P.O. BOX 167
COLUMBIA, SC 29202

FINAL
FEBRUARY 1, 2025

INTRODUCTION TO THE SUPPLEMENTAL VOLUME OF SPECIES AND GUILD ACCOUNTS

This Supplemental Volume: Priority Species and Habitat Accounts is a compilation of written accounts, each following a standardized format to make sure Required Elements 1-6 are included. Authors describe the species, their status, population size and distribution, habitat requirements, challenges faced, conservation accomplishments thus far, conservation recommendations for future action, and how to measure success.

This supplemental volume can also be found on the South Carolina Department of Natural Resources' (SCDNR) State Wildlife Action Plan (SWAP) website. In the main SWAP document, Chapter 6, the last column in Table 6-2 references how each individual Species of Greatest Conservation Need (SGCN) was incorporated into the Supplemental Volume—either individually or as part of a guild. However, the last column in the Plants taxa section references an Excel spreadsheet in the Supplemental Volume. It details each species' priority habitat associations as determined by the taxa committee and presented in a format reminiscent of those of Hamel (1992), Trani et al. (2007), and Wilson (1995) in which X's appear in rows and columns. The Insects and Allies taxa's last column contains generalized location and habitat associations if know. These alternative SGCN representations serve as the plant and insect alternative to the species/guild narrative approach as many of these species are so data deficient that there is not enough information to discuss. Although habitat needs and life history traits are not expounded upon for insects and plants, they are still viable portions of this SWAP as threats and action items are addressed for them in Chapter 4 of the SWAP.

DESCRIPTION

Taxonomy and Basic Description

The American Oystercatcher (*Haematopus palliatus*) is a large shorebird found only in coastal habitats. Five races are distributed in North, Central and South America on the Atlantic, Pacific and Gulf Coasts. On the Atlantic Coast of the United States, the eastern race of the American Oystercatcher (*Haematopus palliatus palliatus*) breeds from Massachusetts to Florida, with highest concentrations of wintering birds from Virginia to Florida (Humphrey 1990).

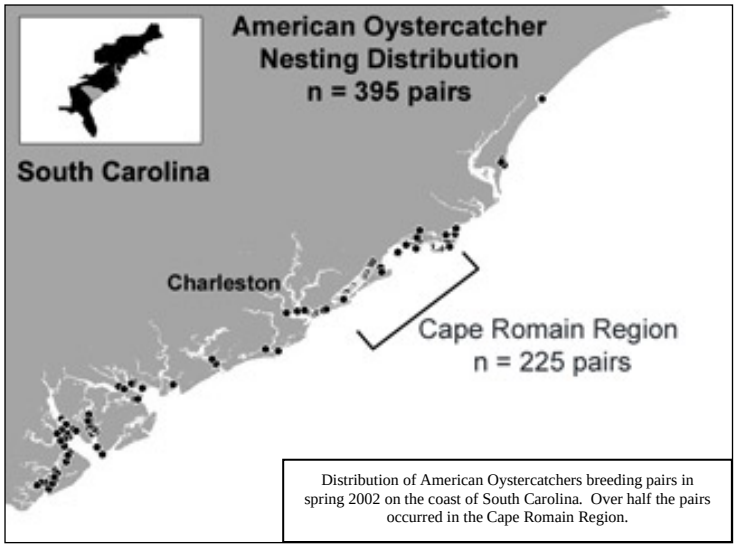
Oystercatchers have a long orange bill, specialized for prying open bivalves (oysters, mussels, clams, etc.). Yellow eyes and an orange eye ring contrast with a black head and dark brown back and wings. The abdomen and portions of the wings and tail are white while the legs are light pink. The juvenile oystercatcher's head and back are speckled brown and the tip of its bill is brown.

Status

Photograph of oystercatcher chick by Felicia Sanders

The eastern race of the American Oystercatcher has been identified as an extremely high priority shorebird in the US Shorebird Conservation Plan (Brown et al. 2001). The rationale for this designation is based on population estimates that total less than 25,000 birds and on threats to the race posed by the degradation of beach nesting habitat.

POPULATION SIZE AND DISTRIBUTION



South Carolina supports just over one third (3,536) of the estimated oystercatcher population that winters on the Atlantic and Gulf Coasts of the United States (approximately 10,000; Brown et al. 2003; Sanders et al. 2004). The most recent winter census conducted by Manomet in 2023 recorded 3,545 oystercatchers in South Carolina during February (S. Schulte personal communication, February 20, 2024). This late February survey did not cover most of the nesting habitat but focused on shell rakes with large wintering flocks. Many resident oystercatchers were already on their nesting territories in late February; thus the 2023 count may have underestimated

the number of wintering oystercatchers. These surveys suggest that during the last two decades, the American Oystercatcher population is stable to increasing.

