboreal habitat (i.e. Trees, downed logs, stumps, rhododendron, etc) that occur adjacent to rock outcrops (Waldron and Humphries 2005).

CHALLENGES

Detection of green salamanders is incredibly low and dependent on several factors. Habitat degradation on the macro and micro habitat level both have negative impacts on individual green salamander populations. At the micro level, damage to rock outcrops leading to reductions in suitable habitat can cause declines. At the macro level deforestation, clearcuts and other large forestry operations between inhabited rock outcrops can limit or eliminate gene flow between populations. Increases in epidemic disease, climate change and illegal collection are also concerns for current and future populations.

WOOD FROG

DESCRIPTION

Photo by Todd Pierson

The wood frog is a small member of the true frog family and so it is related to the bullfrog, leopard frog, and gopher frog. This species can attain a size of 3.5 to 7 cm (1.3 to 2.7 in.); the maximum size is approximately 8 cm (3.1 in.). The body color of the wood frog is highly variable ranging from pink to brown to almost black. The major distinguishing characteristic is the dark patch that extends backward from the eye (Conant and Collins 1991; Martof et al. 1980).

Status

The wood frog is ranked vulnerable (S3) in the State of South Carolina and secure globally (G5) (NatureServe 2024). This frog is also listed as Species of Concern.

POPULATION SIZE AND DISTRIBUTION

To date no exhaustive population study for the wood frog exists in South Carolina. However, surveys by Clemson University, researchers from the University of Connecticut and SCDNR biologists have documented several new breeding locations and incorporated historic locations in the Natural Heritage Database.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The wood frog breeds in small ponds, bogs and other wetlands during late winter and early spring in South Carolina. This species is typically associated with wet or moist areas, but it can be found some distance away from water during the non-breeding season (Palmer and Braswell 1995).

CHALLENGES

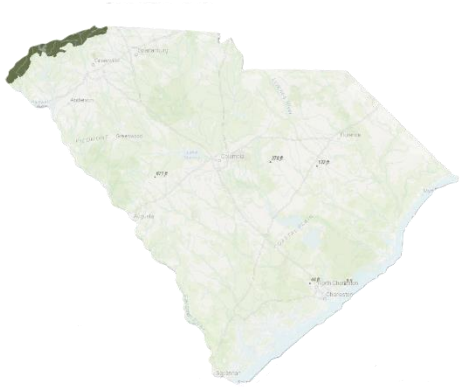
Lack of data on the distribution of the wood frogs in South Carolina makes conservation planning for this species problematic. Habitat loss of small breeding pools and wetlands that receive no protection negatively impact populations of wood frogs.

DWARF BLACK-BELLIED SALAMANDER

This species was formerly included in *Desmognathus amphileucus* (black-bellied salamander). It was recognized as a distinct species on the basis of adult size, body proportions, color pattern, and fixed differences at four allozyme loci (Camp et al. 2002).

DESCRIPTION

Photo by Todd Pierson



This is a large, semi-aquatic salamander that occurs in small streams. Adults of this species are not as large as the black-bellied salamander, ranging from 56 to 76 mm (2.2-3.0 in.) snout-vent length. The two species can be separated morphologically based on the dwarf black-bellied salamander attaining adult pattern and coloration, particularly on the venter, at a smaller size than the black-bellied salamander. This species has aquatic larvae.

Status

The dwarf black-bellied salamander is ranked as imperiled (S2) in the State of South Carolina and imperiled globally (G2, NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

To date this species has been documented from only two sites in South Carolina, one in Oconee County and the other in Greenville County. The species was originally described from populations in Georgia. Camp et al. 2002 indicate that the species is abundant where it occurs in Georgia and that is also true at the two sites in South Carolina. However, sites in South Carolina comprise a few small streams, located on public property, in the extreme western portion of Oconee County. A survey of several additional sites was conducted in 2015-2016 by Clemson University and while some individuals appeared to be dwarf black bellies, no new occurrence records were documented.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Adults have been collected in high-gradient, turbulent first- and second-order streams. They are most abundant in shallow areas of streams where they take cover under rocks. At night they are occasionally seen wandering away from cover; however, they usually remain with only their heads and/or anterior parts of their bodies protruding from cover sites. No differences in habitat have been noted between the sexes (Camp, personal observations).

CHALLENGES

Lack of data on the distribution of the dwarf blackbelly salamander in South Carolina makes conservation planning for this species problematic.

PATCH-NOSED SALAMANDER

Patch-nosed salamanders were first discovered in Georgia in 2007 and subsequently described as a new genus and species (Camp et al, 2009). This species was first described from populations in Georgia and documented to occur in South Carolina in 2009 (Bennett, personal observation).

DESCRIPTION

The patch-nosed salamander is a miniature species, with adults reaching a length of only 25 to 26 mms (0.98-1.0 in.). The species has aquatic larvae. Unlike other dwarf salamanders in the related genus Eurycea, which have four toes on their hind limbs, the patch-nosed salamander has five toes on its hind limbs. In addition, unlike any other known salamander species, the patch-nosed salamander is sexually dimorphic with regard to coloration and pattern. Adult males have a bright yellow dorsum with two darker pigmented dorsolateral stripes. Adult females have a more muted brownish yellow coloration due to a suffusion of numerous dark melanophores, and the dorsolateral stripes are absent. Adults have a distinctive saffron yellow patch on the snout; in larvae this patch is white. A thin dorsal stripe stretches down the center of the tail; this stripe is yellow in adults and white in larvae. The venter is yellow and without markings.

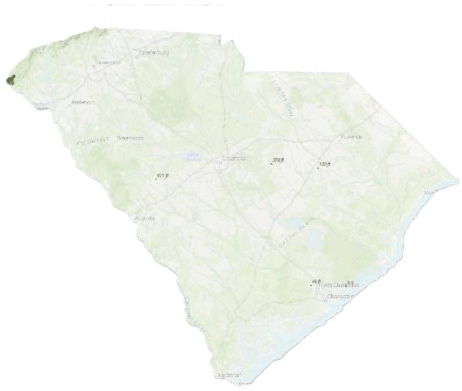


Photo by Todd Pierson

Status

The patch-nosed salamander is ranked as critically imperiled (S1) in the State of South Carolina and globally (G1, NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

From 2020-2022 a State Wildlife Grant (SWG) project was funded for Clemson University to better understand the distribution of, and define suitable habitat for, the patch-nosed salamander in South Carolina. Using multiple survey techniques, Clemson researchers and students were able to identify 2 additional locations for patch-nosed salamanders in South Carolina, bringing the total known locations in the state up to three, with all three occurring on the same public land in western Oconee County. The particular life history of this species makes it

difficult to survey though a follow up State Wildlife Grant (SWG) project awarded to Clemson University will survey additional nearby streams and attempt to produce abundance estimates at each location using the information gleaned from the previous survey.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The patch-nosed salamander has been found in or in association with headwater streams. Adults have been observed typically in the leaf litter adjacent to these streams. The aquatic larvae have been observed in portions of these streams lacking a steep gradient, with a bottom of mixed sand and cobble and ample rocks or woody debris to use as refugia.

CHALLENGES

Lack of data on the distribution of the patch-nosed salamander in South Carolina makes conservation planning for this species problematic. Impacts from nonnative species, especially wild hogs, continue to a be problem in the small tributaries where this species is found.

CONSERVATION ACCOMPLISHMENTS

Approximately 40,500 hectares (100,000 acres) of land is in public ownership in South Carolina's southern Appalachians and vicinity. The majority of this land is in the Sumter National Forest, Andrew Pickens District and the Jocassee Gorges Wildlife Management Area, the latter of these owned and managed by SCDNR. Several other smaller tracts, including Heritage Preserves and State Parks, are also protected in this region. Amphibians and reptiles are not the primary management targets on any of these sites, but these species do benefit from conservation management on most, if not all, of these public lands.

In 2015-2016, Clemson University surveyed for six reptile and amphibian species found in the Blue Ridge region of South Carolina. Their surveys resulted in wood frog detections in 15 wetlands, pickerel frog detections in 5 wetlands, Shovel-nosed salamander detections at four locations and milk snake detections as three locations. This survey added significant location data to our heritage and herpetological databases.

In 2019, regulations pertaining to all native reptiles and amphibians were updated, adding protections for all native species from commercial exploitation. A major component of these regulation changes were increased protections for turtles, added possession limits for individual species as well as in aggregate. Additionally, new regulations prohibit export and transfer of possession for all native reptiles and amphibians.

From 2016-2019 a Competitive State Wildlife Grant (CSWG) project was funded for several Southeastern states to better understand the green salamander populations in their states. In South Carolina, Clemson University staff and students were tasked with assessing presence/absence of over 60 historic sites, as well as swabbing individuals for disease prevalence in South Carolina. Results indicated that green salamanders were present at about half of the sites surveyed. Additionally, opportunistic swabs of green salamanders in South Carolina showed an incredibly low prevalence of disease; 2.4% for *Bd* – a single individual and no detections for *Bsal* or *Ranavirus.* Two manuscripts were produced as a result of this project.

Newman, J.C., K. Barrett and J.W. Dillman. 2018. Green salamander estimated abundance and

environmental associations in South Carolina. Journal of Herpetology, 52(4): 438-444.

Newman, J.C., J.L. Mota, R.H. Hardman, J.W. Dillman and K. Barrett. 2019. Pathogen detected in green salamanders (Aneides aeneus) in South Carolina, USA. Herpetological Review, 50(3): 503-505.

From 2020-2022 a State Wildlife Grant (SWG) project was funded for Clemson University to further investigate information gleaned from the previous CSWG. Specifically, they derived occupancy probability estimates for rock crevices, estimated population size across a gradient of forest disturbance and estimated population connectivity, inbreeding and likelihood of past bottlenecks across 15-30 sites. In addition to the results of these objectives Clemson University also provided SCDNR with Conservation and Management recommendations to help SCDNR make more informed decisions using this data as it pertains to green salamanders in South Carolina. The following manuscript was produced from this project.

Novak, M**.** and K. Barrett. 2023. Within-site microclimate and connectivity can help predict the presence of discrete patch inhabitants, *Aneides aeneus*. Herpetological Conservation and Biology 18:111-117.

In 2020-2021, the South Carolina Department of Natural Resources funded a project led by Clemson University to assess the use of salamanders as live fishing bait in South Carolina. This has been reported as a problem impacting salamander populations and we were interested in its current prevalence in the state. Surveys via mailed and emailed questionnaires, as well as physical visits to upstate bait shops suggested that salamanders haven't been sold in the last 5-12 years but that some individuals still use them and ask for them when purchasing bait. The overall survey suggested that anyone using salamanders as fishing bait, likely collect them themselves for personal use.

From 2020-2022 a State Wildlife Grant (SWG) project was funded for Clemson University to better understand the distribution of, and define suitable habitat for, the patch-nosed salamander in South Carolina. Using multiple survey techniques, Clemson researchers and students were able to identify 2 additional locations for patch-nosed salamanders in South Carolina, bringing the total known locations in the state up to three.

A follow-up State Wildlife Grant (SWG) was funded for Clemson University and Kennesaw State University to build upon the previous project and clarify the distribution and status of patch-nosed salamanders by surveying the "core" range in South Carolina (identified in the previous project) as well as to better characterize the population genetic structure and diversity for this species. This project began in late 2023 and will be completed in 2026.

A multi-state competitive State Wildlife Grant was funded to conduct bog turtle surveys at historic locations throughout the southern range of the species. As such SCDNR has visited four historic locations for bog turtles in South Carolina. Two of which no longer have suitable habitat. The other two will be surveyed, beginning in 2024, using multiple techniques, including bucket camera traps which have been shown to significantly increase detection for this incredibly cryptic species. Access to additional historic locations is ongoing.

A survey, partly funded by a State Wildlife Grant, began in 2023 to identify presence, habitat use, and seasonal activity patterns for timber rattlesnakes in South Carolina. Preliminary results have identified several important habitats for this species.

SCDNR staff continue to work with partners (State Parks, State Forests, National Forests, Conservation groups and private landowners) to disseminate information regarding important habitats, natural history, management techniques and how all of those things and compliment each other to better manage habitat for reptiles and amphibians.

Since the last revision in 2015, we (SCDNR) have added a significant number of new records to the heritage database identifying new areas of interest for many of our native reptiles and amphibians found in the blue ridge region.

CONSERVATION RECOMMENDATIONS

- Determine the current extent of bog turtles in South Carolina.
- Re-survey all known historical sites for bog turtles.
- Protect bog turtle habitat through acquisition or conservation easement at all known sites, based on the inventory work.
- Educate local landowners who have populations or suitable habitat for bog turtles on their properties about the ecological importance of this species.
- Work with private landowners to provide bog turtle habitat management recommendations through habitat management guidelines for Southeastern amphibians and reptiles currently being developed by Partners in Amphibian and Reptile Conservation (PARC).
- Implement management techniques for restoring bog turtle habitat. These include cutting shrubs and trees, diking streams, restoring sheet flow to wetlands, burning and use of livestock to mimic native herbivore grazing.
- Consider captive breeding and reintroduction programs if inventory results indicate that bog turtles have been extirpated in South Carolina.
- Conduct research to determine the effectiveness of bog turtle habitat management (scrub clearing and grazing) in South Carolina.
- Create or expand existing education programs for public and private land managers about the presence and ecological importance of eastern milk snakes and ways to protect this species.
- Determine the extent of the distribution of eastern milk snakes in South Carolina.
- Monitor known pet trade collection sites for eastern milk snakes.
- Work with US Forest Service and South Carolina State Park Service (SCSPS) to protect known timber rattlesnake (mountain race) den sites.
- Develop an education program promoting the ecological importance of venomous snakes, including timber rattlesnakes.
- Conduct surveys to identify denning sites of timber rattlesnake populations in the Blue Ridge Mountains.
- Monitor known timber rattlesnake denning sites in the Blue Ridge Mountains to assess any potential human impacts.
- Investigate life history requirements for timber rattlesnakes in South Carolina, including adult sex ratios, recruitment and mortality, habitat use, and seasonal activity patterns.
- Partner with the US Forest Service and the South Carolina Park Service to make recommendations regarding seepage salamander habitat requirements during preparation of forest plans.
- Conduct baseline research to identify seepage salamander distribution, abundance and specific habitat requirements.
- Work with land conservancy groups, the US Forest Service, and the SCSPS to protect watersheds that contain shovel-nose salamanders.

- Include the importance of protecting shovel-nose salamanders in general education materials.
- Survey the Andrew Pickens National Forest to determine the presence of shovel-nose salamanders on that property; monitor any populations discovered.
- Protect sandstone cliffs, the habitat of the green salamander, by eliminating or reducing timber activities that expose these cliffs to drying or allow fragmentation of connective forest habitat.
- Develop an education program highlighting the green salamander and their rock outcrop habitat as a unique species and structure that illustrates biodiversity in the Blue Ridge Mountains.
- Encourage the USFS to consider avoiding isolation of sandstone cliffs from the forest matrix as a result of timber cutting operations on Andrew Pickens National Forest.
- Survey appropriate habitat for the green salamander, including Andrew Pickens National Forest and South Carolina State Parks in the region; monitor any populations discovered.
- Conduct research to determine dispersal mechanisms for green salamanders through intervening forest habitat.
- Use LiDAR imagery to identify additional habitat for green salamanders and other rare and cryptic species that rely on similar habitats.
- Collaborate with public land managers to protect wood frog habitat.
- Include the importance of protecting wood frogs in general education materials.
- Work with USFS and consider the needs of wood frogs when creating wildlife watering ponds in the mountains.
- Inventory appropriate habitat in the Blue Ridge Mountains for presence of wood frogs; monitor any populations discovered.
- Conduct calling frog surveys to determine the presence of wood frogs.
- Monitor successful metamorphosis of larval wood frog tadpoles.
- Conduct surveys for the coal skink, dwarf black-bellied salamander, seepage salamander and northern pine snakes.
- Monitor and conduct research on the impacts of nonnative species on this guild.
- Work with the South Carolina Department of Transportation (SCDOT) and other partners to design wildlife crossings to reduce road mortality of reptiles and amphibians.
- Evaluate the impacts of disease on this guild.

MEASURES OF SUCCESS

For many of these species, the first measure of success will be to document basic life history requirements as well as population status and distribution. As results from current research and surveys or future efforts are identified and analyzed, projects will be initiated to address specific needs that arise from these results. Data from status surveys will be used to direct future research on life history, ecology, and limiting factors for the target species. Such data will also be used to direct future habitat acquisition and management projects. Stable or increasing populations of the primary target species on public lands will be the ultimate measure of success.

GUILD DESCRIPTION

This guild comprises eight species. Five of the species are snakes and 2 are lizards and one is a tortoise. All the species are commonly associated with one or more of the natural communities that comprise the longleaf pine ecosystem.

All of the species in the Longleaf Pine Reptile Guild are associated with the longleaf pine ecosystem that was extensive across the Southeastern United States at the time of European settlement (Bartram 1791; Guyer and Bailey 1993). The longleaf pine ecosystem has declined to less than 10% of its original land area (Frost et al. 1986). Much of the previously forested lands are now urban or agricultural (Gibbons and Buhlmann 2001). Those lands that are forested have been planted in pine species other than longleaf and have been managed on shorter rotations, in many cases without prescribed fire and without concern for the diverse herbaceous plant species that once occurred with the longleaf pine. It is not surprising, therefore, that the reptiles associated with this ecosystem are also species of concern.

Taxonomy and basic description

The mimic glass lizard is a recently described species that reaches a maximum length of approximately 65 cm (25.6 in.). This is the smallest glass lizard and is generally similar in color and pattern to the slender and island glass lizards, making identification difficult. The mimic glass lizard is typically light brown with dark brown or black longitudinal stripes. A dark mid-dorsal stripe is typically present. All glass lizard species lack any limbs and are also known as legless lizards. (Conant and Collins, 1991; Martof et al. 1980)

There are two subspecies of pinesnakes in South Carolina the Northern (*P. m. melanoleucus*) and the Florida pinesnake (*P. m. mugitus*). It was once thought that both subspecies overlapped in South Carolina, creating a hybridization zone somewhere in the coastal plain. However, a recent genetic study suggests that northern pinesnakes may only be found in the upstate and mountains of South Carolina while the Florida pinesnake subspecies, is found further south throughout the coastal plain (Apodaca et al. 2021). The Florida pinesnake is a large snake with a maximum length of approximately 228 cm (11 in.). This species can be variable in pattern. The Florida pinesnake typically has a light brown to ivory background color with large brown or black blotches down the length of the body. In the Florida subspecies, the anterior blotches are typically not present, and the pattern is indistinct. Pinesnakes from different regions of South Carolina can be very different in coloration and pattern, ranging from light backgrounds with distinct, dark blotches to dark animals with indistinct patterns, and occasionally individuals occur that have red (erythristic) blotches or background colors (Conant and Collins 1991; Martof et al. 1980).

The Southern hog-nosed snake is the smallest of the hog-nosed snakes, a group of snakes that possess a sharply upturned snout, believed to be an adaptation for burrowing. This species averages 36 to 51 cm (14-20 in.) in length. The Southern hog-nosed Snake is typically a tan-brown snake with darker blotches running down the back. The colors of this snake are typically less variable than its more common relative, the Eastern hog-nosed (Conant and Collins 1991).

Originally described by Palisot de Beauvois in 1799 (type-locality: Charleston, South Carolina; Schmidt, 1953) the Eastern diamond-backed rattlesnake is the largest venomous snake in the United States. The maximum reported length is 243 cm (96 in.), but most adult specimens in South Carolina are typically much smaller, averaging approximately 84 to 183 cm (33-72 in.). Typical of crotaline pitvipers, the Eastern diamond-backed rattlesnake is heavy-bodied, with keeled dorsal scales, a large head, and a tail rattle composed of avascular keratinized epidermis (Klauber, 1972; Ernst, 1992). Coloration ranges from olive green, yellow, tan, and light to dark brown, with 24-35 dark, diamond-shaped blotches running the length of the body (Means, 2017; Camper, 2019). These blotches are typically outlined by a single row of yellow-white scales but often become compressed and sandy-colored towards the snake's tail (Wright & Wright, 1957). There is a distinctive wide, dark stripe across the eye, surrounded on either side by a narrow, light stripe (Conant and Collins 1991; Martof et al. 1980). Adults express sexual size dimorphism such that males attain larger body sizes than females; males typically have larger heads and longer tails than females of the same age class (Means, 2017). Neonatal Eastern-diamondback rattlesnakes resemble adults in both pattern and coloration but are usually less than 48 cm (19 in.) in length and possess only one, singularly lobed rattle segment that is vascularized and thus dark in color. This "pre-button" segment emerges further following the snake's first post-natal shed and is avascular following the second post-natal shed (Means, 2017).