Statewide surveys by SCDNR in 2002 and 2003 averaged 394 breeding pairs (Sanders 2008). A statewide survey in 2008 documented 453 pairs, but this increase may be a result of increased effort. Additionally, South Carolina has nonbreeding flocks during the summer. In 2002, 378 nonbreeding Oystercatchers and 383 in 2003 were recorded during statewide breeding season surveys (Sanders et al 2008). The Cape Romain Region of the South Carolina coast includes the Cape Romain National Wildlife Refuge (CRNWR) south to Dewees Inlet. Between 50 and 60% of South Carolina's wintering Oystercatchers are in this region. Censuses in the winter of 1988 and 1989 and again in 2001, suggest a 21% decline in Oystercatchers in the Cape Romain region over these 14 years (Marsh and Wilkinson 1991; Sanders et al. 2004).

In 2002, SCDNR estimated immature to adult ratios at all oystercatcher roost sites in South Carolina. Of the birds examined, 9% had immature bill coloration. This suggests that breeding success may not have been sufficient to maintain the population.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

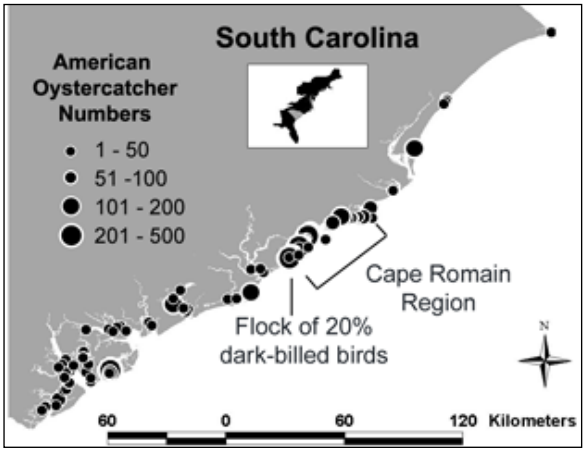
Distribution of American Oystercatchers breeding pairs in spring 2002 on the coast of South Carolina. Over half the pairs occurred in the Cape Romain Region.

Oystercatchers nest in coastal habitats with little vegetative cover. They lay their eggs in a shallow depression on sandy beaches, shell mounds and spoil islands. Although historically oystercatchers may have nested primarily on front beaches in South Carolina, statewide surveys documented only 28% of the breeding pairs on barrier island beaches, 27% on estuarine islands, and 45% on edge shell mounds. Out of all the pairs in South Carolina, 24% were on edge shell mounds adjacent to the Atlantic Intracoastal Waterway (AIWW) (Sanders et al. 2008). Oystercatchers are territorial and solitary or semi-colonial nesters. Nesting territory size is variable, but frequently only a few pairs will occupy a mile of beach or shell rake. Therefore, extensive coastal habitat is required to maintain the present nesting population.

During the winter, outer beaches are not used as much as in the breeding season. Statewide surveys during the winter documented 89% roosted at high tide on washed shell rakes, 6% on docks, 4% on barrier island beaches, and 1% on estuarine islands (Sanders et al 2004).

Oystercatchers feed on oyster bars, intertidal mud flats and sandbars. A study conducted in the Cape Romain Region during the winter found Eastern oysters comprised 95.4% of the items consumed by frequency while ribbed mussels and unidentifiable items comprised 3.8% and 0.8%

of consumed prey, respectively (Hand et al. 2010). During the nesting season, they utilize a more diverse range of bivalves, mollusks and other invertebrates near their nest site.



CHALLENGES

Oystercatchers are present in South Carolina during both the breeding and wintering seasons and are susceptible to catastrophic events such as hurricanes, oil spills, and harmful algal blooms.

Increased development of the South Carolina coast continues to reduce suitable oystercatcher nesting habitat and may force breeding pairs into less suitable sites. Although actual nesting sites are rarely destroyed, suitability of the sites is greatly reduced when nearby development increases disturbance of nesting birds. Disturbance from sources such as humans, dogs and boats negatively affects reproductive success by causing threatened oystercatchers to leave eggs and/or chicks unattended.

Oystercatcher nests are also at risk from native avian and mammalian predators. Recent studies in Cape Romain Region found chicks are also vulnerable to predation, and increases in American mink appear to be the primary cause of low chick survival. Human disturbance increases vulnerability to predation and can cause adults to abandon eggs. Nesting Oystercatchers are absent from areas with even moderate human disturbance.

Nests can also be destroyed by high tides and boat wakes; climate change is increasing the risk of nest wash-over. Barrier beaches, islands and shell rakes where Oystercatchers nest experience tidal inundation and the frequency and amplitude of coastal flooding has increased in the Charleston area with an average of 57 flood events a year since 2020 (Coastal Flooding Database: https://www.weather.gov/chs/coastal flood). During a 2-year study in the Cape Romain Region, overwash was the most frequently identified cause of nest loss of 200 oystercatcher nesting attempts (Thibault 2008).

Distribution of wintering American oystercatchers for 2002

In South Carolina, most wintering Oystercatchers roost in flocks of over 100 birds on shell rakes along heavily traveled waterways. In the Cape Romain Region, 75% of the wintering birds roost along the Atlantic Intracoastal Waterway. Increased boat traffic will increase the frequency at which birds are flushed from roost sites.

Because Oystercatchers feed primarily on shellfish, degradation of this resource through either disease or over-harvesting negatively affects oystercatchers. Healthy oyster reefs adjacent to nesting sites may be important for successful reproduction. Oystercatcher parents which had shellfish reefs adjacent to nest sites, spent more time at the nest site and fledged more chicks compared to parent oystercatchers nesting where shellfish reefs were not commonly adjacent to nest sites (Thibault et al. 2010).

CONSERVATION ACCOMPLISHMENTS

South Carolina over-winters the largest concentration of Oystercatchers on the Atlantic Coast of the United States. The winter population includes resident breeding birds as well as a large numbers of migratory Oystercatchers from all areas north. Statewide winter censuses have provided data on the abundance, age class partitioning, and distribution of Oystercatchers. Multi-year breeding season censuses provide data on abundance of nesting pairs and identify important nesting habitats. These surveys provide baseline numbers that are important for trend analysis. An American Oystercatcher working group was formed in 2001 to coordinate banding and survey efforts, prioritize conservation needs, and communicate evolving research techniques (American Oystercatcher Working Group, Nol & Humphrey, 2020). The working group's web site is an important tool to disseminate information on the status, management, and natural history of Oystercatchers (http://amoywg.org). The working group wrote a conservation plan for the species, and this plan is a guide for managers and researchers. Some important nesting areas, primarily on federal and state lands, are regularly closed to the public to allow Oystercatchers to nest undisturbed. Private coastal communities are also protecting select nesting sites and the number of communities willing to close portions of their beach for nesting birds continues to grow. Information about adult and juvenile survival rates, migratory patterns, and nest site fidelity has been collected from the color banding project. State wildlife grants funded research investigating nest success and causes and timing of nest loss in South Carolina (Thibault 2008). This research also piloted a head-starting program to test methods of increasing hatching success; research in this area is ongoing. Research on wintering foraging ecology identified prey items that are important for overwinter survival. A health assessment of Oystercatchers in the Cape Romain Region will serve as a baseline for future assessments (Carlson-Bremer et al 2010).

CONSERVATION RECOMMENDATIONS

- Protect American Oystercatchers during the nesting season, concentrating on public land. Adequate and timely posting and law enforcement may be required.
- Identify and protect important roost sites statewide. Identify important sites for protection during the permit review process.
- Continue cooperative efforts with the US Fish and Wildlife Service to census and manage nesting sites within Cape Romain National Wildlife Refuge (CRNWR). Control predators (especially raccoon and American mink) on important nesting areas and prioritize beaches that will benefit both sea turtles and shorebirds.
- Cannon net wintering Oystercatchers at high tide roosts to document the natal source of wintering birds and to color band resident breeding birds.
- Document adult mortality rates by annually monitoring color-banded adults on breeding territories. Adult mortality rates are required to evaluate the status of the species.
- Color band pre-flight chicks and monitor non-natal banded juveniles to determine movement and survivorship of juvenile Oystercatchers.
- Continue regionwide cooperative studies such as banding of wintering birds and resighting of color marked migratory birds.

- Develop standardized techniques to document nesting success and annual chick production because current estimates suggest that low reproductive success may be a limiting factor.
- Document important foraging areas and nocturnal roost locations using GPS and/or satellite tags. Protect these identified sites from disturbance.
- Evaluate possible state listing of the species to provide additional legal protection.
- Support research and conservation efforts to maintain a healthy marine environment, free of pollutants, and maintain or enhance shellfish populations.
- Conduct low tide observations of foraging oystercatchers to identify and quantify prey items taken during the nesting season.

MEASURES OF SUCCESS

As research and management needs are identified, we will initiate projects to address those needs. Factors leading to declines in oystercatcher populations are poorly understood and the rate of decline is poorly documented. As current population trends are documented and limiting factors are identified, appropriate research and management actions will be initiated.

Peregrine Falcon

Falco peregrinus anatum

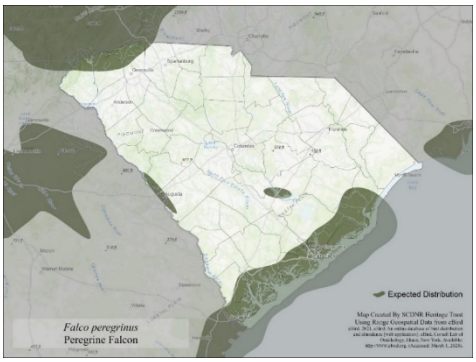
Contributors (2005): Ben Thatcher (USFWS) and Anna Huckabee Smith (SCDNR)
Reviewed and Edited (2012): Mary-Catherine Martin (SCDNR)
Reviewed and Edited (2024): Mary-Catherine Martin (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Peregrine Falcon is a crow-sized raptor in the family Falconidae (Order: Falconiformes). *F. p. anatum* adults have slate-gray upperparts, pale to buffy underparts with dark bars and spots, and a dark facial stripe from the eye down the side of the cheek (White et al. 2020). Immature birds are similar to adults, but with pale to brown upperparts and dark streaks on buffy underparts. Male Peregrines measure 36 to 49 cm (14 to 19 in.) while females measure 44 to 58 cm (17 to 23 in.).