Photo by Wade Kalinowsky

EDBs exhibit juvenile biased dispersal, with adult EDBs having high spatial fidelity that makes them unlikely to redistribute at the landscape scale (Waldron et al. 2013a). EDBs exhibit a slow life history characterized by delayed maturation, high site fidelity, high longevity, and long birthing intervals. In SC, EDBs reach sexual maturity in 7 years (Waldron et al. 2013a); exhibit high adult survival (82%), and can live > 20 years. Juvenile EDB survival is low, reflecting susceptibility to predation and risks associated with dispersal.

The harlequin coralsnake is the only member of the Family Elapidae (cobras and relatives) found in South Carolina. This venomous snake is very different from all of South Carolina's other venomous snakes, which are all pit vipers. Instead, this species has short, fixed fangs.

Photo by J.D. Willson

The harlequin coralsnake is a brightly colored species with red, yellow and black annular rings running the length of the body. There are two species of non-venomous snakes, the scarlet kingsnake and the scarlet snake, which are similarly patterned. On the harlequin coralsnake, the red and black bands don't touch, whereas on the non-venomous species, the red and yellow bands never touch. In addition, the harlequin coralsnake has a black head and the non-venomous species have red heads. The harlequin coralsnake can reach a maximum length of 120 cm (47 in.); however most specimens are typically in the range of 51-76 cm (20-30 in.), (Conant and Collins 1991; Martof et al. 1980).

Photo by Andrew Grosse

The gopher tortoise was described by Daudin in 1791. This is the only species of tortoise found in the eastern United States and one of only four tortoise species found in North America. The gopher tortoise is a large, terrestrial turtle with front legs that are spade-like, an adaptation for digging and hind legs that are elephantine. The carapace of the gopher tortoise can vary from brown to dark gray. Carapace length averages 25.4 to 30.5 cm (10 to 12 in.) for adults; maximum length is approximately 38 cm (15 in.). The carapace of the adult tortoise is generally dull and unmarked. Adult tortoises can weigh up to 4.5 kg (10 lbs.). The head of a tortoise is square in profile with a flat, blunt nose (Conant and Collins 1991). Juvenile tortoises are typically lighter colored than adults, varying from yellow-brown to light gray. Juveniles may have light colored centers on their carapacial scutes, and visible growth annuli. As tortoises grow, their annuli become worn and are seldom apparent on adult specimens (Ernst et al. 1994). Tortoises are herbivorous, feeding primarily on grasses and plants, but they have also been documented to scavenge on carrion and other materials, as available (Conant and Collins 1991; Ernst et al. 1994). The gopher tortoise is a long-lived species, possibly reaching 50 to 60 years, or greater, in age. This species is believed to reach sexual maturity between 12 to 14 years of age and can be reproductively active until death. Tortoises mate in spring and nesting occurs during April though July. Clutch sizes typically number five to seven eggs. Hatchlings emerged in late summer to early autumn (Conant and Collins 1991; Ernst et al. 1994).

The slender glass lizard is a moderately large lizard that can reach lengths from 56 to 106 cm (22-42 in.) (Conant and Collins 1991). This species is typically brown with dark longitudinal markings that are similar to those of the mimic glass lizard. The slender glass lizard differs from the mimic glass lizard and the island glass lizard, another rare species, in that it has numerous dark markings (dark spots, dashes or lines) below the lateral fold (Palmer and Braswell 1995). There is sufficient variation in the glass lizard species to make casual identification problematic, and the use of a good dichotomous key is typically required for accurate identification.

Photo by Parker Gibbons

The pine woods littersnake is a small, secretive species that rarely exceeds 33 cm (13 in.) in length. This species varies from golden brown to light reddish-brown, becoming paler along the sides. There is a dark line through the eye, and the lip scales are white to yellowish in color (Conant and Collins 1991).

Photo by Todd Pierson

Status

The members of this guild are listed as Species of Concern in South Carolina with the Southern hog-nosed snake listed as state threatened and the gopher tortoise listed as state endangered. The Heritage Trust Program currently ranks the species as follows: mimic glass lizard (S1/G2), Florida pinesnake (S2/G4), Southern hog-nosed (S1/G2), Eastern diamond-backed rattlesnake (S2/G3), Harlequin coralsnake (S2/G5), slender glass lizard (S4/G5), gopher tortoise (S1/G3) and pine woods littersnake (S3/G4; NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Little is known of the actual population status of any of these guild members other than the gopher tortoise. The mimic glass lizard, possibly the most rare guild member, has only been reported once in South Carolina. The slender glass lizard is more widespread and better represented in collections than the mimic glass lizard, but no data exists on its population status. Glass lizards as a group are not well known in terms of their population status, life history or demography.

The Florida pinesnake is widespread in South Carolina but appears to be restricted to several specific habitat types that are either subsets of the longleaf pine ecosystem, or share some of the characteristics of this system, primarily the relatively open canopy and xeric conditions. Pinesnakes are not abundant in any particular area of the state, even where they are found with some regularity. To date, no exhaustive population study for the Florida

pinesnake exists in South Carolina.

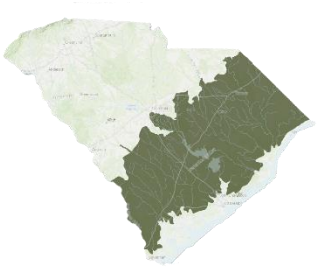
The Southern hog-nosed snake has been documented from several counties in South Carolina however this species is both fossorial and cryptic, making survey efforts difficult. As such, population estimates are not available for this species and observations are infrequent.

The Eastern diamond-backed rattlesnake is primarily restricted to the lower terraces of South Carolina's Coastal Plain. This species was once believed to be common and widespread but is now thought to be declining range-wide (Martin and Means 2000; Timmerman and Martin 2003). In South Carolina, the species is most abundant in the lower coastal plain and barrier or sea islands south of the Santee River.

The harlequin coralsnake is one of South Carolina's least known reptile species. This fossorial, secretive species appears to be colonial in distribution. No population data exists for this species, and its fossorial habits make it a very difficult species to survey.

In South Carolina, gopher tortoise populations currently occur in the Sandhills and Inner Coastal Plain ecoregions in three counties: Jasper, Hampton and Aiken. There are additional records of the tortoise in Colleton and Dorchester Counties and an anecdotal record for Bamberg County. Another additional record for the gopher tortoise came from Allendale County; this is believed to be an introduced population, although it is likely that Allendale County was in the historic range of the tortoise. The currently accepted (historic) range of the gopher tortoise in South Carolina includes the southern portion of the state. Additional records have added to the range of this tortoise in South Carolina. Based on all the records for the tortoise, it is reasonable to believe that the gopher tortoise once occurred throughout the southeastern portion of South Carolina. Native, extant, reproducing populations of the gopher tortoise are currently known from three different "metapopulation" areas: 1) the sandhills along the South Edisto River in Aiken County; 2) the sandhills along the Coosawhatchie River in both Jasper and Hampton Counties; and 3) The sandhills along the Savannah River in Jasper County.

A minimum viable population (MVP) is defined as “a species-specific abundance threshold below which stochastic threats pose an unacceptable risk to an isolated population” (Shaffer 1981; Shoemaker et al. 2014). The Gopher Tortoise Council defines a gopher tortoise MVP as a population of at least 250 adults with a density of no less than 0.4 tortoises/ha on a site that is at least 100 ha in size and of superb quality (Gopher Tortoise Council 2013). Anything less than that is considered a support population and Gopher Tortoise Council (2014) defined two such population types: A primary and secondary support population which were defined as:

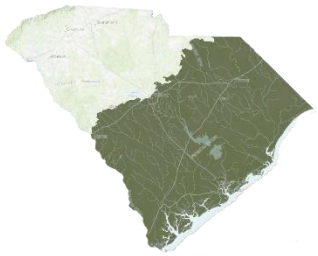


Primary Support Populations: Populations with between 50-250 adults which are candidates for population restoration by improving habitat to increase natural recruitment, or through population augmentation to attain MVP status. By definition, Primary Support Populations must occur on sites large enough to sustain a MVP.

Secondary Support Populations: Populations of <50 adults, some of which are constrained from reaching primary support status because of limited habitat or management options. Secondary Support Populations are important for education, community interest, or can be used for augmentation purposes. If sufficient potential habitat is present and managed, Secondary Support Populations are candidates for habitat restoration and/or population

augmentation to attain Primary Support Population or MVP status.

In South Carolina, a survey initiative to estimate abundance of gopher tortoise populations in South Carolina began in 2015 and continued through 2018. Surveys were done using Line Transect Distance Sampling methods (LTDS) and survey results suggest that South Carolina has two MVP's, four PSP's and 3-5 SSP's. While this survey was not exhaustive of all gopher tortoise habitat in the state, it does suggest that South Carolina likely has fewer than 1500 adult gopher tortoises. Based on survey results, the SCDNR and other conservation groups currently own the properties that hold the four largest gopher tortoise populations in South Carolina.



Little or no data on the distribution or status of the slender glass lizard and the pine woods littersnake exists for South Carolina. These species are not necessarily rare, but they are not frequently encountered.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Members of this guild are closely associated with, but not necessarily endemic to, natural communities that are part of the Longleaf Pine Ecosystem. The Florida pinesnake, Southern hog-nosed snake and harlequin coralsnake are typically associated with the more xeric longleaf communities and can be found in the same habitat types that support gopher tortoise populations. The Eastern diamond-backed rattlesnake, mimic glass lizard and slender glass lizard are more commonly associated with the mesic longleaf communities, including longleaf pine flatwoods. All species show some overlap in their habitat preferences and can be found in habitats other than longleaf.

While closely associated with Longleaf pine habitats (e.g., sandhills, savannas, and flatwoods; Timmerman & Martin, 2003; Martin & Means, 2000; Means, 2006, 2017; Waldron et al., 2006; Waldron et al., 2008), Eastern diamond-backed rattlesnakes are also found in coastal maritime communities such as maritime grassland and maritime forests, particularly those on barrier or estuarine islands. Coastal habitats are probably hospitable in that they share some physiognomic similarities (e.g., open-canopies, low basal areas) with Longleaf pine savannas (Fill et al., 2015; Means, 2017). The occurrence of EDBs in coastal island habitats is patchy and poorly understood. Populations can reach high densities on barrier and sea islands, but island occupancy is difficult to predict based on current habitat structure. The occurrence of island EDB populations might coincide with the availability of inland (upstream), high-integrity pine savannas and woodlands. The EDB's propensity for swimming in coastal and tidal water bodies likely facilitates down-river dispersal influenced by extreme tidal events. EDBs rely on open-canopy pine savannas and woodlands at multiple spatial scales (Waldron et al. 2008, Waldron et al. 2006, Fill et al. 2015). At the microhabitat scale, EDB ambush site selection is influenced by mast availability, indicating a bottom-up trophic effect (Heres et al. 2018). Eastern diamond-backed rattlesnakes can be found in mixed forests, old fields, prairies, and edge habitats around agricultural land (Klauber, 1972; Means, 2017; Camper, 2019). They may also use closed-canopy hardwood hammocks in proximity to open pine woodlands (Timmerman, 1995; Means, 2017). Similarly, the harlequin coralsnake prefers Longleaf pine habitats but can also be found in maritime and hardwood forests within the Southeastern Coastal Plain.

The gopher tortoise is a fossorial, burrowing species that primarily inhabits xeric longleaf pine sandhills in South Carolina. The deep, droughty sands of such habitats provide the ideal substrate for the excavation of the tortoise's burrow. Adult tortoises may excavate a burrow that can be from 3 to 9 m (10 to 30 ft.) in length; at its deepest point the burrow may be 3 m (10 ft.) underground (Ernst et al. 1994). An individual tortoise may excavate several such burrows over its lifetime; it may also take over and utilize burrows excavated by other tortoises. Tortoises typically use more than one burrow during the active period of the year, but typically over-winter in only one burrow (Ernst et al. 1994). The burrow system within a tortoise colony may provide the organization and structure for these social animals. Courtship occurs at burrow mouths and egg deposition typically occurs within 4 m (12 ft.) of the burrow (Ernst et al. 1994). Tortoise burrows are not just important to the tortoises but are also a critical resource for many species that are found in sandhill habitats. Over 360 species of vertebrate and invertebrates have been documented to use tortoise burrows, whether active or abandoned. Longleaf pine sandhill habitat is fire adapted, that is, it requires periodic wildfire (historically) or prescribed burning (currently) for establishment, restoration, and maintenance of this vegetative community. This habitat type has declined

due to the suppression of fire in the southeast and the conversion of longleaf pine forests to commercial loblolly plantations. Historical tortoise habitat would consist of longleaf pine in an open, park-like stand with a lush ground cover dominated by wiregrass (*Aristida stricta*). Herbaceous plants such as gopher apple, goat's rue, lupine and other grass species would have also occurred. A sparse understory would have been composed of scrub oaks.

All members of this guild spend some portion of their life using underground shelters, such as stump holes, rodent burrows, root channels or gopher tortoise burrows. The Eastern diamond-backed rattlesnake is typically found underground during the colder months. EDBs rely on underground structures for reproduction (gestation and parturition), ecdysis, and overwintering. Selection of microhabitats for gestation and overwintering is driven by thermal conditions of the microsite, reflecting thermoregulatory and metabolic requirements specific to behaviors (e.g., access to basking opportunities during winter and access to shade/cool temperatures during gestation). This ambush predator can, however, be found on the surface during the active (warmer) season. The other species spend far greater amounts of time underground, coming to the surface for only short periods of time. Longleaf pine habitats provide open canopies with abundant stump holes. These are created when pine trees are blown over by storms or killed by lightning. In the case of lightning-killed trees, the root ball is typically burned out by periodic fire, creating underground chambers. In addition to stump holes, this habitat typically features friable, sandy-loam soils that are easily excavated by rodents and other animals. Many reptiles take advantage of these burrows, exploiting the food resource by eating the occupants and then using their burrows for refuge.

Numerous amphibian and reptile species are closely associated with some form of longleaf pine habitat. Several species of conservation concern in South Carolina, other than the primary guild members, would benefit from conservation efforts directed at this habitat type, including species that have been covered either individually or under another guild type. The following species are highly likely to benefit from such conservation efforts: Frosted flatwoods salamander (*Ambystoma cingulatum*), Mabee's salamander (*Ambytoma mabeei*), Eastern tiger salamander (*Ambystoma tigrinum*), gopher frog (*Lithobates capito*), oak toad (*Anaxyrus quercicus*), and ornate chorus frog (*Pseudacris ornata*). In addition, numerous species whose status is not fully understood or are relatively common would also benefit from longleaf pine habitat conservation. Examples of such species include the coachwhip (*Masticophis flagellum*), scarlet kingsnake (*Lampropeltis triangulum elapsoides*) and barking treefrog (*Hyla gratiosa*).

CHALLENGES

The primary threat confronting members of this guild is habitat loss and degradation. Longleaf pine habitat has been greatly reduced both in extent and in quality subsequent to European settlement of the Southeast (Noss 1989). Vast acreages of longleaf pine have been converted to agriculture and/or loblolly pine plantations in South Carolina. The loss, or degradation of longleaf pine habitat results in the loss of key components, such as stumpholes and open canopy conditions, required by the guild members.

Certain guild members, such as the Eastern diamond-backed rattlesnake and pinesnake, are under pressure from illegal collection for the pet trade and venom collection. Larger bodied snakes are particularly vulnerable to habitat fragmentation and an increasing road network. Additionally, persecution and direct killing of snakes by humans affects these populations. Negative attitudes and misguided risk perception are particularly harmful to rattlesnake

populations, challenging efforts to effectively mitigate human-rattlesnake conflicts (Dunn et al. 2024, Keener-Eck et al. 2019, Waldron et al. 2013b). Some of the large snakes, particularly pinesnakes and eastern diamond-backed rattlesnakes, are long-lived with large home ranges. Maintaining viable populations becomes more difficult when additive mortality from humans and automobiles occurs. Many species associated with the imperiled longleaf pine ecosystem have poor dispersal ability and cannot return to restored habitats, requiring repatriation efforts to restore populations.

The introduction of fire ants throughout the Southeastern United States has been implicated as a potential reason for the apparent decline of the Southern hog-nosed snake (Tuberville and Jensen 2008). Fire ants may also be having unknown/unseen population effects on other fossorial and egg-laying snakes. Additionally, intensive or chronic soil disturbance may also pose a threat to fossorial snake species (Tuberville and Jensen 2008). Fire suppression, stump removal, and short timber rotations may limit population numbers by reducing availability of nesting sites and large stump holes for refugia (Tuberville and Mason 2008).

Further, infectious disease (e.g., *Ophidiomyces ophiodiicola*; *Oo*) is an emergent threat to snakes across the eastern seaboard. *Oo may* cause abnormal shedding (dysecdysis) and epidermal disfigurement or systemic growths that can result in death (Lorch et al., 2016; Baker et al., 2019). Sublethal effects interfere with standard seasonal behaviors such as reproduction and brumation (Lind et al., 2019; McKenzie et al., 2021; Lind et al., 2023). Though there is little data on population-level impacts of *Oo* in southeastern snakes, recruitment rates could be negatively affected by truncated reproductive effort and by the potential for decreased offspring survival resulting from vertical (mother-to-progeny) transmission (Lind et al., 2019; Stengle et al., 2019). Additionally, *Oo* could reduce the number of mature, reproductive individuals within a population, thus altering demographic composition and impeding vital rates necessary for population stability. Recent findings suggest that *Oo* could pose a serious threat to vulnerable snake populations in South Carolina; 9 adult female Eastern diamond-backed rattlesnake mortalities within the state have been attributed to *Oo* between 2022-2024. Between 2022-2023, research conducted on the Marine Corps Recruit Depot at Parris Island, SC indicated that *Oo* infection severity was negatively associated with annual survival of mature female Eastern diamondback rattlesnakes; estimated annual survival (calculated using a known-fates framework) was 68% (Gray et al., unpbl. data), which is the lowest survival estimate available for the species of this age class.

Efforts to conserve coastal populations that are threatened by climate change are challenged by a limited ability to predict how populations will respond to temperature and precipitation changes. The southeastern US faces warming temperatures and an increasing frequency of extreme precipitation events, with climate models predicting that warming temperatures will continue through the 21st century. Climate change may not only result in ambient conditions that are unfavorable to wildlife, but indirectly challenge populations via habitat degradation and increase incidence of infectious disease and human-wildlife conflict (Gibbons et al., 2000; Acevedo-Whitehouse & Duffus, 2009; Newsom et al., 2023). The ability to identify vulnerable populations hinges on an improved understanding of how changing weather patterns will affect population demographics and population viability.

Tortoise populations have been historically adversely affected by take or harvest. The gopher tortoise was collected for food throughout the southeast prior to its range-wide

protection. Illegal take for food still occurs, especially on private lands where little or no management or protection occurs. Gopher tortoises have also been confiscated when found for sale as pets. It is often unknown from where these individuals originated. The primary challenge to the gopher tortoise is habitat loss, either through direct means, such as type conversion to loblolly plantations, agriculture or development; or through indirect means, such as fire suppression that results in successional changes that render the habitat unsuitable for tortoises. Direct threats to habitat may cause immediate mortality in tortoises or result in displacement of tortoises into unsuitable habitats. Heavy equipment can collapse burrows; this can result in additional tortoise mortality. Indirect threats to habitat may result in long-term population declines correlated to declines in available food and burrow sites and increases in predators. While adult tortoises have few predators, with the exception of man, juvenile tortoises are predated by a wide array of animals, including foxes, coyotes, domestic dogs, raccoons and snakes. Additionally, armadillos may pose a threat to the tortoise by modifying existing burrows and potentially predating tortoise eggs.

CONSERVATION ACCOMPLISHMENTS

Several members of this guild have been the focus of research and survey either conducted by SCDNR personnel or funded by SCDNR in the past decade. Surveys for the pinesnake, Southern hog-nosed snake, gopher tortoise, and mimic glass lizard have been ongoing at several SCDNR owned and managed preserves.

Documented occurrences of the Eastern diamond-backed rattlesnake, Southern hog-nosed snake, harlequin coralsnake and pinesnake are known from several publicly owned and managed sites and several new records for these species were added to the heritage database over the last decade resulting from survey and monitoring by SCDNR staff and collaborators.