Status



The Peregrine Falcon was listed as Federally Endangered in 1970 and transferred to the 1973 Endangered Species Act because of large-scale population declines from the 1950s to mid-1970s. The species saw total extirpation in the US east of the Rocky Mountains, and an overall reduction in North America to 324 nesting pairs in that time. Population declines were caused mainly by effects of synthetic organic chemicals, like DDT, on nesting success. After listing, Peregrine Falcon populations rebounded, largely due to captive breeding programs and reductions in DDT and other organic chemicals in the environment. By 1998, the species had returned to much of its former range and continental populations were viable. Therefore, the species was federally de-listed in 1999 (USFWS 2003).

As of 2003, the Peregrine Falcon was listed as endangered on the South Carolina Rare, Threatened and Endangered Species Inventory. In addition, the Peregrine Falcon and other birds of prey are protected by South Carolina state wildlife law section 50-11-852 which states that it is: “unlawful to molest or kill birds of prey.” Federal law protects the Peregrine Falcon under the Migratory Bird Treaty Act, while internationally, the Peregrine Falcon is protected under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES 1975).

POPULATION SIZE AND DISTRIBUTION

Peregrine Falcons have a worldwide distribution. In the United States, the species breeds in western, northern, midwestern and eastern states. Partners in Flight estimates a population of 72,000 birds in the US and Canada in 2023 (pif.birdconservancy.org).

In South Carolina, Peregrine Falcons have successfully bred at Table Rock State Park in Pickens County since 1990. The Table Rock nesting pair has produced on average at least 2 young each year through 2019 (Scott Stegenga, per. comm.) The state's second nesting pair of Peregrine Falcons appeared at Jocassee Gorges in 2008, and nesting activity continues to the present with an observation of 1 juvenile in 2023 (Ken Forrester, pers. comm.).

Distribution of Peregrine Falcon in SC

Most other Peregrine Falcon observations in South Carolina occur during the winter or migration. Post and Gauthreaux (1989) note the peregrine as an uncommon winter visitor on South Carolina's coast and a rare winter visitor to the coast, interior, or Piedmont of South Carolina. Monthly beachfront shorebird surveys conducted in Cape Romain National Wildlife Refuge from 2007 through 2016 observe the presence of Peregrine Falcons on barrier islands every month except for June, July, and August (CRNWR, USFWS, shorebird data). Research indicates that Peregrine Falcons from Greenland and eastern Canada migrate southward along South Carolina's coast, and some birds may remain through the winter (Fuller et al. 1998).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Peregrines breed in most North American terrestrial biomes, although occupied habitats usually contain cliffs for nesting with open gulfs of air for foraging (White et al. 2020). The species historically nested on ledges along cliffs 8 to 400 m (26 to 1,312 ft.) high. However, they will also use nest boxes and artificial structures like towers and buildings, as well as abandoned stick nests such as those previously built and occupied by Osprey, Red-tailed Hawk, Bald Eagle and Common Raven (White et al. 2020). Peregrine Falcon density is limited by availability of suitable nest locations and by territorial spacing (White et al. 2020).
Peregrine Falcons mainly prey upon birds (77 to 99% by frequency), ranging in size from Hummingbirds (2.5 to 3.5 g or 0.08 to 0.12 oz.) to small Canada Geese (1,400 g or 49 oz.). They also occasionally eat mammals, and rarely, amphibians, fish and insects. In North America, Peregrines eat more than 429 avian species and 23 mammal species, 10 of which are bats. Prey is usually captured in the air while the falcon is in flight, but also from the surface of the water or ground. The Peregrine Falcon generally captures prey with its feet and kills by dislocating the cervical vertebra. Surplus prey is cached (White et al. 2020).

During migration and the wintering period, peregrine falcons prefer wetland areas that have concentrations of waterfowl and shorebirds (White et. al. 2002).

CHALLENGES

Peregrines are sensitive to loss or modification of nest sites, though they can switch among alternate sites if more than one exists in a territory (White et al. 2020). They are also sensitive to human presence above a nest cliff (Cely, pers. comm.). Loss or degradation of wetlands may negatively impact non-breeding Peregrines. Continued conservation of this species will require more precise knowledge of breeding and potential breeding sites as well as information regarding winter distributions.

CONSERVATION ACCOMPLISHMENTS

By 1998, most North American populations had stabilized due to intensive captive breeding programs and reductions in DDT and other organic chemicals in the environment. The species was federally de-listed in 1999. In 2003 the "Monitoring Plan of the American Peregrine Falcon" was implemented by the USFWS. South Carolina's Peregrine Falcon nesting territories are within the Southeastern region, and reports are annually submitted on the status of nesting and number of fledged young. Annual closure of climbing areas in Table Rock State Park to prevent disturbance to Peregrine Falcon nesting sites occurs in coordination with the Carolina Climbers Coalition, state park staff, and SCDNR (carolinaclimbers.org).

CONSERVATION RECOMMENDATIONS

- Conduct statewide surveys to identify areas used by breeding and migrating Peregrine Falcons; especially survey state and federally owned coastal properties for migrating and wintering peregrine falcons.
- Protect existing and potential Peregrine Falcon nest sites from destruction, physical alteration and excessive human disturbances.
- Conserve barrier islands, inland lagoons and other coastal and inland wetlands that support abundant prey for migrating peregrines.
- Monitor nesting Peregrine Falcons and breeding productivity in coordination with USFWS personnel at the Table Rock and the Jocassee Gorges nesting sites.
- Conduct banding of juveniles and assessment of prey items at the present nesting locations to determine migration and foraging needs.

MEASURES OF SUCCESS

The protection of nesting and foraging sites should result in a net increase in South Carolina's Peregrine Falcon population and in an increase in use during migration. Peregrine population trends and distributions in South Carolina should be monitored over time to assess potential changes.

American Woodcock

Scolopax minor

Contributor (2005): Billy Dukes (SCDNR)
Reviewed and Edited (2012): Billy Dukes (SCDNR)
Reviewed and Edited (2024): Billy Dukes (SCDNR)

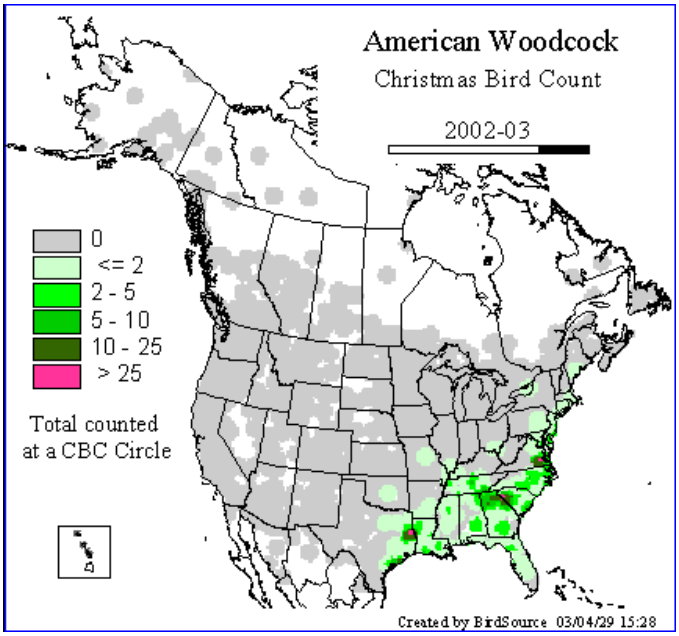
DESCRIPTION

Taxonomy and Basic Description

The commonly accepted scientific name of the American Woodcock is *Scolopax minor* (ITIS 2011) as described by Gmelin in 1789. Common names for Woodcock include “timberdoodle”, “bogsucker” and “wood snipe”. They are alternately characterized as marsh birds, shore birds or upland ground birds.

The Woodcock is a mottled brown bird, weighing from 125 to 240 g (4.4 to 8.5 oz.) (Owen and Krohn 1973) and averaging approximately 28 cm (11 in.) in total length (eNature 2012). The unusual physical appearance of the Woodcock is characterized by the bird’s buff-colored body, long beak, bulging eyes, and short wings. The diet of Woodcock consists primarily of earthworms, although other invertebrates and some vegetative matter are also consumed. Woodcock foraging for earthworms is aided by a prehensile beak, which allows Woodcock to grasp earthworms and extract them from below the soil surface (Krementz and Jackson 1999).

Status



The US Shorebird Conservation Plan (USSCP) lists Woodcock as a Species of High Concern and as a species known or thought to be declining (Brown et al. 2004). Woodcock are listed by the US Fish and Wildlife Service as a Game Bird Below Desired Condition (USFWS 2004). They are listed on the Audubon Watchlist “yellow list” of those species that are in slow decline and of national conservation concern (National Audubon Society 2004). Woodcock are identified as apparently secure (S4) in South Carolina and as secure (G5) globally and (NatureServe 2011).

POPULATION SIZE AND DISTRIBUTION

Woodcock are managed on the basis of two regions or populations, eastern and central, as recommended by Owen et al. (1977). Singing ground surveys from the US Fish and Wildlife Service indicate a significant long-term decline of 1.0% annually for Woodcock in the Eastern region (Cooper and Parker 2011).