A State Wildlife Grant (SWG) funded a survey from 2016-2020 to use camera traps to document upland snake species, specifically, southern hog-nosed snakes, pinesnakes and eastern diamond-backed rattlesnakes. While the funding ended in 2020, many of the fences that were originally constructed are still monitoring the same properties and additional fences have been constructed in new locations. In total, over 20 fences have been installed with some still in operation. In total, we were able to document presence of pinesnakes on seven properties, southern hog-nosed snakes on one property and eastern diamond-backed rattlesnakes on one property using this method. Full results can be found in the 2020 completion report to the USFWS.

Coastal Carolina students and staff used radio telemetry to track movements and habitat use of pine snakes in the coastal plain of South Carolina. Eight pine snakes were tracked between 2021 and 2023, and locations were documented every 1-2 days. Male straight-line movements averaged 373 m/move with the longest straight-line movement averaging 1811 m. Female straight line movements averaged 331 m with the longest straight-line movement averaging 1270 m. Male total home range averaged 185 ha while female total home range averaged 99 ha. Finally, males were underground for 94% of their observations and females were underground for 88% of their observations. The data from this study is currently being written into a manuscript for publication and will be useful for future management decisions that impact this species.

The Eastern diamond-backed rattlesnake is currently being evaluated for listing through the USFWS Species Status Assessment Process. A decision should be made in 2024.

SCDNR partnered with the Marine Corps Recruit Depot Parris Island (MCRDPI) and Marshall University to conduct an EDB translocation study. The project examined the utility of long-distance translocation for mitigating negative human-rattlesnake conflicts. Kelley et al. (2022) used pre- and post-translocation radio telemetry to examine the impact of long-distance translocation on EDB movement and survival. In 2018, they moved 12 adult EDBs from the MCRDPI to the James W. Webb Wildlife Center and Management area (WEBB). Using insight gained from the SCDNR's long-term monitoring of the WEBB EDB populations (i.e., Waldron et al. 2013, Waldron et al. 2008, Waldron et al. 2006), translocated EDBs were released in high-quality pine savannas known to be used by the WEBB EDB population. Post-translocation activity ranges were larger than pre-translocation ranges and daily movements were longer following translocation. Translocation did not significantly affect survival probability, and post-translocation movement patterns likely reflected the need to find suitable microsites. The study suggests that translocations may be a viable conservation and mitigation strategy for EDBs; however, more research is needed to identify correlates of post-translocation mortality.

Four areas that support gopher tortoise populations are protected in South Carolina, due to partnerships and collaborations of SCDNR and its conservation partners. Two areas, Tillman Sand Ridge Heritage Preserve (TSRHP) and Aiken County Gopher Tortoise Heritage Preserve (AGTHP), were already owned and managed by SCDNR. In 2020-2022, the Open Space Institute, Knobloch Foundation and Nature Conservancy purchased a total of ~12,000 acres of land in Jasper and Hampton counties separated by the headwaters of the Coosawhatchie River. The uplands on each side of the Coosawhatchie River Floodplain are longleaf pine habitat and represent a separate group of gopher tortoises. Based on Line Transect Distance Survey efforts in 2015-2018, these four properties represent the four largest gopher tortoise populations in the state and will eventually all be under the ownership of SCDNR.

TSRHP is one of the two MVP's in South Carolina and encompasses about 1400 acres with approximately 400 acres of suitable tortoise habitat. Beginning in 2015 and continuing through 2021, SCDNR partnered with several other state agencies and collaborators on a Competitive State Wildlife Grant (CSWG) to restore about 100 acres of potentially suitable habitat at TSRHP. Through a combination of timber harvest, thinning, hand removal and herbicide of recruiting hardwoods, prescribed fire, and replanting native ground cover, we've been able to significantly increase the quality and quantity of habitat for gopher tortoises at the TSRHP.

AGTHP is about 1600 acres in size, most of which is suitable tortoise habitat. SCDNR initiated a population augmentation project for the gopher tortoise at the Aiken Gopher Tortoise Heritage Preserve in 2005, funded initially by State Wildlife Grant dollars. Since then, significant improvements to habitat and the gopher tortoise population have been made, through collaboration with partners.

- Several hundred waif gopher tortoises were transported to the AGTHP through our agreement with the Florida Fish and Wildlife Commission and other partners. SCDNR staff have coordinated the transport of waifs to the AGTHP from sixteen different states in the US.

    - Funding from the USFWS helped support a 2017-2020 study done by the University of Georgia's Savannah River ecology Lab, which documented

long-term site fidelity, survivorship, and tested for disease at the AGTHP. Results indicated that >75% of penned gopher tortoises are present within 400 m of the original release pen, some of which have been on the preserve for over a decade. Additionally, adult survival was between 90-95%, similar or better than natural populations. Additionally, disease screening did show positive results of *M. agassizii* and M. testudineum. However, prevalence was similar to what is found in natural gopher tortoise populations. Full results can be found in the 2020 completion report to the USFWS. Additionally, this project produced a master's degree and resulted in the two below publications:

- McKee, R.K., K.A. Buhlmann, C.T. Moore, J. Hepinstall-Cymerman and T.D. Tuberville. 2021. Waif Gopher Tortoise Survival and Site Fidelity Following Translocation. The Journal of Wildlife Management 85(4):640-653.

- McKee, R.K., K.A. Buhlmann, C.T. Moore, M.C. Allender, N.L. Stacy and T.D. Tuberville. 2022. Island of Misfit Tortoises: Waif Gopher Tortoise Health Assessment Following Translocation. Conservation Physiology 10:1-18.

- All waif gopher tortoises transported to the AGTHP are penned in 1-hectare pens, in groups of 15-20 individuals for at least 12 months (Tuberville et al 2005) before the pen walls are removed and the tortoises can roam the preserve. To-date we've constructed 19 pens.

- Several hundred headstarted gopher tortoises have been raised and released by partners (Savannah River Ecology Lab and Longleaf Alliance). Headstarted gopher tortoises are first collected as eggs from natural reproduction at the AGTHP, raised for one or two years and released at AGTHP.

    - A State Wildlife Grant (SWG) project from 2016-2020 provided funding to radio track over 70, one- and two-year headstart gopher tortoises. Results from the study provided insight on habitat use, survival and movements of young gopher tortoises at AGTHP and allowed methodological shifts that will potentially improve survival. Results can be found in the 2020 completion report to the USFWS.

The first of the two properties purchased in 2020-2022 (Coosawhatchie WMA or CWMA) was transferred to SCDNR in the fall of 2023. Management and restoration activities have ensued.

SCDNR was a collaborator in a large multi-state grant with funds that will go directly toward restoration of both upland and wetland communities on CWMA, TSRHP and the Webb Wildlife Center and benefit several wildlife and plant species. This work will occur over the next three years.

In 2011, after a two-year review following a petition to list the gopher tortoise, the USFWS issued a finding that listing the gopher tortoise as endangered was warranted, but precluded at this time due to budgetary constraints, in effect adding the species to the candidate list. The Service reviewed the species through the Species Status Assessment Framework and in

2022 determined that a federal listing for gopher tortoises was not warranted. While this did not change its state endangered designation and protection in South Carolina it did have a ripple effect on the conservation of the species throughout its range. One impact is the future of the gopher tortoise Candidate Conservation Agreement (CCA) and the retention of its signatories. SCDNR is a partner in the Candidate Conservation Agreement (CCA) for the gopher tortoise in the non-listed (federal) portion of the species range. The CCA details the voluntary conservation measures to be undertaken on behalf of the tortoise by the CCA partners. Since the listing decision deemed gopher tortoise not warranted, the future of the CCA and retention of signatories is uncertain.

CONSERVATION RECOMMENDATIONS

- Continue presence/absence surveys for species of this guild
- Inventory known gopher tortoise populations and relict individual localities to determine the extent of the population.
- Protect all gopher tortoise sites identified in the inventory through land acquisition or conservation easement. Monitor these sites to determine the stability of known populations at minimum, every 10 years.
- Conduct landowner workshops to educate landowners about the importance of gopher tortoises and methods for protecting this species.
- Conduct fire management operations at known gopher tortoise locations on SCDNR properties.
- Continue life history research for species in this guild
- Continue gopher tortoise repatriation/relocation technology research.
- Monitor impacts to gopher tortoise burrows from species such as armadillos, domestic dogs and other nonnative species.
- Monitor and conduct research on the impacts of non native species on this guild.
- Work with the South Carolina Department of Transportation (SCDOT) and other partners to design wildlife crossings to reduce road mortality of reptiles and amphibians.
- Evaluate the impacts of disease on this guild.

MEASURES OF SUCCESS

As results from current research and surveys or future efforts are identified and analyzed, projects will be initiated to address specific needs that arise from these results. Habitat protection and management projects of the longleaf pine habitat will be considered successful steps to conservation of the habitat and species that depend on it. The maintenance and growth of existing gopher tortoise populations in South Carolina and recovery of the tortoise population at Aiken Gopher Tortoise Heritage Preserve will serve as two measures of success.

The following reptile species do not fit logically into any guild or group but are a mix of species that have been studied intensively and species that we know little about in South Carolina. For some of these species, the primary conservation objective will be to determine their status through surveys in South Carolina.

DESCRIPTION
Taxonomy and Basic Description

The diamondback terrapin is a small, long-lived estuarine turtle endemic to coastal marshes, estuarine bays, lagoons and creeks ranging from Cape Cod, Massachusetts to the Gulf Coast of Texas. Currently, there are 7 (Ernst et al. 1994) subspecies. More recently, Hart (2004) identified six management units. The subspecies most common in South Carolina is the Carolina diamondback terrapin (*Malaclemys terrapin centrata*). Terrapins have varied coloration from black to spotted patterns on the soft tissue and dark or light-colored scutes with strong concentric layers on the carapace. The hind margin of the carapace curls up instead of flaring. Hind legs are large, and toes have extensive webs. These turtles are strong, fast swimmers that feed on a variety of mollusks, crustaceans and other invertebrates. In South Carolina, salt marsh periwinkles (*Littoraria irrorata*) and blue crabs (*Callinectes sapidus*) are among the terrapin's primary food sources (Tucker et al. 1995; Levesque 2000). Terrapins are sexually dimorphic. Females are much larger than males and reach 15 to 18 cm (6 to7 in.) in length; males reach 10 to 13 cm (4 to 5 in.) in length. Adult females also have enlarged heads. Terrapins mate in the spring. Eggs are laid from May through early August and clutches have 5 to 12 eggs (Pritchard 1979).

Eastern box turtles are small, terrestrial turtles that can be found statewide in a variety of habitats, including mesic hardwood forests mixed with pine, open grassy habitats and wetlands. Some populations seem to be able to persist in developed suburban environments, provided there is some intact natural habitat (Camper 2019). Currently there are two or four subspecies of eastern box turtles but the only one native to South Carolina is *Terrapene carolina carolina* (NatureServe, 2024). However, three-toed box turtles *T. c. triunguis* are common in the pet trade and have been found in suburban areas. While these are likely released pets, the

Photo by Andrew Grosse

risk of breeding with naturally occurring populations of eastern box turtles *T. c. carolina* is a concern. Box turtles have a domed shell with a hinged plastron. When frightened, they can retract and completely close their shell, protecting them from many predators. Box turtles are omnivorous and have been documented eating various fungi, plants, fruits and invertebrates (Camper 2019). Adult eastern box turtles are around 10-15 cm (4-6 inches) in length. Males typically have a concave plastron and vibrant yellow to red eyes, while females tend to have a flatter plastron and brown eyes.

Eastern kingsnakes are a large nonvenomous snake found statewide. They are typically between 91-121 cm (36-48 in) in total length, though larger individuals are not uncommon. Eastern kingsnakes are usually dark black or brown with white or yellow markings that connect along the back and sides to give a chain-link appearance (Camper 2019). They inhabit a variety of habitats but are typically close to some form of aquatic habitat (streams, swamps, wetlands, bays, marshes and even man-made impoundments). Eastern kingsnakes will eat a variety of prey though they are best known for their propensity to eat other snakes.

Island Glass Lizards are one of four species of glass lizards found in South Carolina. Island glass lizards grow to a max of about 60 cm (24 in) and are only found in coastal counties of South Carolina. Like other glass lizards the tail is typically twice the length of the body and there is a lateral fold on the sides that extends the length of the body. Island glass lizards have a single black stripe that extends down each side of the body above the lateral fold and typically a dark vertebral stripe on a dark brown or tan body. There are no markings below the lateral fold. This species is typically found in upland sandy, dry habitats and likely feeds on invertebrates (Camper 2019).

Mole kingsnakes are moderately sized nonvenomous snakes that are not commonly seen due to their fossorial nature. They are typically 60-121 cm (24-48 in) in total length. Mole kingsnakes can vary in color and pattern with a gray to brown background and brown to red blotches down their backs, usually outlined with dark borders. Their bellies are cream colored with small red, gray, or brown blotches. While this species has a large distribution in South Carolina it is much more common in the piedmont and few specimens found in the coastal plain (Camper 2019).

Pygmy rattlesnakes are the smallest of the rattlesnakes native to South Carolina, averaging between 30-60 cm (12-24 in) as adults. Currently there are three subspecies, two of which are thought to occur in South Carolina, as well as integrades which have been found in the lower coastal plain. Pygmy rattlesnakes are typically found in well-drained soils in the sandhills, pine flatwoods and mixed hardwood forests, although they have also been documented in forested habitat near swamps. They have a tiny rattle that is difficult to hear compared to other native rattlesnake species. The dorsal pattern consists of a gray or brown background, with brown to red blotches and orange to red vertebral stripe that extends down the spine (Camper 2019).

Status

The Diamondback terrapin is listed as vulnerable in South Carolina (S3) and apparently secure globally (G4) (NatureServe 2024). The eastern box turtle is listed as vulnerable in South Carolina (S3) and secure globally (G5) (NatureServe 2024). The eastern kingsnake is listed as listed as apparently secure in South Carolina (S4) and secure globally (G5) (NatureServe 2024). The island glass lizard is listed as imperiled in South Carolina (S2) and vulnerable globally (G3) (NatureServe 2024). The mole kingsnake is listed as apparently secure in South Carolina (S4) and secure globally (G5) (NatureServe 2024). The pygmy rattlesnake is listed as vulnerable in South Carolina (S3) and secure globally (G5) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The current status of most populations of terrapins is unknown or declining (Seigel and Gibbons 1995). The species experienced near extinction in the early 1920s because of commercial over-harvest. Commercial harvest declined in the late 1920s, and terrapin populations increased (Gibbons et al. 2001). Mr. Robert Gault, the last terrapin harvester in the state, reported catches of nearly 500 turtles in two to three days of net fishing in the Beaufort area in the 1970s. Diamondback terrapins occur in all coastal counties, with Horry county being the last to confirm presence in 2016, through citizen-scientist documentation. Two decades of monitoring terrapins in four creeks adjacent to the Kiawah River has documented a decline since the early 1990s and local extirpation (Gibbons et al. 2001; Tucker et al. 2001). Along the South Carolina coast, incidental capture of diamondback terrapins in trammel net surveys have been documented each year from 1995 through 2023. Since about 2005 relative abundance of diamondback terrapins has shown a steady decline.

Genetic studies in North and South Carolina indicate that terrapin populations from these states are not significantly different (Hart 2004; Hauswaldt 2004) and should be treated as one management unit. A previous genetic study using a different genetic marker was unable to detect a difference between the Carolinas and Georgia (Lamb and Avise 1992). It should be noted that in 1947, several thousand diamondback terrapins were released into Cape Romain National Wildlife Refuge (CRNWR) waters from the North Carolina Beaufort Fishery Station (Anonymous 1947). The genetic stock of these terrapins is not known. This should be taken into consideration when determining the genetic stock of diamondback terrapins in South Carolina waters.

Eastern box turtles occur statewide in South Carolina however few population level studies have been done. Brisbin et al. (2008) show long term survival and habitat use of a box turtle population in a suburban setting. Naturally, box turtles can be abundant in appropriate habitat but several past and emerging threats to this species are a concern.

Eastern kingsnakes occur statewide and are generally considered a "common" species, however, some documented declines have occurred in portions of their range (Winne et al 2007). Overall, little population level data exists for this species in South Carolina, and the combination of isolated declines and several past and emerging threats are a concern.

The island glass lizard is virtually unknown in South Carolina, with less than ten records of occurrence for this state, all of which occur in coastal counties. This species was listed as a species of concern at the 1978 Endangered Species Symposium based on our lack of knowledge. Very little information or data exists for any glass lizard species in our state; this whole group deserves attention regarding taxonomy, distribution, and demography.

Mole kingsnakes are cryptic, fossorial snakes that are most commonly found in the piedmont and upstate but also occur in isolated locations in the coastal plain. While several element occurrence records exist for this species in South Carolina, very little information exists regarding distribution, demography, and other population level parameters, especially for coastal plain populations.

Element occurrence records for South Carolina suggest pygmy rattlesnakes occur statewide however, very little population level information exists for them in South Carolina and their absence in some areas of suitable habitat is concerning.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Diamondback terrapins are endemic to estuarine habitats. They are the only emydid turtle that can survive in a high salinity environment without accessing a freshwater source. Terrapins nest on land and require access to dry, soft sand/soil to deposit their eggs. There is also evidence of high site fidelity and low recruitment and/or dispersal among tidal creeks. If a population were extirpated from a tidal creek, recruitment from other creeks would be very slow to repopulate the area (Gibbons et al. 2001).

Eastern box turtles can be found in a variety of habitats including mesic hardwood forests, mixed pine-hardwood forests, grasslands, old fields and pastures and some even persist in suburban landscapes (Camper 2019). Seasonal wetlands, marshes and bogs can be important micro habitats. Openings in the forest canopy and forest edges can be important nesting habitats.

Eastern kingsnakes can be found in a variety of habitats as they are widely distributed in South Carolina however they are mostly found in terrestrial habitats in proximity of aquatic habitat including streams, rivers, swamps, ponds and Carolina bays (Camper 2019), though they also can be found around managed impoundments.

As the name implies, island glass lizards are found on coastal islands in South Carolina typically inhabiting xeric habitats, such as sand dunes, pine and maritime forests and have been found under an accumulation of spartina and other debris in the wrack line (Camper 2019).

Mole kingsnakes can be found in a variety of habitats though they can be quite fossorial and cryptic. Mole kingsnakes can be found in open woodlands, old fields, meadows and prairies as well as sandhills, especially for coastal plain populations (Camper 2019)

Pygmy rattlesnakes are widespread in South Carolina; however, populations are not found everywhere. Suitable habitat can include longleaf pine-turkey oak sandhills, pine flatwoods, mixed hardwoods forests and some mesic forest habitats (Camper 2019).

CHALLENGES

Diamondback terrapins face several challenges. On land, the loss or degradation of nesting habitat resulting from coastal development continues to be a problem. Also, nests are destroyed by native (raccoons and mink) and non-native predators (fire ants) as well as erosion and storm events. Vehicle inflicted mortality of females during the nesting season is common where a highway separates nesting sites from tidal creeks. Mortality is also associated with the mowing of causeway shoulders (T. Murphy, SCDNR, pers. comm.). In the water, terrapins may be increasingly vulnerable to injury or mortality due to encounters with watercraft (Cecala et al. 2009). A major source of mortality in the marine environment is the presence of recreational, commercial and abandoned/ghost crab pots. In the Ashley and Wando Rivers, Bishop (1983) estimated that the mean daily terrapin catch per baited crab pot was 0.16 in April and May with 10 % mortality. A statewide survey in the fall of 2003 documented nearly 10,000 commercial hard crab pots (M. Maddox, SCDNR, pers. comm.). Grosse et al. (2011) found terrapin density in Georgia tidal creeks to be negatively correlated with crabbing intensity. In a Kiawah Island study, mean terrapin size increased in the presence of crabbing; these results were attributed to the greater survival of larger terrapins (females) too big to gain entry into pots (Dorcas et al. 2007). Other problems include destruction of food resources, environmental degradation and contamination (through increased sedimentation, nutrient enrichment, oil spills and filling/draining marshes), boat and propeller mortality, and the commercial pet trade (D. Owens,

College of Charleston, pers. obs.). Climate change is a potential threat to sea turtles as it may affect these species in three ways: (1) loss of dry sand beaches to sea level rise; (2) lethal high temperatures within the nest that would cause egg/hatchling mortality or decrease hatchling fitness; or (3) a female biased sex ratio of hatchlings due to increased nest temperatures. Terrapins, like many other turtles, have temperature-dependent sex determination (TDSD) with higher temperatures favoring the development of female terrapin offspring and lower temperatures favoring males (Roosenburg 1996; Jeyasuria and Place 1997; Jeyasuria et al. 1994). Additionally, diamondback terrapins are a species that is highly sought after in the "wild-caught" pet trade.