The range of American Woodcock extends from the Maritime Provinces in southern Canada westward to southeastern Manitoba and southward into eastern Texas. All states east of this line are within the species' range. The principal breeding range includes New England and the Lake States, although limited breeding occurs throughout almost the entire range (Roberts 1989). The estimated population of Woodcock in North America is approximately 5 million individuals (Brown et al. 2004). North American Breeding Bird Survey (BBS) data indicate a 1.5 percent annual declining trend in the U.S. between the years 1966 and 2009 (Sauer et al. 2011). Christmas Bird Count data indicate no significant declining trend for South Carolina and North America (National Audubon Society 2012). Christmas Bird Count data also reveal higher wintering populations of Woodcock in the Lower Coastal Plain and Piedmont than in the Upper Coastal Plain of the State. Wintering Woodcock numbers peak between mid-December and mid-February in South Carolina Coastal Plain habitats (Pace and Wood 1979).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Unlike most other shorebirds and marsh birds, Woodcock are a forest-dwelling species. Woodcock are often associated with forested wetlands. In the Southeast, alluvial floodplains with a brushy forest understory are apparently a preferred habitat type. Swamp privet (*Forestiera acuminata*), holly (*Ilex* spp.), switch cane (*Arundinaria gigantea*), honeysuckle (*Lonicera japonica*), peppervine (*Ampelopsis arborea*), trumpet creeper (*Campsus radicans*), greenbriar (*Smilax* spp.), and grapes (*Vitis* spp.) have been identified as important understory species (Owen et al. 1977; Roberts 1989). The composition of the tree overstory appears unimportant (Owen et al. 1977).

Old fields, croplands, pasturelands, wet seeps, and damp thickets also provide important habitat for Woodcock on wintering grounds. Old fields and other early successional habitat types are

often used as nocturnal habitat and should be located within 230 m (251 yds.) of diurnal habitats (Berdeen and Krementz 1998). While a high density of plant stems is preferred by Woodcock, open ground underneath the canopy is a necessity to provide easy access to worms and other invertebrates in the ground litter (Roberts 1989; Krementz and Jackson 1999).

CHALLENGES

Declines in Woodcock populations are currently unexplained, but may be linked to natural forest succession within the breeding range of the species. Bottomland hardwood loss due to reservoir construction, drainage and clearing for agricultural uses and urbanization has negatively impacted the availability of winter habitat for Woodcock in the Southeast (Straw et al. 1994; Krementz and Jackson 1999).

CONSERVATION ACCOMPLISHMENTS

Although little research on Woodcock has been conducted in the past 35 years in South Carolina, research projects have been completed on Woodcock habitat selection, food habitat and migration chronology. Woodcock hunter surveys were conducted in 1983 and 1985 to provide information on hunter effort, harvest, and Woodcock age ratios. The Harvest Information Program (HIP) has been fully implemented nationwide and allows a better assessment of Woodcock hunter numbers and harvest in South Carolina. Comprehensive hunter harvest surveys were conducted for all species in South Carolina, including Woodcock, in 2000, 2003, and 2005. Since 1997, Woodcock flushing rates and harvest by South Carolina quail hunters have been tracked through annual quail and rabbit hunter surveys. Several large land acquisitions in South Carolina, notably Wee Tee State Forest, Bonneau Ferry Wildlife Management Area, Woodbury WMA, and Marsh WMA have preserved significant acreages of prime Woodcock wintering habitat. Forestry Best Management Practices (BMPs) now strongly encourage the conservation of Streamside Management Zones (SMZs), which persist as Woodcock wintering habitat following timber harvest operations.

A draft *Interim American Woodcock Harvest Strategy*, which sets regulatory packages and thresholds for regulatory changes, has been developed and implemented (USFWS 2010). Additionally, a strategy which prioritized research and information needs for improving habitat and harvest management decisions for American Woodcock has been developed (Case 2010). Finally, the *American Woodcock Conservation Plan* which identifies Woodcock habitat needs and sets goals for the restoration of breeding and wintering habitat across the range of the species was completed in 2008 (Kelley et al. 2008).

CONSERVATION RECOMMENDATIONS

- Focus habitat protection efforts (acquisition and easements) on significant tracts of bottomland hardwoods and isolated forested wetlands to preserve Woodcock wintering areas in South Carolina.
- Implement management practices that promote habitat diversity, like timber harvest and prescribed burning, on SCDNR lands with high potential to provide wintering habitat for Woodcock.

- Maintain early successional upland habitat associated with wetlands conservation efforts (acquisition, easements) to provide roosting habitat for Woodcock. Early-successional habitats can be maintained through prescribed burning.
- Using remote imagery, identify potential areas of Woodcock wintering habitat to guide habitat conservation efforts.
- Identify winter microhabitat requirements for Woodcock in South Carolina.
- Assess population densities of Woodcock on wintering grounds in South Carolina and the state's contribution to range-wide wintering populations.
- Increase the number of yearly Christmas Bird Count (CBC) routes.
- Monitor habitat loss through mapping of landscape-level habitat changes.
- Continue hunter surveys as an assessment of Woodcock hunting effort and harvest.
- Insure that upland buffers are included in the Wetlands Reserve Program (WRP) and similar programs, and that proper management practices are recommended and implemented to provide quality Woodcock habitat.
- Provide Woodcock habitat recommendations to natural resource agencies with management responsibility for extensive acreages of Woodcock habitat.
- Provide Woodcock habitat recommendations to private landowners through on-site technical assistance, fact sheets, management bulletins, and websites.
- Work with USFWS to identify Woodcock hunters in South Carolina and increase hunter participation in the Woodcock parts collection survey.
- Partner with other agencies and organizations such as the US Forest Service, US Fish and Wildlife Service, Clemson University and National Audubon Society (South Carolina Chapter) in order to conduct surveys for Woodcock.
- Provide DNR representation to the Association of Fish and Wildlife Agencies Migratory Shore and Upland Game Bird Working Group Woodcock Task Force to assist in setting rangewide priorities for Woodcock management, research and monitoring.
- Establish a dedicated funding source for management, research and monitoring of webless migratory game birds (including Woodcock) by combining the Migratory Game Bird (HIP) permit with the Migratory Waterfowl Permit.

MEASURES OF SUCCESS

Following identification of Woodcock winter habitat requirements in South Carolina, experimental habitat manipulations should be conducted to test habitat models. Woodcock flushing rates by rabbit hunters and quail hunters should continue to be monitored through the statewide Rabbit Hunter Survey and Quail Hunter Survey. Christmas Bird Count data should be utilized as a statewide index of wintering Woodcock populations and trends evaluated periodically to determine changes in winter population status. As opportunities arise, directed research should examine changes in wintering Woodcock densities, which occur as a result of incidental or intentional habitat manipulation. Woodcock winter habitat changes should be monitored through remote imagery and mapping.

Black-capped Petrel

Pterodroma hasitata

Contributors (2024): Cami Duquet (SCDNR), Yvan Satgé

Black-capped Petrel, Photo credit: USFWS

DESCRIPTION

Taxonomy and Basic Description

The Black-capped Petrel is a long-winged black and white seabird, in the gadfly (*Pterodroma*) petrel genus. It has a clearly defined black cap that is separated from the dark mantle by a white collar. The white upper tail which forms a 'U' shape on the upper tail coverts, differentiates it from other gadfly petrels in its range. In flight, it shows a white-black-white pattern, with mostly dark upperparts and light underneath. Varying amounts of dark and white plumage exist, with two distinct forms within the nominate subspecies, although the differences between the two forms are not well understood (Satgé et al. 2024).

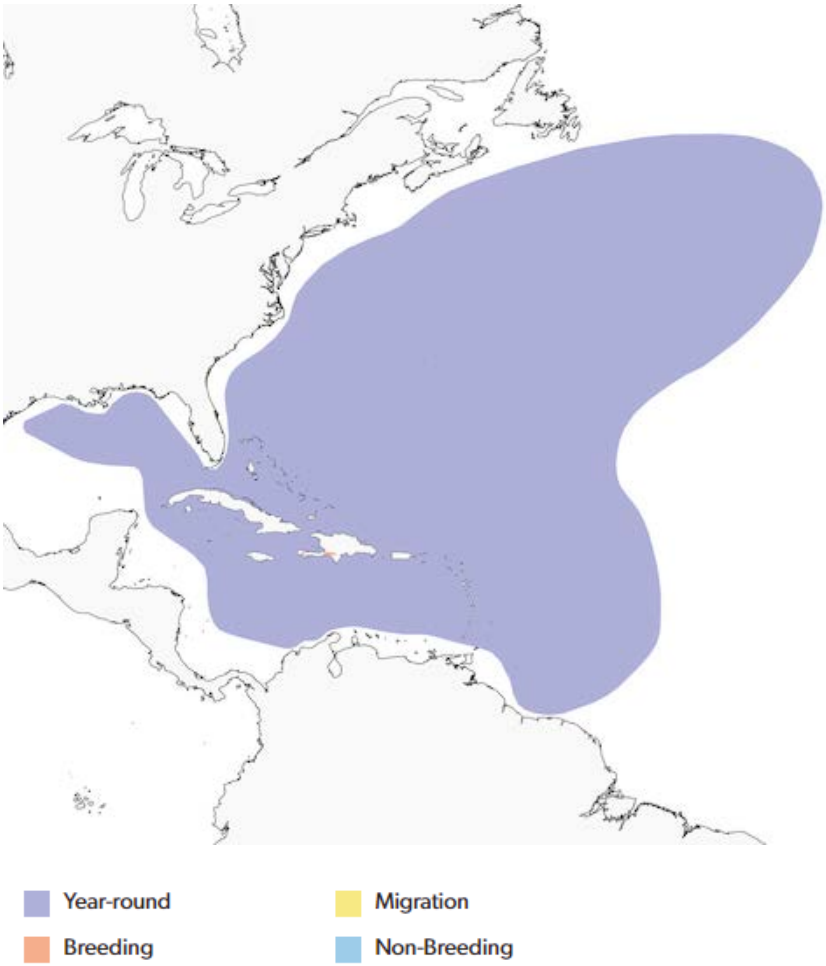
Black-capped Petrels are highly pelagic species and occur in tropical and sub-tropical waters in the western North Atlantic and adjacent basins of the Caribbean Sea and Gulf of Mexico (Simons et al. 2013). The South Atlantic Bight, the U.S. Coast from Cape Canaveral, Florida to Outer Banks of North Carolina, serves as the primary foraging region for the Black-capped Petrel during the nonbreeding season (Wheeler et al. 2021). During the breeding season, Black-capped Petrels come to land in the Caribbean region and nest in burrows in mountainous areas.