Box turtles are a long-lived species whose life history may not allow population recovery if large numbers of reproductively active members are removed from the population (Dodd et. al. 2006). Eastern box turtles are considered to be relatively common in SC but are a popular target for the "wild-caught" pet trade. In 2019, over 200 eastern box turtles were seized from a resident in South Carolina who was planning to ship them overseas for the illegal turtle trade. This case severity of illegal collection and further emphasized the importance of protecting this species in South Carolina. In 2020, regulations pertaining to all native reptiles and amphibians were updated, adding protection for all native species from commercial exploitation. A major component of these regulation changes was increased protections for turtles, which prohibited export, transfer of possession, and added possession limits for individual species as well as in aggregate. Other challenges or threats to box turtles include road mortality, habitat loss and fragmentation and disease.

Eastern kingsnakes, mole kingsnakes and pygmy rattlesnakes have a large distribution and are considered relatively common in some areas of South Carolina however they are a popular target for the "wild-caught" pet trade. In 2020, regulations pertaining to all native reptiles and amphibians were updated, adding protection for all native species from commercial exploitation and added prohibitions for export and transfer of possession (buy, sell, trade, etc). Other threats include road mortality, habitat loss and fragmentation and disease, specifically Snake Fungal Disease.

Due to the lack of data, challenges for Island glass lizard are unknown, however, given their preferred habitat and the elemental occurrence records we do have, climate change and its relationship with sea level rise could impact this species.

CONSERVATION ACCOMPLISHMENTS

In 2020, regulations pertaining to all native reptiles and amphibians were updated, adding protection for all native species from commercial exploitation (Code of laws, Title 50, Chapter 15). A major component of these regulation changes were increased protections for turtles, which prohibited export, transfer of possession, and added possession limits for individual species as well as in aggregate. For box turtles specifically, possession limits were limited to two individuals and any legally acquired collections of box turtles, prior to the regulation change, were given an opportunity to apply for a permit within 90 days of the new regulations. Additional changes included, all individuals permitted must be notched uniquely (with a SCDNR issued code that is unique to every permitted turtle) and photographed annually. Failure to do so results in denial of permit applications/renewals. Notching and annual permit renewals with photographs have addressed the identified loophole. Diamondback terrapin possession limits remained at two.

University of Georgia's Savannah River Ecology Laboratory (SREL), in collaboration with SCDNR and USFS-Savannah River, responded to a large confiscation of eastern box turtles and partnered to release them on the Savannah River Site in 2019. In 2020, they partnered to release former long-term captive turtles that had been surrendered to SCDNR to comply with new legislation. SREL researchers conducted post-release

monitoring of released confiscated and long-term captive turtles, as well as sympatric resident turtles. They evaluated health, survival, movement, and reproduction. Two master's theses and three publications resulted from the project to date.

Since the last revision in 2015, SCDNR has added a significant number of new records to the heritage database identifying new populations or areas of interest for most of the species in this guild.

From 2014-2016, a State Wildlife Grant was funded to evaluate headstarting as a means to augment diamondback terrapin populations in South Carolina. Over the course of three nesting seasons 206 female diamondback terrapins were examined for eggs and 1,089 eggs were collected from 154 clutches. Overall hatching success was 88.2%. Eggs hatched more quickly at female producing temperatures though there was no statistical difference in hatching success between male and female producing temperatures. Further, no significant differences in hatching success were detected between gravid females collected in-water vs on land or between gravid females that were induced to lay eggs vs those that laid eggs naturally. Overall, during the course of this study 638 diamondback terrapins were produced (411 headstarts, 227 hatchlings) and released into the Charleston Harbor system, suggesting that a substantial number of diamondback terrapins could be collected and headstarted should population augmentation or establishment be warranted in the future.

In 2016, a thorough web page (https://www.dnr.sc.gov/wildlife/diamondbackterrapin/index.html) was launched which provided a centralized overview SCDNR research for this species. Shortly thereafter, an online citizen-scientist reporting form was also launched, with a direct link accessible from the home page of the terrapin website. In 2023 the online reporting platform switched from Survey Monkey to the ArcGIS-based Survey123. Through May 2024, nearly 900 entries were submitted by nearly 400 citizen-scientists, with >100 reports filed for the top participant. Report submission rate varies with season as well as outreach intensity. Two-thirds of sightings involve terrapins on land, including 19% of overall reports associated with nesting activity (i.e., nest deposition, observation of eggs and/or hatchlings). In-water sighting reports predominantly pertain to terrapins in natural habitats (23% overall); however, 10% of all reports either reflect terrapins in swimming pools (usually young-of-the-year in spring) or incidentally captured by fishing gear (hook-and-line, crab nets, and crab pots). These data are accessed by the SCDNR Office of Environmental Programs when making land-management policy and thus address prior CA's to "identify and protect" (a) nesting habitats and (b) mating aggregations.

Across habitats, 90% of reports filed by citizen-scientists reflect observation of live terrapins. The 2015 SWAP stipulated four CA's directed at quantifying and reducing mortality along roadways; thus, despite being relatively few, terrapin mortalities reported through the online tool provide a valuable starting point for informing future conservation actions. Through May 2024, the online reporting tool documents several consistent terrapin roadway mortality point-sources that can hopefully be better mitigated through (a) collaboration with the South Carolina Department of Transportation and (b) appropriate motorist alerting to terrapin crossings. Due to intra- and inter-agency considerations, addressing these later CA's received less attention than other CA's following the 2015 SWAP but remains a high focal area following the 2025 SWAP.

A terrapin population study in four tidal creeks adjacent to the Kiawah River has been ongoing since 1983; to date, there have been 1,821 individual terrapins captured and 2,015 recaptures (K. Cecala, pers. comm. 2024). Recreational crab pots have been shown to adversely affect diamondback terrapin populations in the Kiawah River (Hoyle and Gibbons 2000). Crab pots with BRDs showed an increase in the number of legal crabs caught in a Louisiana study (Guillory and Prejean 1998), and a significant decrease in terrapin capture without a change in number or size of blue crabs caught was shown in Florida (Butler et al. 2007) and Chesapeake Bay (Rook et al. 2010).

Progress for reducing terrapin mortality in crab traps was marked by the Arendt et al. (2018) publication of a 25-year synthesis of excluder design studies from Texas through New Jersey and subsequent validation of proper device sizing for target and non-target species. Following this publication, SCDNR enlisted the help of >30 commercial and >60 recreational crabbers to voluntarily test a new bycatch reduction device (BRD) designed to optimize blue crab catch while excluding the maximum number of terrapins by emphasizing the width of both species during entry through crab pot funnels. Subsequent measurement of commercially landed blue crabs across the South Carolina coastal plain (n = 328) substantiated slight morphological differences in the southern portion of the state that led to sub-optimal impression of catch among crabbers. From north to south, subsequent testing of this BRD by researchers has occurred in New Jersey (Wynek et al. 2019), Virginia (Grubbs et al. 2018), North Carolina (UNCW, unpublished data), Georgia (Howard 2022), and Florida (FWC, unpublished data). In May 2020, SCDNR BRD performance in North Carolina inspired seasonal fishery management action (NCDMF 2023). Favorable results have also been reported with respect to legal-sized blue crab capture and retention in all other studies; however, findings from those studies have not yet been translated into management action. Likewise, South Carolina does not also require BRDs in crab traps.

In addition to reducing terrapin mortality in actively fished traps, SCDNR researchers conducted several studies to (a) identify the root-causes and reduce the prevalence of abandoned crab traps and to (b) salvage abandoned crab traps and repurpose them for oyster reef substrate (SRFAC Report 2014). In 2023, findings from the former initiative continued to favorably reverberate among regional Marine Debris Removal funding initiatives, particularly with reducing the generation of derelict crab traps following vessel strikes. Although the collection of derelict traps for upcycling remains an active area of SCDNR research, investigation of biodegradable panels to reduce ghost trap fishing has not received as much attention as closely related CA's associated with derelict gear.

Crucial to population assessment, the 2015 SWAP stressed a need to "develop and implement long-term coastwide standardized surveys to estimate the abundance and distribution of South Carolina's terrapin population." However, during 2013-2016, a new acoustic telemetry study (Arendt et al 2016) that built on earlier efforts by Estep (2005) and Broyles (2010) validated the multi-decadal trammel net survey as a good source of temporal trend data for diamondback terrapins captured along the marsh-edge of larger waterbodies such as the Ashley River. Relative to other strata, the Ashley River also exhibits an outlier effect for diamondback terrapins, with >40% of all captures for this species

occurring there during 1995-2013. Specifically, proportionate distribution of terrapins in the Ashley River did not correspond to the number of creeks in the trammel net survey area whereas an inverse relationship between proportionate distribution and number of creeks was observed across the remaining seven trammel net survey strata.

Several funded and non-funded studies that provide insight into population parameters were also conducted following the 2015 SWAP. Nest temperatures and predators were monitored in known areas of terrapin nesting activity in Charleston, SC and at Botany Bay Heritage Preserve, Edisto Island, SC over a five-year period, 2017 – 2021 (Levesque and Grosse 2022). Study locations were either defined as natural (limited human activity) or disturbed (increased human activity) to assess differences between these areas and potential differential nest success. Predator identification was largely qualitative, however predators detected on natural nesting beaches were numerous, potentially because shorebirds and sea turtles used these areas to nest and predators optimized that season to feed on eggs and hatchlings. Predators included racoons, mink, bobcats, crows, armadillos and ghost crabs. In 2021, 18 clutches of eggs were buried at on open beach at Botany Bay (natural) and 9 clutches were buried in a landscaped residential neighborhood in Charleston (disturbed). Mean hatching success across 21 nests that endured the entire incubation period was 75.6% (Botany Bay 70.8% and Wappoo Creek 82.0%). A 100% hatch rate occurred in nests with mean daily temperatures between 27.3ºC – 29.9ºC, a mean maximum no greater than 35.2ºC and a mean daily range no greater than 9.2ºC. Hatching rate decreased significantly with increasing mean maximum daily temperatures and mean daily range in temperatures. The mean, maximum and range of daily temperatures were significantly higher at the open beach Botany Bay site and hatching success was significantly lower there. The mean temperatures, mean maximum temperature and mean temperature ranges recorded over the five year study period in vegetated/open habitats and natural/disturbed habitat in areas with documented terrapin nests fell within the limits that would produce successful hatching; however, there were some nesting areas that were significantly hotter than the nests that produced highest hatching success.

Following 28 diamondback terrapin encounters in the backyard of a marsh front property in 2016, SCDNR researchers began collaborating with a citizen-scientist to conventionally tag nesting females on the property beginning in 2017. Over the course of this novel pilot study, fewer than two dozen individual terrapins have accounted for annual nesting activity, with most females encountered in subsequent years (but rarely more than once per nesting season). This study entered its eight consecutive year in 2024 and has since expanded into a neighborhood awareness effort; however, tagging continues to be conducted by the original citizen-scientist.

CONSERVATION RECOMMENDATIONS

- Quantify anthropogenic sources of terrapin mortality, with focus on life stage and sex- specific mortality rates.
- Establish several intensive studies to determine population parameters required for evaluating the status of diamondback terrapins, such as mortality rates and nesting effort/success.
- Evaluate the need for predator control programs on critical diamondback terrapin nesting beaches.
- Develop terrapin culture program through salvage of eggs from road-killed females and collection of eggs from gravid females in critical areas with the intent of releasing head-started terrapins in areas where contribution of stocked terrapins can be determined in the future
- Evaluate the benefits of headstarting for population augmentation or reestablishment
- Identify and protect critical diamondback terrapin mating aggregations throughout the state.
- Collaborate with the South Carolina Department of Transportation (SCDOT) to negotiate restrictions of causeway mowing during the terrapin nesting season.

- Educate the public about how they can help conserve the diamondback terrapin and specifically emphasize responsible actions when using crab pots. Produce education materials to be distributed coastwide.
- Erect crossing signs along roadways alerting motorists about crossing diamondback terrapins during the breeding season. Signs should be theft proof or removed each year at the end of the breeding season.
- Work with the South Carolina Department of Transportation (SCDOT) and other partners to design wildlife crossings to reduce road mortality of reptiles and amphibians.
- Determine mole kingsnake, island glass lizard, and pygmy rattlesnake distribution, locations of viable populations and collect data on life history and demography in South Carolina.
- Monitor the impacts of habitat loss, disease, illegal collection and road mortality on box turtle populations.
- Monitor Eastern kingsnake populations.
- Monitor and conduct research on the impacts of nonnative species on this guild.
- Evaluate the impacts of disease on this guild.
- Monitor changes in the demand for turtles and turtle products and the effectiveness of the new law.

MEASURES OF SUCCESS

As results from current research and surveys are identified and analyzed, we will initiate projects to address specific needs that arise from these results.

The following amphibian species do not fit logically into any guild or group but are a mix of state protected species and several species that we know little about in South Carolina. Many of these species are listed as data deficient but are listed here to avoid the potential risk of overlooking a species in need. For many of these species, the primary conservation objective will be to determine their status through surveys in South Carolina.

DESCRIPTION
Taxonomy and Basic Description

Photo by Todd Pierson

The Bairds dusky salamander was recently described in 2023 (Pyron and Beamer 2023). This is a moderately sized dusky salamander reaching lengths between 2.4-5.5 cm (SVL) and is described by Pyron and Beamer (2023) as having a heavily keeled tail and a distinct brown to yellow dorsal stripe with defined, yet irregular borders. Additionally, a 2nd row of "portholes" along the sides is usually present in this species (Pyron and Beamer 2023).

Bird-voiced treefrogs are a small frog in the treefrog family, Hylidae. This species reaches lengths of 2.8 to 4.4 cm (1.1-1.7 in.) with a maximum length of approximately 5 cm (1.9 in.) (Conant and Collins 1991). Bird-voiced treefrogs are similar in appearance to gray treefrogs though the latter tends to have brighter orange coloration on the inside of the thigh. Additionally, calls of the two species are unique and easily distinguishable. They have a very limited distribution in our state but can be common to abundant within their range.

Photo by Todd Pierson

Photo by Todd Pierson

Chamberlain's dwarf salamander was described in 2003 and recognized as distinct from the more common, dwarf salamander (*Eurycea quadridigittata*; Harrison and Guttman 2003). Chamberlain's dwarf salamander is lighter in color than the dwarf salamander, having a yellow underside that lacks any markings. Chamberlain's dwarf salamander is a very small salamander averaging approximately 2.5 cm (0.9 in.) in total length (Harrison and Guttman 2003).

Dwarf Waterdogs are a relatively large salamander species in South Carolina but represent the smallest species in the genus *Necturus*, reaching lengths from 11.5-15.9 cm (4.5-6.25 in; Conant and Collins 1991). They tend to be a uniform gray, brown or black color with a creamy belly. Dwarf waterdogs have red external gills and 4 toes on all feet.

Photo by Todd Pierson

Photo by Todd Pierson

Four-toed salamanders range in size between 5-10 cm (2-4 in). They are reddish to brown, with the appearance of chevrons extending down their backs. The belly is white with distinct, irregular black spots. The connection point of the tail to the body is constricted. Similar to a lizard, four-toed salamanders will drop their tail if needed to distract a predator and escape (Conant and Collin 1991).

The Gulf coast mud salamander is one of two subspecies of the more widely distributed mud salamander that occurs in South Carolina. The known range of this subspecies in South Carolina is small though more survey efforts are warranted. Gulf coast mud salamanders grow to about 12 cm (about 5 in) and have a dark brown to pinkish color on their backs with a lighter underside. They have brown eyes (Conant and Collins 1991).

Photo by Todd Pierson

Photo by Todd Pierson

The many lined salamander is a small salamander that ranges in size from 6-9.5 cm (2-4 in). They typically have a dark brown back with a lighter yellow to brown coloration down their sides with several small, thin black stripes or sometimes a series of very small dots. This species is mostly aquatic and not generally found far from water (Conat and Collins 1991).

The pickerel frog can grow to lengths between 4-8 cm (2-4 in) and can be identified by the two rows of dark spots that are usually in pairs, down its back. Pickeral frogs have dorsolateral folds running down their backs, stripes on their legs and a lighter colored belly with some dark blotches (Conant and Collins 1991).

Photo by Kiley Haberman

The pine barrens treefrog is a small member of the treefrog family, Hylidae. This species reaches lengths of 2.8 to 4.4 cm (1.1-1.7 in.) with a maximum length of approximately 5 cm (1.9 in.) (Conant and Collins 1991). The pine barrens treefrog is green with a broad lavender stripe on either side of the body. This stripe has a thin, white outline. The concealed portions of the legs and inner thigh are bright orange with numerous yellow dots (Martof et al. 1980).

River frogs are one of the larger Ranids, reaching size of 7-13 cm (3-5 in). Their skin has a bumpy appearance, they have no dorsolateral folds and usually some pattern of white spots on the lips. The belly is lighter in color, usually with some pattern consisting of spots or wavy lines. In young frogs and tadpoles, the eyes are usually red. River frog tadpoles are large, reaching lengths of up to five inches and can be found schooling, like fish, in the swamps and black water rivers and wetlands, where they live (Conant and Collins 1991).

Photo by Todd Pierson

Webster's salamander is a small member of the woodland salamander family. This species reaches lengths of 7 to 8.2 cm (2.7-3.2 in.; Conant and Collins 1991). Both striped and unstriped individuals of this species may be found. Striped individuals typically have a wavy yellowish brown to orange-red dorsal stripe extending from the head to the tail tip (Petranka 1998). Unstriped individuals are usually uniform in color, ranging from brown to reddish-orange. The belly of the salamander is mottled with black, white, and reddish-orange (Martof et al. 1980). This is a relatively non-descript salamander but is typically the only salamander of its size and coloration within its limited range in South Carolina.

Status

Bairds dusky salamander was recently described in 2023 (Pyron and Beamer 2023) and has a state ranking of S3 (vulnerable) due to the lack of information on its life history and apparent small distribution in South Carolina (NatureServe 2024). Bird-voiced treefrogs are listed as vulnerable (S3) in South Carolina and secure (G5) globally (NatureServe 2024). Chamberlain's Dwarf Salamanders are listed as vulnerable (S3) in South Carolina and apparently secure (G4) globally (NatureServe 2024). Dwarf waterdogs are listed as apparently secure (S4) in South Carolina and secure (G5) globally (NatureServe 2024). Four-toed salamanders are listed as vulnerable (S3) in South Carolin and secure (G5) globally (NatureServe 2024).Gulf coast mud salamanders are listed as vulnerable (S3) in South Carolina and apparently secure (G4) globally (NatureServe 2024). Many-lined salamanders are listed as vulnerable (S3) in South Carolina and secure (G5) globally (NatureServe 2024). Pickeral frogs are listed as vulnerable (S3) in South Carolina and secure (G5) globally (NatureServe 2024). Pine barrens treefrogs are listed as threatened in South Carolina with a state designation of imperiled (S2) and apparently secure (G4) globally (NatureServe 2024). River frogs are listed as apparently secure (S4) in South Carolina and secure (G5) globally (NatureServe 2024). Websters salamanders are listed as endangered in South Carolina with a state designation of imperiled (S2) and vulnerable (G3) globally (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Baird's dusky salamander was recently described and is known to occur in the upper portion of the fall line sandhills and into the piedmont. This species population size and distribution in South Carolina is currently unknown, though it is not thought to have a very extensive range in the state.

In South Carolina, the bird-voiced treefrog has a very limited distribution, but it can be common to abundant within its range. Population sizes are currently unknown for this species. The primary conservation objectives for this species are to monitor the populations in South Carolina and collect data on the life history and demography.

Chamberlain's dwarf salamanders have an unusual distribution in South Carolina, occurring in the southwestern portion of the upper piedmont and coastal plain and extending the length of the fall line sandhill ecoregion. A survey is currently underway to determine the full distribution of this species in North and South Carolina. Population sizes are currently unknown.

Dwarf waterdogs are found throughout the coastal plain of South Carolina though more survey is needed to better understand their abundance, distribution, and population level parameters within different watersheds.

Four-toed salamanders are found north of the fall line in South Carolina. Very few populations are known for this species and even less is known about their natural history in South Carolina. A study is currently being conducted to better understand their natural history, abundance, nesting behavior, and longevity in South Carolina.

Gulf coast mud salamanders are known to occur in the southern portion of the coastal plain of South Carolina, but their full distribution is not fully known in the state.

Very little data exists for many-lined salamanders in South Carolina. Their distribution is thought to extend throughout the coastal plain though few records exist.

Pickerel frogs occur in the upper piedmont, mountains, lower coastal plain and have a spotty distribution near the fall line sandhills. They seem to be abundant in the northern portion of the state, but little abundance and population level data exists for this species.

The pine barrens treefrog is found in the upper (northern) portion of South Carolina's Coastal Plain in the Sandhills (Fall-line) Ecoregion. Between 1979 and 1982, Cely and Sorrow (1982) surveyed 222 potential treefrog sites, in this region, and found that approximately 50 (23%) supported pine barrens treefrog colonies. Colony sizes ranged from a few frogs to several dozen, but larger colonies were difficult to estimate. During this study, the researchers used a mark- recapture method to develop a population estimate for one large colony. The estimate for this colony of 159 frogs (95% C.I.= 91-637) was much higher than the 25 to 50 individuals originally estimated by call counts. The researchers concluded that estimates of pine barrens treefrog populations, based on call counts, will typically underestimate the actual population size. The pine barrens treefrog was found to be more widespread in South Carolina than previously believed. Based on their findings, Cely and Sorrow recommended that the status of the frog be changed from Endangered to Threatened and considered a Species in Need of Management in South Carolina. Currently, no valid estimate exists for the number of extant pine barrens treefrog colonies in South Carolina or estimates for population size at any colony. More recently, opportunistic surveys were conducted at 20 historic locations in 2021 and 2022 and pine barrens tree frogs were detected at 14 of those locations.

River frogs are distributed throughout the coastal plain of South Carolina. Recent survey efforts at several historic sites (2022-2023) have not detected this species. While fluctuations from year to year certainly have an impact on detectability, this species requires further monitoring to determine its status and distribution in South Carolina.

Webster's salamander occurs across the southeast in several disjunct populations. The majority of the species' range is in western Georgia and eastern Alabama in the lower Piedmont. In South Carolina the species is restricted to several counties along the Savannah River in the lower Piedmont. Semlitsch and West (1983) surveyed this region of the state and found several new populations of this species. Little data exists on the size of the Webster's salamander populations in South Carolina; however, the species is seemingly abundant where it occurs.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Pyron and Beamer (2023) describe the Baird's dusky salamander's habitat as streamside habitats, usually under rocks, logs or leaf packs. It seems to be abundant in ravine habitats though has also been found in swampier habitats in some portions of its range.

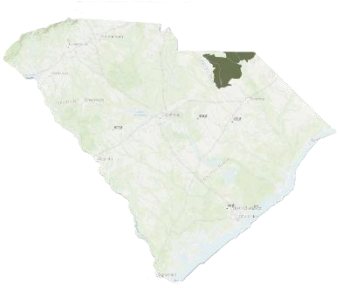
Bird-voiced treefrogs are found in the forested floodplains and swamps of large river systems in

South Carolina.

Chamberlain's dwarf salamander is typically found in wet areas, particularly seepages near small streams, and other wetland types. This species is most typically found under leaf litter, sphagnum, and small debris in these habitats (Harrison and Guttman 2003).

Dwarf waterdogs are found in slow-moving black water streams and rivers in South Carolina. Leaf packs and other accumulated debris can be important structure for this species.

Four-toed salamanders are found in small seepages, bogs, other ephemeral, fishless wetland types and the forested uplands that surround these habitats. Sphagnum moss in these wetland habitats is important.

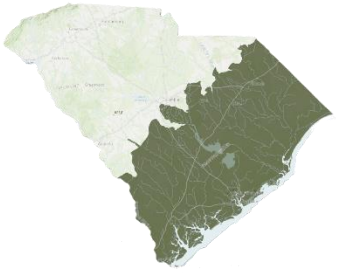


Many-lined salamanders and Gulf coast mud salamanders can be found using slow-moving swamps and streams with an abundance of mud and leaf packs.

Pickerel frogs are known to use a variety of habitats in South Carolina. They are often found in streams, seepages and other wetlands in the northern part of the state. They are also frequently found in entrances of caves and old mines. In the coastal plain they can be found using black water swamps and streams (Conant and Collins 1991).

The pine barrens treefrog, in South Carolina, occurs in herb shrub bogs, pocosins and other related communities in the Sandhills (Cely and Sorrow 1982; Conant and Collins 1991; Martof et al. 1980). Typical pine barrens treefrog habitat is found in transition zones on the down-slope of sandhills where water percolates out of the soil in some sort of seepage zone. These habitats would burn periodically—prior to European settlement of the Southeast and the exclusion of fire—and these fires would maintain an open character to the seepage bogs. Pitcher plants, sundews and terrestrial orchids are species that typify this habitat type and also require the acidic, open conditions of these bogs. Pine barrens treefrogs live in the thick, pocosin vegetation that often surrounds this habitat, but they also require the open, slow-flowing seeps as breeding habitat. Currently, several pine barrens treefrog colonies exist along power-line and gas line right-of-ways, where mechanical vegetation control (e.g. mowing) keeps the vegetation low, maintaining the open habitat required by the species.

River frogs have been documented using floodplain swamps, black water rivers and streams and man-made lakes, ponds and borrow pits in South Carolina. Man-made structures used by river frogs are typically located in close proximity of natural habitat. Water needs to be permanent to allow for the extended tadpole development period for this species.



Webster's salamander is found in moist, mixed hardwood forests on steep north-facing slopes (Martof et al. 1980). Optimal habitat for this species has a rocky substrate with abundant coarse, woody debris (Petranka 1998). This species is typically associated with forests that have a relatively dense canopy that prevents drying of the forest floor substrate.

CHALLENGES

The primary challenges for all these species include habitat loss or alteration of both terrestrial and wetland habitats (depending on species), disease, illegal collection and impacts from nonnative species.

For Webster's salamanders habitat loss or alteration due to forestry practices, conversion to agriculture, or development could have detrimental impacts to persistence. Loss of the dense hardwood forest canopy this species prefers can lead to drying of the habitat and an elevation of soil temperatures, making the habitat unsuitable for the salamander.

The primary threat facing pine barrens treefrogs is habitat loss due to fire suppression, and other inappropriate management activities such as herbicide application in power-line rights of way, in the preferred herb-shrub bog habitat. Ditching and drainage of small, hillside wetlands or other alterations of these wetlands is a potential threat to pine barrens treefrog populations, especially since these important breeding habitats are non-jurisdictional wetlands and don't receive any protection from development.

CONSERVATION ACCOMPLISHMENTS

Since 2013, no formal surveys have taken place for Websters salamanders but known locations have been visited opportunistically, as recently as 2022, and presence of multiple Websters salamanders have been confirmed. All data collected during all surveys have been compiled and included in the SCDNR Heritage Database.

In 2019, the SCDNR passed new regulations that added significant protections for all reptiles and amphibians native to South Carolina. Specifically, no native species can be exported from SC and transfer of possession (buy, sell, trade, etc) is prohibited.

A State Wildlife Grant funded a survey of historic and new pine barrens treefrog sites in South Carolina from 2011-2016. At the onset of the survey, 31 historic sites were known for pine barrens treefrogs (Cely and Sorrow 1982). Over the course of the survey, 48 active locations were documented for this species, including several new occurrences. Most locations that detected pine barrens treefrogs in Cely and Sorrows 1983 surveys were still extant, or populations were in close proximity. Additionally, many of these sites were on public lands where managers expressed an interest in managing habitat for this species.

Opportunistic surveys were conducted at 20 historic pine barrens treefrog locations in 2021 and 2022. At least one calling individual was detected at 14 of those locations.

A recently funded survey effort, funded by the US Fish and Wildlife Service and conducted by Kennesaw State and the Savannah River Ecology Lab, is underway to determine the distribution of Chamberlain's dwarf salamander throughout their range in South Carolina and North Carolina. The results of this project will be important to help inform species status and management decisions for this species in South Carolina.

A survey, funded by a State Wildlife Grant, began in 2023 to identify presence, habitat use, and seasonal activity patterns for four-toed Salamanders in South Carolina. Preliminary results show sphagnum is important for nesting and that communal nesting is not uncommon. Additionally, habitat loss and degradation of important breeding/nesting sites from development, ditching, and nonnative, invasive species (hogs) likely has a negative impact on breeding, nesting, hatching success and population

persistence. Finally, protection of important breeding/nesting sites may be warranted and current wetland BMPs that suggest 50-foot buffers, are likely inadequate to protect this species.

CONSERVATION RECOMMENDATIONS

- Determine the distribution of Baird's dusky salamanders in South Carolina.
- Monitor the populations of bird-voiced treefrogs in South Carolina and collect data on abundance, life history and demography.
- Monitor the populations of Chamberlains dwarf salamanders in South Carolina and collect data on abundance, life history and demography.
- Determine the four-toed salamanders' distribution and collect data on abundance, life history and demography.
- Determine the pickerel frogs' distribution and collect data on abundance, life history and demography, especially in the coastal plain populations.
- Determine the dwarf waterdog's distribution and collect data on abundance, life history and demography.
- Determine the distribution of the Gulf coast mud salamander in South Carolina.
- Determine the many-lined salamanders' distribution and collect data on abundance, life history and demography.
- Ensure appropriate management is in place for pine barrens treefrog populations on public lands.
- Locate additional populations of pine barrens treefrogs and protect them.
- Monitor known populations of pine barrens treefrogs and develop accurate population estimates.
- Obtain life history data for pine barrens treefrogs which will inform our conservation and management efforts.
- Determine the river frog's current distribution and collect data on abundance, life history and demography.
- Ensure appropriate management is in place for websters salamander populations on public lands.
- Monitor known populations of websters salamanders and develop accurate population estimates.
- Obtain life history data for websters salamanders.
- Monitor and conduct research on the impacts of nonnative species on this guild.
- Evaluate the impacts of disease on this guild.

MEASURES OF SUCCESS

As results from current research and surveys are identified and analyzed, we will initiate projects to address specific needs that arise from these results. Measures of success for most of these species is to define distribution and population status in the state since most are data deficient.

DESCRIPTION

Taxonomy and Basic Descriptions

This guild contains 9 species with differing levels of federal and state protections, as well as some where reports throughout their range indicate declines and still others that may be considered “common” but have disjunct populations in different ecoregions of South Carolina.

The frosted flatwoods salamander, tiger salamander and mabees salamander are members of the family Ambystomatidae, the mole salamanders. These species are large with the tiger salamander being the largest terrestrial salamander in the eastern United States.

Photo by Todd Pierson

The frosted flatwoods salamander can reach lengths of 9 to 12 cm (3.5 to 4.7 in.) as an adult. This species is dark, ranging from black to dark brown with silver-white reticulated markings (Conant and Collins 1991; Martof et al. 1980).

The tiger salamander can reach lengths of 18 to 20 cm (7.1 to 7.9 in.) as an adult; maximum size is approximately 30 cm (11.8 in.). This species has a dark background, typically black, with bright, yellow-orange irregular markings (Conant and Collins 1991; Martof et al. 1980).

Photo by Todd Pierson

Photo by Todd Pierson

The mabees salamander is the smallest of these three Ambystomatids, reaching lengths between 7-10 cm (3-4 in.) as an adult. Similar to the other two species, mabees salamanders typically have a dark brown or black background with pale/white speckling along the sides (Conant and Collins 1991).

The broad-striped dwarf siren is a member of the family Sirenidae, a family of salamanders that consists of both dwarf sirens and sirens. These are totally aquatic species that retain larval characteristics into adulthood. The dwarf siren is small, only reaching 10 to 15 cm (3.9-5.9 in.) in length and is an eel-like salamander that lacks hind limbs and has external gills. Dwarf sirens are typically brown in color with dark-brown longitudinal stripes flanking a broad, light brown stripe that runs the length of the animal's body (Conant and Collins 1991; Martof et al. 1980).

Photo by Todd Pierson

The Carolina gopher frog is a member of the family Ranidae, the true frogs. Its closest relatives include the bullfrog, leopard frog and bronze frog. This species can reach sizes of 6 to 9 cm (2.4 to 3.5 in.). It has the body shape of a typical frog but is more robust than other frogs with proportionately shorter legs. Gopher frogs are typically light to dark brown with heavy blotching and numerous warts (Conant and Collins 1991; Martof et al. 1980). In fact, while a true frog, the gopher frog does somewhat resemble a toad in appearance. This trait, as with the toad, is evidence of a more terrestrial lifestyle.

Photo by Andrew Grosse

The oak toad is a member of the family Bufonidae, the true toads. This is a small toad species only reaching lengths of 2-3 cm (.75-1.5 in.). The oak toad varies in color with a background of black to gray with a light, cream, yellow or orange mid dorsal stripe and warts that vary from orange to red (Conant and Collins 1991).

Photo by Andrew Grosse

The ornate chorus frog is in the family Hylidae and is a small frog, reaching lengths 2.5-3 cm (1-1.5 in). They can vary in color from reddish brown to silvery white to green but have a black mask-like stripe that runs through the eyes. They typically have dark spots on the sides and yellow in the groin (Conant and Collins 1991)

Photo by Todd Pierson

Four of these species, the flatwoods salamander, gopher frog, mabees salamander and tiger salamander spend their adult lives in terrestrial habitats as fossorial species, inhabiting crayfish holes, root channels, rodent burrows and other subterranean structures. Adults move to breeding ponds where they deposit eggs. Flatwoods salamanders move during autumn (Anderson and Williamson 1976) while tiger salamanders, mabees salamanders and gopher frogs move in late winter (Braswell 1993). Oaks toads and ornate chorus frogs spend their adult lives in the uplands surrounding wetland breeding habitat and move to wetlands during the breeding season. The aquatic larva of these species may spend several months in a pond before metamorphosing to the adult form. Newly metamorphosed individuals move away from breeding ponds; they only return to these ponds when they become reproductively mature adults (Petranka 1998).

The upland chorus frog and the eastern cricket frog are both small frogs; they reach lengths of 1 to 3 cm (0.3 to 1.2 in.). These frogs are in the family Hylidae and are related to treefrogs. The color pattern of the upland chorus frog can be variable; they are typically light brown with dorsal

Photos by Todd Pierson; *Upland Chorus frog (left), Eastern Cricket frog (right*)

striping that is broken at the posterior. The eastern cricket frog is also a highly variable species in terms of coloration; it ranges from red-brown to green (Conant and Collins 1991; Martof et al. 1980). Both species are common throughout most of their range, which, in South Carolina, is primarily the Southern Appalachian and piedmont ecoregions. These species both have populations in the coastal plain, disjunct from their typical range; it is these populations that are of conservation concern.

Status

The frosted flatwoods salamander is currently listed as endangered in South Carolina and is given a Natural Heritage rank of S1. With a federal ranking of G2, the flatwoods salamander is federally listed as a threatened. The Carolina gopher frog is currently listed as endangered in South Carolina with a natural heritage rank of S1. The gopher frog is considered a federal

candidate for listing and is currently considered a species of concern, G2. The dwarf siren is currently listed as threatened in South Carolina and ranked S1; it has a federal ranking of G5, secure. The tiger salamander is currently a species of concern in South Carolina and is ranked S2; it has a federal ranking of G5, secure globally (NatureServe 2024). The mabees salamander is a species of concern in South Carolina and ranked S3, with a federal ranking of G4. The oak toad is ranked as S3 in South Carolina has a global rank of G5. The ornate chorus is ranked S3 in South Carolina and has a global rank of G4 (NatureServe 2024).

The coastal plain populations of the upland chorus frog are ranked S5, secure, and G5, secure globally. The eastern cricket frog is considered secure, both federally and in South Carolina with rankings of G5/S5 (NatureServe 2024).

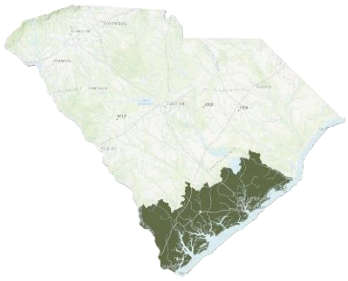
POPULATION SIZE AND DISTRIBUTION

Historically, the flatwoods salamander was known from Orangeburg, Jasper, Berkeley, and Charleston Counties. This species has been the object of intense survey efforts in South Carolina but has not been detected since 2010. The most recent records consisted of one or two individuals at breeding ponds. There has been no documentation of any significant reproduction for this species in South Carolina in over 20 years (Moulis and Seyle 1987; Harrison 2001; Bennett et al. 2002). While it's unlikely this species still occurs at historic locations on public land, there are significant private land holdings where this species may still occur.

The range of the Carolina gopher frog in South Carolina is generally believed to have included the entire Coastal Plain. Currently, the gopher frog is only known to occur in Aiken, Barnwell, and Berkeley Counties, although historic records include Aiken, Barnwell, Bamberg, Orangeburg, Dorchester, Hampton, Berkeley and Charleston Counties. Recent records indicate that gopher frogs are only present on large, public properties. Such properties include: the Savannah River Site, owned by the US Department of Energy and managed by the US Forest Service and the Francis Marion National Forest, owned and managed by the US Forest Service. Gopher frog breeding has been documented within the last decade and at multiple isolated wetlands at these sites, with evidence of successful reproduction at both the Savannah River Site and Francis Marion National Forest. The gopher frog has been the object of significant survey effort by the SCDNR in recent years. Efforts to relocate historic breeding ponds outside of the previously mentioned public lands have been met with little success. All of these historic ponds have been altered, drained or the surrounding habitat has been significantly altered.

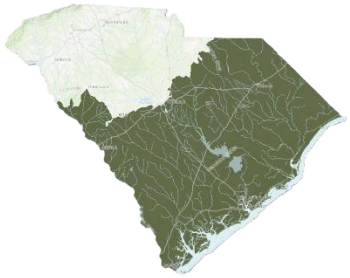
Broad-striped dwarf sirens were last known to occur in Jasper, Hampton, Orangeburg, and Charleston counties in South Carolina. SCDNR documented this species from several new sites in Jasper and Hampton Counties in the early 1990s, however no records for this species at new or historic locations have been documented since. Extensive surveys for this species have not been conducted throughout the general range; it is likely that previously undocumented populations exist.

There are historic records for the tiger salamander from McCormick, Aiken, Barnwell, Bamberg, and Charleston Counties. Since the last revision, tiger salamanders have been documented in Allendale, Berkely, Chesterfield, Darlington, Aiken and Barnwell counties. The tiger salamander has not been the object of a range- wide survey in South Carolina. Little is known about the population biology of this species in this state.



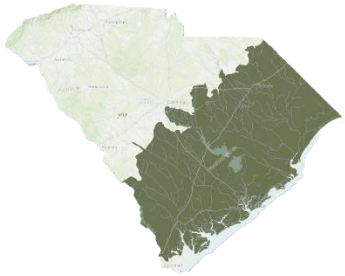
There are historic records for the mabees salamander from Jasper, Dorchester, Berkely, Charleston, Orangeburg, Bamberg, Marion and Sumter counties with the most recent records

occurring in Sumter, Charleston, Berkely and Hampton counties. The mabees salamander has not been the object of a range-wide survey in South Carolina. Little is known about the population biology of this species in this state.



Oak toads occur throughout the coastal plain of South Carolina, however, they seem to be limited to large, well-managed, contiguous properties with well-managed isolated ephemeral wetlands and may be in decline due to habitat loss. The oak toad has not been the object of a range-wide survey in South Carolina. Little is known about the population biology of this species in this state.

Historic records of ornate chorus frogs show they occur throughout the coastal plain. However, most records north of the Santee River are over a decade old with most recent records occurring further south. Due to reports of recent declines in adjacent states, primarily due to habitat loss, and the lack of a range wide survey, this species may be declining in South Carolina. Local populations in the southern portion of the coastal plain seem to be robust where they occur.



The coastal plain populations of the upland chorus frog and eastern cricket frog were previously believed to be restricted to areas near Charleston, South Carolina. Surveys by Dr. Emily Lemmon of Florida State University and Dr. Jeff Camper of Francis Marion University, indicate that both of these species are more widespread in the South Carolina Coastal Plain than previously thought. At this time, however, the actual distribution of these species in the Coastal Plain is not completely known. These two species are common to relatively abundant throughout the Piedmont and Southern Appalachian Ecoregions of South Carolina. The presence of these disjunct populations in the coastal plain is of scientific and conservation interest.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Aquatic (Breeding) Habitat

The primary species in this guild typically breed or live in isolated, temporary freshwater wetlands. Examples of these naturally occurring wetlands include Carolina Bays, limesinks, flatwoods wetlands and other such related features. While these wetlands may differ in their geologic origin and geomorphology, they share certain characteristics. Typical breeding wetlands are isolated from flowing streams, particularly any inflows. Occasionally such wetlands will have an outflow "stream" that only flows when exceptionally heavy rains fill the pond above full pool (Bennett and Nelson 1991).

Due to the lack of stream-fed water, these wetlands typically fill and dry with rainfall cycles. Most, if not all, of these wetlands represent perched water tables, holding rainwater and runoff "perched" above the normal water table. The perching mechanism generally consists of an impermeable layer, such as clay, underlying the wetland basin. Typical breeding wetlands fill during the late autumn and winter and dry, due to evaporation and evapotranspiration, during the mid to late summer.

Breeding wetlands may exhibit a diversity of vegetative communities including open-shallow water, grass-sedge prairie (depression meadow), pond cypress savanna, and tupelo gum pond (non- alluvial swamp forest). The amphibian guild members tend to favor wetlands with an open canopy and abundant grasses and sedges. The clumped-bases of these plants provide refuge and habitat structure for many species of amphibian larvae. Hydroperiod, defined as the duration and seasonality in which a wetland holds water, ultimately determines the suitability of a wetland for specific amphibian species. Tiger salamanders and gopher frogs require wetlands that fill by mid- winter; further, they need to hold water continuously until May or June for successful larval metamorphosis to occur (Buhlmann et al. 1999; Mitchell and Buhlmann, 1999). Several wetlands with a variety of hydroperiods located in proximity within a landscape yields a high diversity of pond-breeding amphibian species.

Fish species, which may prey on amphibian larvae, are typically absent from these wetlands, due to their cyclical hydrology. Certain fish species, such as pigmy sunfish, do colonize wetlands in low- lying areas that have connection to other water bodies during flooding. Large, predatory fish such as pickerel and sunfish may invade these wetlands at times of abundant rainfall and high water, using deer trails, other natural channels, and man-made ditches and firebreaks to move from areas of permanent water into wetlands. However, in general, high quality amphibian breeding sites for members of this guild are free of fish.

Terrestrial (Non-breeding) Habitat

The species comprising this guild are typically found in the Coastal Plain in natural communities associated with the longleaf pine ecosystem, including longleaf pine flatwoods, longleaf pine savanna and xeric longleaf pine sandhills. Breeding wetlands are nested within the upland longleaf pine matrix of these communities.

In South Carolina, the flatwoods salamander is closely associated with the longleaf pine savannas of the lower coast. These communities typically exhibit a sparse canopy of longleaf pine with a rich herbaceous layer. The water table in such habitat is usually close to the surface and small, isolated wetlands may be numerous.

The tiger salamander, mabees salamander, oak toad, ornate chorus frog and gopher frog may occur in a wider array of longleaf pine habitats, including the savanna. These species also occur in longleaf pine flatwoods, which typically have a lower water table and a denser canopy, and xeric sandhills, which have a very low water table and deep, droughty sands. wetlands are generally less common in these two habitat types.

Other Habitats

The dwarf siren has been documented from small Coastal Plain streams that exhibit little or no flow and have muck bottoms. Such streams are typically too small to have established populations of predatory fish such as pickerel and sunfish. All of the members of this guild have been found to occasionally breed in man-made wetlands such as borrow-pits and ditches, when they occur within the appropriate terrestrial habitat. Long-term breeding success in these habitats is currently unknown; therefore, artificial habitats should not be considered as replacements for the destruction of natural wetlands.

CHALLENGES

The requirement for both suitable aquatic (breeding) habitat and terrestrial (non-breeding) habitat has made these species susceptible to alterations in either one of these habitats. The following activities have been suggested as reasons for the perceived decline of the species:

- Drainage of temporary wetlands
- Alteration of wetland hydroperiod
- Filling of wetlands
- Conversion of wetlands to other uses such as agriculture or development
- Exclusion of fire in longleaf pine forests
- Conversion of longleaf forest to loblolly pine plantations
- Commercial and residential development
- Conversion of longleaf forest to agriculture

Isolated wetland breeding amphibians are known to require adequate upland habitat around breeding wetlands. Populations of amphibians may be extirpated by the elimination of adequate upland habitat despite the protection of the breeding wetland. Conversely, the drainage or alteration of wetlands in an otherwise unaltered forest may result in the extirpation of local amphibian populations.

Many isolated wetlands that still exist are now unsuitable for breeding by amphibian species of

this guild because they have been left isolated in the landscape as a result of farming or timber operations. Such land management likely causes local extinctions of amphibian populations because the surrounding upland forests are removed, thus eliminating the terrestrial habitat required by these species when they are not breeding in the wetlands (Gibbons and Buhlmann 2001; Semlitsch 1998; Semlitsch and Bodie 1998).

Typically, isolated, ephemeral wetlands are non-jurisdictional and receive little protection, However, these wetland systems provide critical habitat for numerous amphibian and reptile species in addition to the species listed for this guild.

CONSERVATION ACCOMPLISHMENTS

Due to continued declines in gopher frog populations, headstart programs for the species began in 2019 with the goal of boosting gopher frog populations. This occurred in three distinct locations: The Francis Marion National Forest, the Savannah River Site and the Webb Wildlife Center. Partners from the US Fish and Wildlife Service, US Forest Service, Savannah River Ecology Lab, South Carolina Department of Natural Resources, Riverbanks Zoo and the Amphibian and Reptile Conservancy are all involved in this effort and have produced and released several thousand gopher frog metamorphs back into their natal wetlands.

Comprehensive surveys begin in 2015 at the lone wetland in the Francis Marion National Forest where headstarting occurred, the highest number of gopher frog egg masses were documented in 2023 and then again in 2024. Also, near the headstart area, egg masses were discovered at one wetland that had been surveyed since 2015, but never documented any breeding. This suggests that headstarting is likely having a positive impact on breeding numbers and that the headstarted wetland’s population is at least stable and possibly increasing and expanding to other nearby wetlands. Due to the positive response, in 2024, headstarting in the Francis Marion National Forest was expanded to allow headstarting at a second historic breeding wetland.

In the fall of 2021, as part of a Competitive State Wildlife Grant, three historic isolated, ephemeral wetlands were restored at the Webb Wildlife Center to aid in gopher frog population augmentation and re-establishment on the site. This effort was of benefit to a multitude of species, including oak toads and ornate chorus frogs (also SWAP species), who showed evidence of breeding within a few months of the restoration work.

A South Carolina gopher frog working group was created to improve communication among partners involved in gopher frog surveys, conservation, research, habitat restoration, and headstarting to benefit the species. This group includes partners from US Fish and Wildlife Service, US Forest Service, Savannah River Ecology Lab, South Carolina Department of Natural Resources, Riverbanks Zoo, The Longleaf Alliance and the Amphibian and Reptile Conservancy and officially meet annually to report on each year’s efforts.

The U.S. Forest Service and Amphibian and Reptile Conservancy gained approval to restore and enhance several significant isolated wetlands on the Francis Marion National Forest that will directly benefit gopher frogs, frosted flatwoods salamanders, oak toads and ornate chorus frogs, as well as a multitude of other species. Those efforts started in 2023 and significant progress has already been made. Similar to the restoration work at the Webb Wildlife Center, in just a few months following restoration of a portion of an isolated wetland in the Francis Marion, Gopher frog egg masses were detected for the first time.

Several new location records for Eastern tiger salamanders have been added to the SCDNR

heritage database. Since the last revision, tiger salamanders have been documented in Allendale, Berkely, Chesterfield, Darlington, Aiken, and Barnwell counties. The most significant finding was the population in Allendale County, which is located on a large, well-managed private property with several suitable isolated wetlands. This property is under a conservation easement and will be protected.

Research and survey efforts on pond breeding amphibians by SCDNR personnel, have been supported in the past by State Wildlife Grants. The primary focus of past work has been survey efforts to verify historic populations and document new populations. Little data exists on the demography, population dynamics, or conservation requirements for these species.

Since the last revision in 2015, we (SCDNR) have added a number of new records to the heritage database identifying new areas of interest for ornate chorus frogs, eastern tiger salamanders, mabees salamanders and oak toads. The Amphibian and Reptile Conservancy began comprehensive herpetofauna surveys in 2015 in the Francis Marion National Forest and have added many new records to the heritage database. These survey efforts have provided information on the status and distribution of several species in the National Forest, including mabee's salamanders, oak toads and ornate chorus frogs. Future surveys will continue to target these species as well as dwarf sirens, tiger salamanders and upland chorus frogs.

In 2019, the SCDNR passed new regulations that added significant protections for all reptiles and amphibians native to South Carolina. Specifically, no native species can be exported from SC and transfer of possession (buy, sell, trade, etc) is prohibited.

CONSERVATION RECOMMENDATIONS

- Inventory historic frosted flatwoods salamander breeding sites; Continue to monitor, protect and enhance these sites and surrounding uplands.
- Meet with public and private land managers to discuss the imperilment of the frosted flatwoods salamander and methods to ensure its protection.
- Survey potential new locations for frosted flatwoods salamanders in South Carolina
- Conduct habitat restoration or enhancement in wetlands of conservation importance for wetland breeding amphibians.
- Develop positive working relationships with key South Carolina landowners to allow inventory to proceed on private lands and plantations.
- Protect all known Carolina gopher frog population sites.
- Include the importance of protecting all isolated wetlands breeding amphibians and their habitat in general education materials.
- Survey and inventory new wetlands for all species of this guild with an emphasis on those that occur in intact, protected habitat and have connectivity to one another. Historic wetlands or those in close proximity to known breeding sites should be prioritized.
- Inventory sites that have historically contained Carolina gopher frogs. Monitor these sites for continued population by this species.
- Research the effects of fire management and wetland restoration on wetland breeding habitat for wetland breeding amphibians.
- Work with partners to establish a fire regime of late growing season or summer burns of dry wetland basins and surroundings uplands of important amphibian breeding wetlands.
- Work with partners to strategically thin timber stands that surround critical amphibian

breeding wetlands to create an open canopy forest with a diverse herbaceous and graminaceous understory. All stumps from any timber harvest should remain on the landscape to become future refugia.

- Investigate Carolina gopher frog life history to determine the status of "protected" populations and to address habitat requirements, seasonal activity, adult sex ratios, recruitment, mortality, and longevity.
- Evaluate the effectiveness of releasing headstarted members of this guild for population augmentation or re-establishment.
- Evaluate the success of gopher frog headstarting through the use of genetic analysis and monitoring.
- Evaluate the most effective release strategies for headstarted member of this guild.
- Investigate the feasibility of a captive breeding program or rearing of metamorphic frogs in semi-wild enclosures to help assure the availability of breeding adults.
- Consider broad-striped dwarf siren habitat needs when managing Carolina bays and similar wetland ecosystems.
- Inventory appropriate broad-striped dwarf siren habitat, primarily Carolina bays, for this poorly known species to determine actual distribution in South Carolina.
- Once identified, protect, and monitor habitat for broad-striped dwarf sirens.
- Collaborate with appropriate partners to identify, protect, and monitor sites that contain tiger salamanders.
- Determine distribution of the tiger salamander in South Carolina.
- Survey new and monitor known breeding sites of ornate chorus frogs, oak toads and mabees salamanders to determine presence and distribution in South Carolina.
- Conduct surveys for the upland chorus frog in the coastal plain, particularly in Francis Marion National Forest, to determine if the species is still present and if so, the status of this disjunct population.
- Monitor and conduct research on the impacts of nonnative species on this guild.
- Evaluate the need for invasive species control (fire ants, feral hogs, etc) in proximity of critical amphibian breeding wetlands and if done, evaluate the success of this management action.
- Work with the South Carolina Department of Transportation (SCDOT) and other partners to design wildlife crossings to reduce road mortality of reptiles and amphibians.
- Evaluate the impacts of disease on this guild.

MEASURES OF SUCCESS

As results from current research and surveys or future efforts are identified and analyzed, projects will be initiated to address specific needs that arise from these results. Data from surveys will be used to identify and develop appropriate life history and ecology research projects to detail causes of decline and limiting factors to population. Stable or growing populations of the target species, on protected lands, will be a measure of success.

Photo: Dr. Phil Schneider

DESCRIPTION

Taxonomy

The leatherback (*Dermochelys coriacea*) is the largest and most migratory of the living turtles, with the most extensive geographic range (Eckert et al. 2012). It is so distinctive that it is placed in a separate family, Dermochelyidae and is the only extant species remaining in this family. Blainville introduced the generic name *Dermochelys* in 1816. The binomial refers to the distinctive leathery, scaleless skin of the adult turtle. The specific name, *coriacea,* was first used by Vandelli in 1761 and adopted by Linneaus in 1766 (NMFS & USFWS 1992).

Basic Description

The carapace of the leatherback is distinguished by a rubber-like texture unlike hard-shell sea turtles. It is black with white spots and has seven prominent longitudinal ridges, which taper posteriorly to a blunt point. No sharp angle is formed between the carapace and the plastron, resulting in the animal being somewhat barrel-shaped; hence one common name was "trunkback". Adult leatherbacks possess a pink spot on the top of their heads (Eckert et al. 2012), associated with the pineal gland (Wyneken 2001). The undersurface is mottled, pinkish-white and black and is highly variable. They have long clawless front flippers, pointed tooth-like cusps for foraging on soft body prey, and keratinized spines in the mouth and throat to retain prey as water is expelled from their mouths (Pritchard 2015). Mean curved carapace length for adult

females nesting in the United States Caribbean is 155 cm (61 in.) with weights of 262 to 506 kg (578 to 1274 lbs.) (NMFS & USFWS 1992). Leatherback hatchlings are dorsally mostly black and covered with bead-like scales appearing as stripes along the length of the back. Their long flippers, reaching lengths as long as the carapace, are margined in white.

Conservation Status

The United States Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) share jurisdiction for sea turtles under the Endangered Species Act (ESA) with the USFWS's responsibility for turtles on the beach and NMFS's jurisdiction in the marine environment. The leatherback sea turtle was listed as Endangered throughout its global range on June 2, 1970, under the Endangered Species Conservation Act of 1969 (35 FR 8491), the precursor to the Endangered Species Act of 1973, as amended (ESA; 16 U.S.C. 1531 *et seq*). The leatherback is included on Appendix I of CITES (Convention on International Trade in Endangered Species) that recognizes the species is threatened with extinction and in need of the greatest level of protection. The leatherback is listed as Vulnerable globally under the IUCN (International Union for Conservation of Nature) Red List though separate subpopulations (also called populations in ESA reviews) have different listings. Leatherback subpopulations in the Pacific have declined and, overall, the Pacific subpopulations are listed as Critically Endangered (Wallace et al. 2013). The Northwest Atlantic Ocean subpopulation is listed as Endangered (Wallace et al. 2013, the Northwest Atlantic Working Leatherback Group 2019).

Critical habitat for the leatherback was designated by USFWS for a small area in US Virgin Islands on September 26, 1978 (43 FR 43688) and by NMFS in marine waters adjacent to Sandy Point Beach on March 23, 1979 (44 FR 17710). On January 5, 2010, the National Marine Fisheries Service proposed regulation to revise the critical habitat designation for the endangered leatherback sea turtle by designating additional areas of protection within the Pacific Ocean. The proposed addition measures approximately 70.6 $mi.^2$ and was designated in January 2012 (77 FR 4170).

Status review of the leatherback has determined there are seven leatherback populations that meet the requirements of discreteness for consideration as distinct population segments (DPSs). Discreteness determination is based on genetics, tagging, satellite telemetry data, and physical factors such as land masses, oceanographic features, and currents. Leatherbacks observed in South Carolina fall within the Northwest (NW) Atlantic DPS (NMFS and USFWS 2020).

POPULATION SIZE AND DISTRIBUTION

The estimated worldwide nesting population of leatherbacks in 1995 was about 34,500 females on 28 major surveyed beaches, with a lower limit of about 26,200 and an upper limit of about 42,900 (Spotila et al. 1996). This is less than one third of the 1980 estimate of 115,000 (Spotila et al. 1996). The largest female nesting aggregation was once located in Gabon (Southeast Atlantic DPS) (Witt *et al.* 2009) but recent analysis shows a steep decline in numbers (NMFS & USFWS 2020). The Northwest Atlantic DPS population now hosts the largest number of female leatherbacks with the largest nesting aggregations occurring in Trinidad, French Guiana, and Panama

(NMFS & USFWS 2020). Leatherback nesting beaches are distributed circumglobally on tropical or subtropical beaches but also on some temperate beaches (Pritchard and Mortimer 1999, NMFS & USFWS 2020). In North America, the northeast coast of Florida was considered the northern limit for leatherback nesting. Nesting in Florida was once considered extremely rare, but now nests number in the hundreds annually (Stewart et al. 2011). Leatherback nesting has been confirmed in South Carolina but is considered a rare occurrence as the state lies beyond the northern edge of nesting range and nests laid in South Carolina typically are not successful. Since 1996, 36 leatherback nests have been documented in South Carolina (SCDNR unpublished data, 2024). Despite expansion of nesting occurring north of historical beaches, evidence of a decreasing nest trend has been observed at nesting beaches with greatest known female abundance in the NW Atlantic DPS (NMFS & USFWS 2020).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Leatherbacks' highly migratory nature, with extensive geographic range, ensures they are rarely encountered except females during nesting and because of such less is known about their overall life history. They are unique among sea turtles in the ability to thermoregulate (maintain their core temperature) utilizing countercurrent heat exchange and due to large size can avoid overheating while nesting (Friar et al. 1972, Greer et al. 1973). Leatherback adaptations such as low metabolic rate, large oxygen storage capacity, ability to withstand crushing hydrostatic pressures at depth, and tolerate cold water temperatures allow them to reach deep depths in the water column over 1 km (Doyle et al. 2008, Robinson and Paladino, 2015)

Mating between adult males and females is thought to occur prior to or during migration from foraging areas before females arrive in waters off nesting beaches. On occasion mating has occurred just off nesting beaches before commencement of actual nesting (Rostal 2015).

Nesting females prefer high-energy beaches with deep, unobstructed access to nesting sites from soft-bottom, deep-water approaches (Pritchard and Mortimer 1999; Eckert et al. 2012, 2015) that occur most frequently along continental shorelines. Foraging areas are typically where zones of upwelling occur including where major currents converge such as continental edges. (Saba 2013).

Leatherback movements are likely in response to seasonal abundance of macroplanktonic prey, jellyfish, their major food item. An annual migration of adult and sub-adult leatherbacks from the

wider Caribbean to the northwestern Atlantic results in spring and fall concentrations of leatherbacks in South Carolina waters. Nearshore concentrations of leatherbacks can occur from April to June during the northward migration when cannonball jellyfish (*Stomolophus meleagris*) are abundant. Based on strandings reported and live in-water observations, there is a second, less apparent peak, during the southward migration in October and November. (Murphy et al. 2006, SCDNR unpublished data).

Information on habitat requirements for post-hatchling and juvenile leatherbacks is limited, with individuals smaller than 100 cm (39 in.) in carapace length confined to waters > 26°C (79°F) Eckert et al. 2012).

CHALLENGES

Loss or degradation of nesting habitat from coastal development and beach armoring results in adverse impacts to leatherbacks. Even if a suitable sandy beach is available, nesting can be aborted because of beach furniture and equipment blocking access to nest sites.

Artificial light pollution along the coast is disruptive to both nesting adult females and emerging hatchlings. The presence of humans using flashlights or cell phone lights at night can also disrupt nesting females. Artificial lighting that illuminates the beach causes females to avoid certain areas to nest and disorients hatchlings when direct and timely migration to the ocean is critical to their survival. (NMFS & USFWS 1992).

Climate change is a potential threat to sea turtles as it may affect these species in three ways: loss of dry sand beaches to sea level rise or inundation of existing nests (Daniels et al. 1993; Fish et al. 2005; Baker et al. 2006); lethal high temperatures within the nest that would cause egg/hatchling mortality or decreased hatchling fitness; or a female-biased sex ratio of hatchlings due to increased nest temperatures (Glen and Mrosovsky 2004, Binckley and Spotila, 2015, Seaman and Milton 2023). Sea turtles, like some other reptiles, have temperature-dependent sex determination (TDSD), with higher temperatures favoring the development of female offspring and lower temperatures favoring males (Spotila 2004). Foraging grounds in the marine environment may also be affected as increased sea water temperatures alter prey species availability, foraging success and reproductive success (Goudarzi, F et al 2024, Spotila, Saba et al. 2015).

Egg clutches on beaches are subject to expected natural predators such as raccoons, coyotes, ghost crabs (*Ocypode quadratus*) (SCDNR, unpublished data, NMFS & USFWS 1992) and yellow crown night herons (*Nyctanassa violacea*) on the beach at night (NMFS & USFWS 1992).

Because of their very large front flippers, leatherbacks become entangled often in longlines, float lines of crab and lobster pots, buoy anchor lines, and other vertical ropes and cables existing in the water column. This can lead to serious injuries and/or death by drowning (NMFS & USFWS 1992; SCDNR unpublished data). Leatherbacks apparently mistake floating plastic bags and sheets for jellyfish and consume these materials. This can cause direct obstruction of the gut or absorption of toxic byproducts and reduced absorption of nutrients across the gut wall.

Mrosovsky (1981) reviewed data from leatherback stomach content studies worldwide and concluded that approximately 44% of the adults examined had plastic in their stomachs.

The shrimp trawl fishery also captured leatherbacks until Turtle Excluder Devices (TEDs) were enlarged to allow their escape. They are also vulnerable to boat and ship collisions, particularly when inhabiting shallow, near-shore waters. Lewison et al. (2004) integrated catch data from over 40 nations and by-catch data from 13 international observer programs. They estimate that 50,000 leatherbacks were likely taken as pelagic longline by-catch in 2000. Eckert and Sarti (1997) reported that, "mortality associated with the swordfish gillnet fisheries in Peru and Chile represents the single largest source of mortality for Eastern Pacific leatherbacks." Incidental mortality in fisheries, implicated in the collapse of the Eastern Pacific population, is a largely unaddressed problem worldwide (Eckert et al. 2012).

Vessel strikes continue to be a threat (NMFS & USFWS 2020). In South Carolina, leatherbacks are vulnerable to vessel strikes where interaction with large propellers lead to direct mortality (SCDNR, unpublished data).

Leatherbacks are still occasionally killed for meat and oil in the Caribbean (NMFS & USFWS 1992). The theft of eggs for local consumption was once a problem in the US Virgin Islands but has been all but eliminated because of nightly patrols and nest protection programs (NMFS & USFWS 1992).

CONSERVATION ACCOMPLISHMENTS

Since 1981, intensive nest survey and protection efforts have been implemented at Sandy Point, St. Croix, US Virgin Islands. In 1984, the US Fish and Wildlife Service purchased the 2.4 km (1.49 mi.) long nesting beach at Sandy Point, which became a National Wildlife Refuge and designated as Critical Habitat under the Endangered Species Act of 1973. In South Carolina, nearshore aerial surveys have documented the spatial and temporal distribution of leatherbacks since 1993. The leatherback Conservation Zone was established as part of the Contingency Plan in 1995 (60 FR 25260, May 12, 1995; 60 FR 25663, May 12, 1995). Additionally, leatherback-sized TEDs were required in all shrimp trawls by the National Marine Fishery Service in 2003.

On January 5, 2010, the National Marine Fisheries Service proposed regulation to revise the critical habitat designation for the endangered leatherback sea turtle by designating additional areas of protection within the Pacific Ocean. The proposed addition measures approximately 70.6 $mi.^2$ and was designated in January 2012 (77 FR 4170).

SCDNR continues to partner with and permit the South Carolina Aquarium Sea Turtle Care Center™, which opened in 2000, to provide medical care for sea turtles in need from both South Carolina waters and surrounding states. To date only one leatherback has been successfully rescued off a barrier island by SCDNR staff and rehabilitated in South Carolina. Leatherbacks do not normally respond well to captivity, even brief stints for rehabilitation. SCDNR partners with the South Carolina Aquarium staff on educational outreach.

In 2020 changes were made to the NMFS South Atlantic Regional Biological Opinion for dredging

activities because of multiple entanglement events associated with a dredging project in South Carolina waters. Gear modification requirements ensured leatherback would not get flipper caught in cable loops of vertical lines used to mark submerged pipelines.

CONSERVATION RECOMMENDATIONS

- Protect areas of high leatherback concentration in water from activities that can have a negative impact on leatherbacks such as longlines, set nets and trawl fisheries that do not require effective TEDs.
- Continue to monitor use of vertical lines for fisheries, dredging projects and other projects that may present a possibility of interaction.
- Continue to monitor presence of leatherbacks in South Carolina waters or just offshore to learn more about migratory paths and ensure protection against vessel interactions.
- Conduct education programs that inform the public about the detrimental impacts of litter on aquatic organisms like the leatherback to assist in reducing the volume of plastics in the marine environment.
- Provide protection from predators and erosion for any nests that are laid on the beaches.
- Continue to work with partners to model sea level rise with leatherback nesting beaches in South Carolina.
- Increase education of boaters to raise awareness of sea turtles in our coastal waters.
- Ensure a continued food source for leatherbacks by protecting the cannonball jellyfish from commercial over-harvest.
- Monitor stranded leatherbacks to determine the number, size, and distribution of mortalities and the source of tagged individuals.
- Perform post-mortem examinations of stranded leatherbacks to document cause of death, food habits, sex ratio, reproductive condition, and extent of ingestion of plastics.
- Continue to gain more information on leatherback distribution from the public through the Marine Turtle Conservation Program web site.

MEASURES OF SUCCESS

While Pacific populations of leatherbacks are in sharp decline, nesting populations in the Atlantic appear to be either declining or stable though nesting areas have expanded. South Carolina research and monitoring efforts will be an important component to document future population trends in this endangered and unique animal. An increase in the number of nests and nesting females may be considered a sign of successful management actions.

Loggerhead turtle

Caretta caretta

Contributors (2005): Sally Murphy and DuBose Griffin, SCDNR
Reviewed and Edited (2013): DuBose Griffin, SCDNR
Reviewed and Edited (2024): Michelle Pate, SCDNR

DESCRIPTION

Taxonomy and Basic Description

The loggerhead was described by Linnaeus (1758) and named *Testudo caretta.* Over the next two centuries more than 35 names were applied to the species (Dodd 1988), but there is now general agreement on *Caretta caretta* as the valid name. The carapace, head scales, and dorsal scales of the flippers of adult and juvenile loggerheads are reddish-brown to brown in color. The plastron, neck, ventral surface of the flippers, and margins of the head scales are cream to yellow in color, but with some variation. Adult loggerheads in the southeastern United States have a mean straight carapace length (SCL) of 92 cm and weigh about 116 kg (NMFS & USFWS 2008).

Hatchlings vary from light to dark brownish to dark gray dorsally, lacking the reddish-brown coloration of adults. Both pairs of flippers are dark brownish to dark gray with distinct white margins. The plastron and other ventral surfaces are a dull tan. Hatchlings have three dorsal keels (prominent spines extending from their scutes) on their carapace and two plastral keels. At emergence their mean straight carapace length is about 45 mm (1.8 in), and they weigh approximately 20 g (0.7oz) (NMFS & USFWS 2008).

Conservation Status

The United States Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) share jurisdiction for sea turtles under the Endangered Species Act (ESA), with the USFWS's responsibility for turtles on the beach and NMFS's jurisdiction in the marine environment. The loggerhead sea turtle was listed as threatened on July 28, 1978 (43 FR 32800) under the ESA. In 2011, the listing was later revised from a single threatened population to nine distinct population segments (DPSs) designated as either threatened or endangered (76 FR 58868). These DPSs are isolated from each other, considered discrete

populations, based on tagging data, telemetry studies, demography, and genetic data (76 FR 58868).

Within the Northwest Atlantic Ocean DPS there are five recovery units because loggerheads are a wide-ranging species, have multiple populations and varying ecological pressures, and differing threats in different parts of their range. The five recovery units include the Northern Recovery Unit, Peninsula Florida Recovery Unit, Dry Tortugas Recovery Unit, Northern Gulf of Mexico Recovery Unit, and the Greater Caribbean Recovery Unit (NMFS & USFWS 2008). Loggerhead sea turtles that nest in southern Virginia, North Carolina, South Carolina, and Georgia fall within the Northern Recovery Unit.

POPULATION SIZE AND DISTRIBUTION

The Northern Recovery Unit is the second largest loggerhead nesting assemblage in the US. Annual nest totals from beaches north of Florida averaged 5,125 nests from 1989-2008, representing approximately 1,272 nesting females per year (NMFS & USFWS 2008). South Carolina loggerhead nesting effort represents over 65% of the Northern Recovery Unit. Historically, the Northern Recovery Unit nesting population showed a significant declining trend of 1.3% annually from 1983-2008 (NMFS & USFWS 2008). Recent data indicate that the overall nesting trend may be stable, neither increasing nor decreasing (NMFS & USFWS 2023).

Research by the South Carolina Department of Natural Resources (SCDNR) Marine Resources Division indicates that juvenile loggerheads in coastal waters off GA, SC, and northern Florida are more abundant by an order of magnitude than they were in the late 1970's and early 1980's (Maier et al. 2004).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Adult females inhabit temperate coastal waters during the nesting season, from mid-May to mid-August. During this time of egg laying, the females are not feeding. After nesting, females migrate to foraging areas both north and south of their nesting beaches. The predominate pattern for South Carolina females is to move to the Mid-Atlantic Bight until November and then return south of Cape Hatteras, North Carolina during winter. In spring, they return to their same foraging area as the previous season. They repeat this until it is time for their breeding migration back to the nesting beach (Hawkes et al. 2011; Griffin et al. 2013). Females nest every three years for a good portion of loggerheads in South Carolina.

The loggerhead sea turtle nests on ocean beaches within the continental US from Texas to Virginia. They are the predominant species nesting on South Carolina coastal islands and estuarine shorelines with

suitable sand (NMFS & USFWS 2008). Nests are typically made between the high tide line and the primary dune front in dry sand.

For early life stages of hatchlings through ages 10-12 years, loggerheads maintain a pelagic existence living amongst sargassum weed and drifting with ocean currents (NMFS & USFWS 2008). Current data suggests hatchlings exhibit swimming instead of passive drifting during the sea turtle "lost years" (Putnam and Mansfield 2015). At 10-12 years of age, loggerheads return to inhabit nearshore coastal waters to also include creeks and tidal rivers of South Carolina's salt marshes.

Juveniles from the various Recovery Units mix on foraging grounds, which include estuarine, neritic, and continental shelf waters in the Gulf of Mexico and the eastern seaboard (NMFS & USFWS 2008). Juvenile loggerheads 40 to 91 cm in carapace length are found in South Carolina on a seasonal basis from early April through November.

CHALLENGES

Because of their highly migratory behavior, with life stages that occupy different habitats, conservation efforts for loggerhead populations in one country and/or state may be offset by activities in another.

One major challenge faced by loggerheads includes the loss or degradation of nesting habitat from sea level rise, erosion, coastal development, and beach armoring, although beach armoring is no longer allowed in South Carolina (Beachfront Management Act 1988), previously built rock revetments and sea walls exist. Even if a suitable sandy beach is available, nesting can be aborted because of beach furniture and equipment left overnight that blocks access to these suitable nest sites. Beach vitex (*Vitex rotundifolia*), an exotic introduced plant, found historically in areas in northern Georgetown and Horry Counties still exists in other communities.

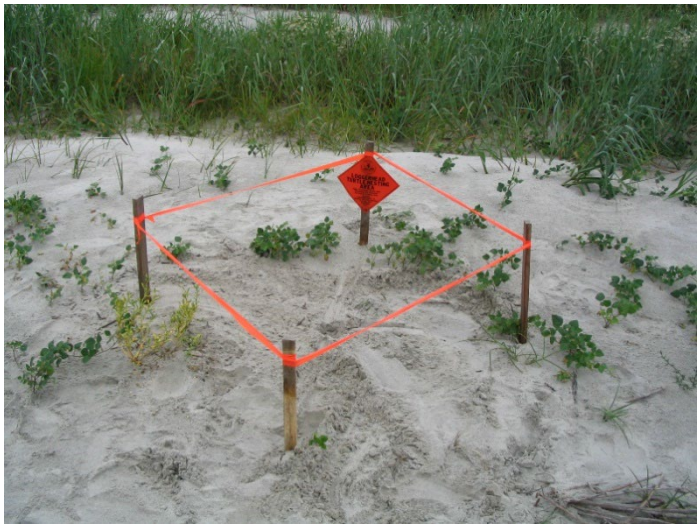
Climate change is a potential threat to sea turtles as it may affect these species in three ways: loss of dry sand beaches to sea level rise or inundation of existing nests (Daniels et al. 1993; Fish et al. 2005; Baker et al. 2006); lethal high temperatures within the nest that would cause egg/hatchling mortality or decreased hatchling fitness; or a female-biased sex ratio of hatchlings due to increased nest temperatures (Glen and Mrosovsky 2004). Sea turtles, like some other reptiles, have temperature-dependent sex determination (TDSD), with higher temperatures favoring the development of female offspring and lower temperatures favoring males (Spotila 2004; Wyneken and Lolavar 2015). Foraging grounds in the marine environment may also be affected as increased sea water temperatures and acidification alter prey species availability (Goudarzi, F et al 2024).

Artificial light pollution along the coast is disruptive to both nesting adult females and emerging hatchlings. The presence of humans using flashlights or cell phone lights at night can also disrupt nesting females. Artificial lighting that illuminates the beach causes females to avoid certain areas to nest and disorients hatchlings when direct and timely migration to the ocean is critical to their survival. Excessive predation by native and non-

native predators, as well as erosion and storm events, destroy nests. Coyotes, feral hogs, raccoons, foxes, and armadillos destroy loggerhead nests as well as negatively impact the maritime forest community on some coastal islands (NMFS & USFWS 2008). Killing of adult loggerheads on land is rare, but human poaching of turtle nests and clandestine markets for eggs may continue to be a problem (NMFS & USFWS 2008).

Another major impact on sea turtles can result from the incidental take in commercial fishing operations. Historically it was estimated that between 5,000 and 50,000 loggerheads were killed annually by the shrimping fleet in the southeastern Atlantic and Gulf of Mexico (National Research Council 1990) and this fishery was responsible for most adult loggerhead deaths at sea. All trawl fisheries operating in South Carolina now require the use of a turtle excluder device (TED) to prevent mortality of sea turtles and allow safe passage out of a net. The shark longline fishery, which operates all year long off the south Atlantic, may impact loggerheads in the neritic environment (Lewison et al. 2004). Loggerheads have been found entangled in a wide variety of materials including fishing line, crab pot lines, buoys associated with marking underwater equipment, rope, and discarded netting (NMFS & USFWS 2008; SCDNR unpublished data). They also ingest many types of marine pollution and debris, resulting in gut blockage (NMFS & USFWS 2008).

Vessel interaction (boat strikes) has become more prevalent and the predominant challenge for sea turtles occupying South Carolina waters. Upwards of one-third of the stranded sea turtles reported in South Carolina had wounds indicating some type of vessel interaction (SCDNR unpublished data).



The use of hopper dredges to manage material in shipping channels and other areas continues to be a threat to sea turtles, especially when allowed to operate during time periods when sea turtles are known to occupy those coastal areas (Van Dolah and Maier 1993; Arendt et al. 2012; SCDNR unpublished data).

Natural mortality factors in-water include predation by large sharks, disease, and parasites (NMFS & USFWS 2008).

Degradation of foraging habitat by physical damage occurs when there is trawling over live bottoms. Clam dredges can cause similar damage in areas further offshore. Over-harvesting of prey species, such as horseshoe crabs and whelks, can deprive loggerheads of their food resource, resulting in longer remigration intervals between nesting (Bjorndal 1997). Data on the quantity and quality of foraging habitat is scarce. Continued protection of foraging habitat, where loggerheads spend most of their time, and migration corridors is necessary to ensure minimal interaction with fishing operations and dredging operations.

CONSERVATION ACCOMPLISHMENTS

Some conservation accomplishments achieved for this species span a regional scale by federal agencies while others were made locally in South Carolina. The Sea Turtle Stranding and Salvage Network (STSSN) was established in 1980 to document the number of sea turtle carcasses that wash ashore.

The loggerhead turtle was designated the State Reptile of South Carolina in 1988 (Act # 588, June 1, 1988).

South Carolina became the first state to enact Turtle Excluder Device (TED) regulations in 1988. Federal regulations requiring TEDs in all waters throughout the year came into effect in 1991.

In 1991, South Carolina also became the first state to require the US Army Corps of Engineers to restrict hopper dredge channel maintenance to the winter months. However, recent changes to the South Atlantic Regional Biological Opinion for dredging (2020) have seen a removal of the previous seasonal hopper dredging windows.

South Carolina became the first state to enlarge TED openings in 2002. Federal regulations requiring larger TED openings came into effect in 2003.

SCDNR in conjunction with local electric service providers continues to produce and distribute large “Lights Out” causeway signs that are erected on roadways leading to beaches. Volunteer turtle projects produce newspaper articles and social media content to inform beach residents and visitors about the necessity to have lights out during the nesting and hatching seasons as well as other conservation measures to aid sea turtles.

Nest protection projects and an associated volunteer network were established along the South Carolina coast from 1981 to the present to increase hatchling productivity. Over 70% of the nests laid in South Carolina are under nest protection management and achieve at least a 60% hatching success (Hopkins-Murphy et al. 1999). Statewide aerial beach surveys were carried out from 1980 to 2007 to provide a standard index for monitoring the nesting population (Hopkins-Murphy et al. 2001). Currently, statewide on the ground beach surveys have replaced the aerial surveys and include an index beach portion to monitor the nesting population that consists of six beach projects continuously operating since 1982 under the same methodology. Use of *Vitex rotundiflora* (Beach Vitex) has been banned in at least 12 municipalities in North and South Caorlina to limit its further spread.

Since 2010 SCDNR has participated in a regional loggerhead genetics research study conducted by state sea turtle coordinators in Georgia, North Carolina, and South Carolina in collaboration with the University of Georgia to answer critical reproductive biological questions.

SCDNR Marine Turtle Conservation Program produced and installed signage on piers to educate anglers what to do in case of an incidental take of a sea turtle while recreational

fishing. Signs were produced in both English and Spanish.

SCDNR Marine Turtle Conservation Program produced and installed signage at boat ramps and marinas alerting boaters to the presence of sea turtles in our inshore waters to avoid collisions. Additionally, a QR code on the sign provides access to our ArcGIS Survey 123 online form to report live healthy sea turtles observed in the water during their travels.

SCDNR continues to partner with and permit the South Carolina Aquarium Sea Turtle Care Center™, which opened in 2000, to provide medical care for sea turtles in need from both South Carolina waters and surrounding states. SCDNR partners with the South Carolina Aquarium staff on educational outreach.

Endangered Species Act Section 6 funding from both the US Fish and Wildlife Service and the National Marine Fisheries Service provide program support for the SCDNR Marine Turtle Conservation Program.

CONSERVATION RECOMMENDATIONS

- Protect any remaining significant loggerhead nesting beaches that are still threatened with development through fee simple purchase or conservation easement (i.e. Bay Point).
- Continue to work with partners to model sea level rise with loggerhead nesting beaches in South Carolina.
- Establish partnerships to determine the quantity and quality of foraging habitat.
- Ensure that important nesting beaches destroyed by storm events are restored. Collaborate with the US Army Corps of Engineers to complete beach restoration projects.
- Reduce coyote, armadillo, and feral hog populations on coastal islands.
- Ensure that predator control is conducted on important loggerhead nesting beaches.
- Continue to monitor effects of a changing climate on sex ratios.
- Consider establishing Marine Protected Areas based on satellite telemetry data of adult female loggerheads on resident foraging areas. This should be done in collaboration with the Atlantic States Marine Fisheries Commission, Fisheries Management Councils, and relevant states.
- Work with the US Army Corps of Engineers to address changes in the South Atlantic Regional Biological Opinion for dredging (2020) where seasonal hopper dredging windows have been removed.
- Increase education of boaters to raise awareness of sea turtles in our coastal waters.
- Increase education of anglers both on land (piers, shore-based) and on boats regarding sea turtles in our coastal waters.
- Collaborate with other states in the southeast on emerging issues affecting loggerheads as the needs are identified.
- Ensure existing surveys that are providing a standardized index to the population are adequately funded.
- Continue to publicize and promote the “Lights Out” efforts and enlist the

assistance of electric utility companies when necessary.
- Continue to work with partners to establish coastal lighting ordinances in coastal counties to reduce artificial illumination of nesting beaches.
- Maintain and improve the SCDNR Marine Turtle Conservation Program web page.

MEASURES OF SUCCESS

As research and management needs are identified, we will initiate projects to address those needs. This was done previously with TED opening sizes when they were found to be too small and with the management of beach vitex through the establishment of a Beach Vitex Task Force using funding from a National Fish and Wildlife Foundation grant.

Because there are multiple threats to loggerheads, both on the nesting beaches and at sea, there are likewise multiple management strategies being implemented to bring about their recovery. We may not know which ones have been responsible for recovery of the species, should population numbers on nesting beaches begin to increase. The state will work to implement any Loggerhead Recovery Plan Tasks where South Carolina is the Responsible Agency.

DESCRIPTION

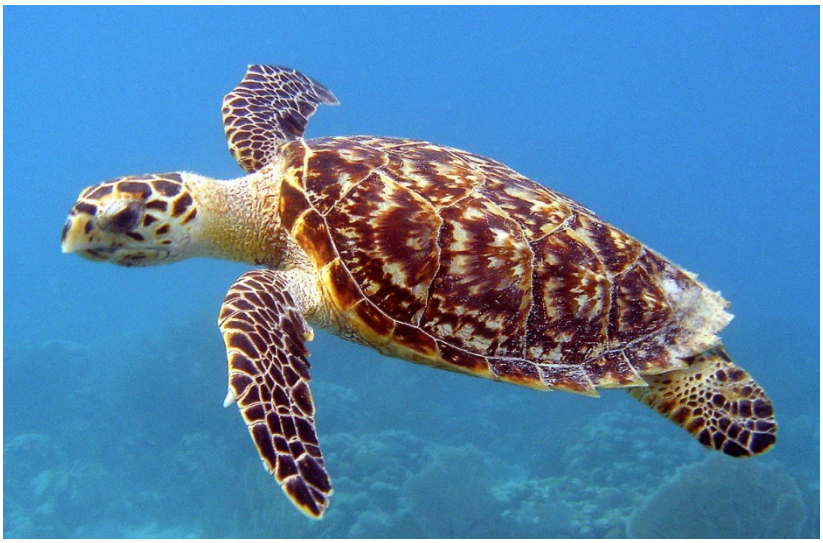
Taxonomy

Samuel Garman first described the Kemp's ridley sea turtle in 1880 as *Thalassochelys kempii*. It was named for Richard M. Kemp, a fisherman interested in natural history who submitted the type specimen from Key West, Florida (USFWS and NMFS 1992). Later *kempii* was allocated to the genus, *Lepidochelys*, when it was realized by Baur in 1890 that the Kemp's ridley and Indo-Pacific olive Ridley were congener. Others considered *L. kempii* as a sub-species of *L. olivacea*. A review by Pritchard justified their status as a full, separate species and this determination is accepted by most authors (USFWS and NMFS 1992).

Linnaeus described the green turtle in 1758 as *Testudo mydas*. Schweigger first applied the binomial, *Chelonia mydas,* in 1812. Although trinomials have been applied to various populations in the past, they are generally not in use today (NMFS and USFWS 1991).

The hawksbill was originally named *Testudo imbricata* by Linnaeus in 1766. Two subspecies (*Eretmochelys imbricata imbricata* in the Atlantic Ocean and *Eretmochelys imbricata bissa* in the Pacific and Indian oceans) are recognized. However, a complex pattern of phenotypic variation exists.

Basic Description



The Kemp's ridley turtle is one of the smallest and rarest of the seven sea turtle species; it has an adult straight carapace length of approximately 65 cm (26 in.) and weighs less than 45 kg (99 lbs.). Adults have an almost round carapace that is as wide as it is long. The coloration changes significantly during development from the almost black hatchlings to the lighter, grey-olive carapace and cream-white or yellowish plastron of adults. There are four inframarginal scutes, each of which contains a pore. Kemp's ridleys possess a hooked beak and almond shaped eyes. Hatchlings generally range from 42 to 48 mm (1.7 to 1.9 in.) straight carapace length and weigh between 15 and 20 g (0.5 and 0.7 oz.) (USFWS and NMFS 1992).

Green turtles are the largest of the hard-shelled sea turtles with adults reaching 1 m (3.3 ft.) in carapace length and 150 kg (330 lbs.) in weight as an adult. They have a smooth carapace with four pairs of lateral scutes and a single pair of elongated prefrontal scales between the eyes. The coloration changes significantly during development. The plastron remains a yellowish white, but the carapace changes color from solid black as a hatchling to a variety of shades of grey, green, brown and black in starburst or irregular patterns as juveniles and adults. Their name is derived from the green fat, or calipee, in their body due to their herbivorous diet. Different from loggerheads, green sea turtles have a significantly smaller head as compared to the rest of the body size as adults. They have a serrated lower jaw for tearing grass. Green turtle hatchlings are about 50 mm (2.0 in.) long and weight about 25 g (0.88 oz.).

Adult hawksbills shell length for nesting females varies between 62.5 and 95 cm (25.0 and 37.0 in.) in the Atlantic. Distinguishing features of hawksbills are four pairs of overlapping scutes, a long neck compared to other sea turtles, and beak-like mouth resembling a hawk that allows them to forage in hard-to-reach cracks and crevices. The adult shell is usually amber with streaks of red-brown, black-brown and/or yellow with the plastron whitish-yellow and may have black spots.

Status

Kemp's ridleys were listed as Endangered throughout their range on December 2, 1970, and are the most seriously endangered of the sea turtles (35 FR 18319). They are also listed as endangered by the International Union for the Conservation of Nature and Natural Resources (IUCN) and are listed in Appendix 1 of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) which prohibited all commercial international trade. The International Union for Conservation of Nature lists the Kemp's ridley as Critically Endangered.

Green turtles were listed as Threatened under the U.S. Endangered Species Act of 1973 on July 28, 1978. Breeding populations in Florida and on the Pacific coast of Mexico were listed as endangered (43 FR 32800). Critical habitat was designated to include waters surrounding Culebra Island, Puerto Rico and its outlying keys in 1998 (63 FR 46693). In 2016 the population was further recognized into eight distinct population segments (DPS) under the ESA with three DPSs listed as endangered and eight as threatened. The North Atlantic DPS, which includes greens nesting in South Carolina, is listed as Threatened (81 FR 20057).

Hawksbills were listed as Endangered in 1970 under the precursor to the Endangered Species Act (35 FR 8491). They are also listed as endangered by the International Union for the Conservation of Nature and Natural Resources (IUCN) and are listed in Appendix 1 of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES).

Kemp's ridleys and green turtles use South Carolina waters as developmental foraging grounds. Hawksbills are rarely seen in South Carolina waters.

POPULATION SIZE AND DISTRIBUTION

<u>Kemp's Ridley</u>

Kemp's ridleys have a restricted distribution with nesting primarily occurring on beaches in

western Gulf of Mexico. In 1947, over 42,000 nesting Kemp's ridleys were estimated in a single day's arribada (mass nesting) (Hildebrand 1963). Their numbers precipitously declined since then. The nesting population produced a low of 702 nests in 1985 (Ross et al. 1989). This initial decline was brought about by decades of harvesting females and the exploitation of eggs. Exploitation was brought under control in 1976 when Mexican marines and biologists began protecting nesting females and their nests. In 1978, the program expanded into an international effort with the assistance of United States biologists where among other goals a secondary nesting colony was established at Padre Island National Seashore in Texas (Ross et al. 1989). Since the mid-1980s, the number of nests laid in a season has been increasing primarily due to bi-national nest protection efforts and the implementation of TED regulations for shrimp trawlers. The total annual number of nests recorded at Rancho Nuevo and adjacent camps in Mexico has exceeded 10,000 in recent years (NMFS et al. 2011).

Green

Green sea turtles are found throughout the world in tropical and subtropical waters. In United States Atlantic waters, green turtles are found around the Virgin Islands, Puerto Rico, and in the continental United States in inshore and nearshore waters from Texas to Maine. (USFWS and NMFS 1992). Historically they were exploited for their fat, meat and eggs resulting in a global population decline. Green turtles were an important source of protein for coastal dwellers, commercial exploitation from the 16th to 18th centuries decimated stocks (Mager 1985) and were fished commercially in Florida and Texas (Hildebrand 1982). Conservation efforts implemented over the decades have improved population numbers.

Hawksbill

Female hawksbills are solitary nesters with nests laid quickly and hidden under vegetation (NMFS and USFWS 1993). Therefore, the hawksbill is a difficult turtle to census by aerial surveys. They nest in small numbers on remote beaches. The largest populations are found in the Caribbean, Indian, and Indo-Pacific Oceans. The largest nesting populations occur in Australia and Solomon Islands. Because of the general lack of intensive effort needed to survey hawksbill populations, reliable estimates for the population size are available for only a few localities. Major nesting and foraging areas in the United State territories in the North Atlantic occur in Puerto Rico and US Virgin Islands. The main cause of depletion of hawksbill populations is the direct harvest (NMFS and USFWS 1993).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Kemp's Ridleys

Kemp's ridleys nest primarily in the daytime on a beach near Rancho Nuevo in Tamaulipas, Mexico and require dry sand beaches for successful nesting. This locale is the only place in the world where large, synchronized nesting aggregations (arribadas) of the species are known to occur (TEWG 2000). Nesting has been documented along the coast of Texas (Shaver and Caillouet 1998) and occurs as a very rare event in the Carolinas and Florida (Bowen et Al. 1994).

Early life stages of hatchlings are assumed to be like other species of sea turtles where they maintain a pelagic existence drifting with ocean currents, either currents of the northern and western Gulf of Mexico or transported to the Gulf Stream of the Northwest Atlantic. The major

foraging habitat for Kemp's ridleys is the nearshore and inshore waters of the northern Gulf of Mexico as well as the Gulf of Campeche in the southern Gulf of Mexico. Kemp's ridleys are often found in salt marsh habitats. Though they do not typically nest in South Carolina, juveniles can be regularly found in South Carolina waters from April through November foraging in our salt marsh habitats and inshore waters. In recent years, the numbers of Kemp's ridley have increased significantly, indicating that the juvenile population in South Carolina's coastal waters is increasing (Duermit et al. 2017).

Green

Adult green sea turtles require dry sand beaches for successful nesting and are found in the Hawaiian Islands, Pacific Island territories, Puerto Rico, the Virgin Islands and Florida. The largest green nesting populations exist at Tortuguero (Costa Rica) and Raine Island (Australia). Nesting in Florida occurs from June through late September in almost every coastal county but is predominantly observed along the southeast coast. Nesting in Florida has been on the increase, although the annual nesting effort fluctuates from year to year. Between 2019 and 2023 green nest counts range between 26,656 to 77,040 (Florida Fish and Wildlife Conservation Commission). Nesting in significantly lower numbers occurs annually in North Carolina, South Carolina, Georgia and Texas.

Juvenile green sea turtles are herbivores but have also been found to consume small invertebrates and mollusks as well. As adults they are exclusively herbivores. Feeding grounds are relatively shallow, sheltered waters. Most commonly, these foraging habitats are pastures of seagrasses and/or algae. Hatchlings and post-hatchlings maintain a pelagic existence drifting with ocean currents. When they reach a carapace length of about 20 to 25 cm (7.9 to 9.8 in.), green turtles leave oceanic habitats and move into benthic habitats. Some feeding grounds only support certain size classes of green turtles; in South Carolina, juvenile green turtle size class ranging from 21 to 40 cm are the most common life stage found in coastal and estuarine waters of South Carolina. In recent years, the numbers of green turtle strandings have increased significantly, indicating that the juvenile population in South Carolina's coastal waters is increasing (Duermit et al. 2017) and that a fair number of juvenile greens may remain in South Carolina inshore waters over the winter.

Hawksbill

Hawksbills are a circumtropical species, preferring warm shallow water areas such as coral reefs, lagoons, shoals and bays. They are omnivorous (feeding on plants and animals) such as marine algae, sea grasses, soft corals, crustaceans and jellyfish, but sponges are the principal diet of hawksbills once they enter shallow coastal waters and begin feeding on the bottom (NMFS and USFWS 1993). The species has been recorded in the continental US from all the Gulf States and from along the eastern seaboard as far north as Massachusetts, but sightings north of Florida are rare (NMFS and USFWS 1993). Hawksbills are infrequent in South Carolina waters likely due to no coral reef habitat. No nesting of this species has occurred in South Carolina, although hybrid hawksbill/loggerhead nests were recorded in 2020, all laid by the same genetically identified female within the Cape Romain National Wildlife Refuge.

CHALLENGES

Coastal development and shoreline hardening and armoring could adversely affect nesting turtles resulting in loss or degradation of dry suitable nesting habitat. Even if a suitable sandy beach is available, nesting can be aborted because of beach furniture and equipment blocking access to nest sites. Beach vitex (*Vitex rotundifolia*), an exotic introduced plant, found historically in areas in northern Georgetown and Horry Counties. Its aggressive growth and impenetrable roots quickly cover the dunes, making them unsuitable for nesting.

Artificial light pollution along the coast is disruptive to both nesting adult females and emerging hatchlings. The presence of humans using flashlights or cell phone lights at night can also disrupt nesting females. Artificial lighting that illuminates the beach causes females to avoid certain areas to nest, misdirect females return to the ocean and disorients hatchlings when direct and timely migration to the ocean is critical to their survival. (NMFS & USFWS 1992).

Climate change is a potential threat to sea turtles as it may affect these species in three ways: (1) loss of dry sand beaches to sea level rise or inundation of existing nests (Daniels et al. 1993; Fish et al. 2005; Baker et al. 2006); (2) lethal high temperatures within the nest that would cause egg/hatchling mortality or decrease hatchling fitness; or (3) a female biased sex ratio of hatchlings due to increased nest temperatures (Glen and Mrosovsky 2004). Sea turtles, like some other reptiles, have temperature-dependent sex determination (TDSD) with higher temperatures favoring the development of female offspring and lower temperatures favoring males (Spotila 2004). Foraging grounds in the marine environment may also be affected as sea water temperatures increase. Warming waters can result in changes in the abundance and distribution of food resources, leading to shifts in migratory and or foraging ranges.

Loss or degradation of Foraging Habitat in the marine environment is another challenge. Anchors and anchor chains of cruise ships and yachts are destroying portions of the reefs, and some ships run aground, causing widespread damage (NMFS and USFWS 1993). Land-based runoff and coral bleaching events can damage coral reefs for which hawksbill rely on as a food resource. Bottom trawling can degrade live bottom habitat on the ocean floor. Sea turtles may ingest many types of marine pollution and debris which they mistake as food, resulting in gut blockage, disease and or death.

Egg clutches on beaches and emerging hatchlings are subject to native and non-native predators such as raccoons, coyotes, ghost crabs (*Ocypode quadratus*) especially in areas where nest management does not exist. Killing of adult greens is rare, but human poaching of turtle nests with clandestine markets for eggs continues to be a problem (NMFS and USFWS 1991). Sharks and other large fish predate on hatchlings and adults.

The main cause of depletion of hawksbill populations is direct harvest associated with the exploitation of eggs, meat, shell, and whole young animals that are stuffed and sold as curios to tourists (NMFS and USFWS 1993). However, the greatest challenge for this species is the continuing demand for “tortoise shell” or the carapace and plastral scutes of the animal. These are reworked to produce hairpins, broaches, fans, inlayed furniture, eyeglass frames and numerous other items (Mager 1985).

Vessel strikes continue to be a threat to sea turtles (NMFS & USFWS 1991; NMFS, USFWS &

SEMARNAT 2011). In South Carolina, greens and Kemp's ridley turtles are vulnerable to boat strikes where interaction with propellers and boat skegs lead to direct mortality and has become more prevalent over the years.

Challenges are associated with unintended captures especially larger juvenile and adult turtles from commercial fishing operations. Juvenile turtles appear to reside in the more sheltered estuarine creeks and marshes and are thus not typically exposed to the threat of incidental catch in shrimp trawlers. The shark longline fishery, which operates all year long off the south Atlantic, may impact sea turtles in the neritic environment.

Sea turtles can become entangled in a wide variety of fishing gear existing within the water column including fishing line, crab pot line, rope, onion sacks, and discarded netting. The unintended capture of sea turtles on fishing gear is an increasing challenge that can result in drowning or injuries that can lead to death or debilitation (swallowing hooks, flipper entanglement). The full scale of these unintended captures is not known as many are not reported or the carcass does not wash ashore. These types of events are typically observed with juvenile Kemp's ridleys and green sea turtles on hook and line fisheries and make up the largest cause of strandings for juvenile greens and Kemp's ridleys in South Carolina.

Cold Stunning is a condition where sea turtles become very weak and unable to swim when water temperatures fall below 50F (10C). Cold stun event regularly occurs in the northeast part of the United States (Massachusetts) from November through January with a small number of cases reported during the winter in South Carolina.

Green turtles develop lobulated tumors (fibropapilloma) on their skin, scales, scutes, eyes (including surrounding tissues), oral cavities, and viscera. The cause of this disease is unknown, but it has increased to epidemic proportions in areas as far apart as Florida and Hawaii (Balazs and Pooley 1991). Fibropapilloma was first positively confirmed on a sea turtle in South Carolina in 2014 and since then a few live captures or stranded carcasses in South Carolina have shown signs of this disease.

CONSERVATION ACCOMPLISHMENTS

Nest protection projects and an associated volunteer network were established along the South Carolina coast from 1981 to the present to monitor nesting activities and increase hatchling

productivity. Use of *Vitex rotundiflora* (Beach Vitex) has been banned in at least 12 municipalities in North and South Carolina to limit its further spread.

Kemp's ridley nesting beach protection at Rancho Nuevo has significantly increased over the past decades; there has also been an increase in the number of Kemp's ridley nests documented at Rancho Nuevo since 1985 (Márquez-M. et al. 2005). An increasing number of Kemp's ridley nests are being laid annually on the Texas coast, some of which are "head- started" turtles (Fontaine and Shaver 2005).

Green turtle nesting is increasing in Florida (Florida Fish and Wildlife Conservation Commission). Research into the cause of fibropapilloma in green turtles is progressing, and field studies have documented cases of natural remission of the disease (Hirama and Ehrhart 2002). This is encouraging since there was no known treatment or cure.

Japan ended import of hawksbill shell in 1993 and dropped its CITES reservation on sea turtles in 1994. Because Japan is the largest importer of hawksbill shells in the world, this should diminish the demand for the species (NMFS and USFWS 1993). The two most important hawksbill nesting beaches in the US Caribbean are now fully protected (NMFS and USFWS 1993).

The US ratified Optional Annex V of the MARPOL Protocol in 1987, which prohibits dumping of all plastics and fishing gear from all ships at sea (O'Hara et al. 1988).

SCDNR continues to partner with and permit the South Carolina Aquarium Sea Turtle Care Center™, which opened in 2000, to provide medical care for sea turtles in need from both South Carolina waters and surrounding states. Cases involving fibropapilloma are isolated from other turtles and tanks to ensure no spread of the disease while undergoing medical care. Removal of recreational fishing gear in a structured medical environment ensures a better outcome for turtles incidentally caught on hooks.

SCDNR Marine Turtle Conservation Program produced and installed signage on piers to educate anglers what to do in case of an incidental take of a sea turtle while recreational fishing. Signs were produced in both English and Spanish.

SCDNR Marine Turtle Conservation Program produced and installed signage at boat ramps and marinas alerting boaters to the presence of sea turtles in our inshore waters to avoid collisions. Additionally, a QR code on the sign provides access to our ArcGIS Survey 123 online form to report live healthy sea turtles observed in the water during their travels.

CONSERVATION RECOMMENDATIONS

- Ensure that live bottoms and marine algae habitats are protected from dredging and dredge spoil dumping through coordination with the US Army Corps of Engineers.
- Map the location of juvenile sea turtle foraging areas for inclusion in protected areas.
- Increase education of boaters to raise awareness of sea turtles in our coastal waters.
- Increase education of anglers both on land (piers, shore-based) and on boats regarding sea turtles in our coastal waters.

- Increase number of estuarine sample areas conducted by SCDNR's Marine Resources Division to discover new foraging areas for juvenile sea turtles.
- Monitor all known juvenile sea turtle foraging areas to document changes in habitat condition, species composition, abundance, and size classes in coordination with SCDNR's Marine Resources Division.
- Collaborate with other institutions, such as the South Carolina Aquarium and the College of Charleston, to protect juvenile sea turtles.

MEASURES OF SUCCESS

As new Recovery Plans are updated and Status Reviews are completed, we will review the needs of the species and implement research and/or management as indicated.