Status

In 2018, BirdLife International confirmed the endangered status of the bird on the IUCN red list due to its very small, fragmented, and declining breeding range and population. It stated that "declines are likely to continue as a result of habitat loss and degradation, hunting and invasive predators" (BirdLife International 2024).

In 2024, the Black-capped Petrel was listed as endangered under the U.S Endangered Species Act and considered in danger of extinction.

POPULATION SIZE AND DISTRIBUTION



Population estimates of the Black-capped Petrel are highly uncertain due to the difficulty in using conventional survey techniques by field researchers. Recent estimates cite 5000 individuals (Howell and Patterson 2008), others estimate 2000 breeding pairs (Ramos et al. 2017), while additional research offers ranges from 1000-2000 breeding pairs (Lee 2000) to 500-1000 breeding pairs (Simons et al. 2013).

Only a handful of breeding sites of Black-capped Petrels have been found and confirmed, located on Hispaniola. Additional islands in the Greater and Lesser Antilles may also provide breeding sites as suggested by historical records and recent evidence (Wheeler at al. 2021).

The South Atlantic Bight, the U.S. Coast from Cape Canaveral, Florida to Outer Banks of North Carolina, serves as the primary foraging region for the Black-capped Petrel during the nonbreeding season.

Concentrations of birds can be found along the Gulf Stream in southeastern US waters, including South Carolina, throughout the year, but are particularly common in mid-July to mid-October, during the nonbreeding season. Concentrations of adult birds during winter, when peak breeding activity is underway, also suggest that breeding birds forage along the Gulf Stream while commuting to and from breeding colonies (Simons et al. 2013).

Recent research tracking individual Black-capped Petrels outfitted with satellite tags confirmed their use of shelf waters west of the Gulf Stream offshore of Cape Hatteras, North Carolina and within the South Atlantic Bight post breeding season (Jodice et al. 2015, Satgé et al. 2023).

Distribution of Black-capped Petrel on land and at sea. Satgé et al. 2024 (reproduced with permission from the authors).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

At sea, the Black-capped Petrel is considered highly pelagic and associated with oceanographic features like the eddies and detached rings of the highly dynamic Gulf Stream and Loop Current. They make use of oceanographic fronts and the area used by petrels in the Atlantic outer continental shelf of the U.S. is also characterized by the mixing of Gulf Stream and upwelling waters associated with Cape Hatteras, North Carolina, and the Blake escarpment off South Carolina and Georgia. (Haney 1987, Jodice et al. 2015, Satgé et al. 2023). Abundance in Black-capped Petrels correlates with more significant upwelling caused by amplitudes in the Gulf Stream as it increases biomass of marine organisms that petrels feed on, specifically in the South Atlantic Bight and notably in Northern Georgia and Southern South Carolina (Haney 1987).

CHALLENGES

Potential threats and challenges faced by the Black-capped Petrels include introduced predators, human encroachment on breeding and foraging habitats, and offshore oil, gas, and wind energy development (Simons et al. 2013, Wheeler et al. 2021).

While the Black-capped Petrels' most significant threats occur on their breeding grounds, their declining numbers necessitate protection along their entire range including nonbreeding and foraging grounds, notably along the South Atlantic Bight including the South Carolina coast.

The increased pressure of offshore wind energy development could pose challenges for Black-capped Petrels as negative impacts of offshore wind energy for marine birds have proven to cause displacement due to avoidance or direct mortality from collision of turbines (Goodale and Milman, 2016). Already, offshore wind energy development in nearby North Carolina has caused concerns as the proposed development area directly overlaps with nutrient-rich waters where the species is known to forage.

Increase severity of storms and storm events will negatively impact Black-capped Petrels as they naturally aggregate in areas along the South Atlantic Bight in the direct path of likely future storms. Simulated models show a loss of 437 petrels over the next century from direct mortality of hurricanes (Hass 2012).

CONSERVATION ACCOMPLISHMENTS

No conservation initiatives have been set specifically for the Black-capped Petrel in South Carolina. Reports of sightings through eBird as well as from tracked individuals through GPS transmitters has provided data showing their presence in South Carolina waters.

Other groups and research initiatives outside of South Carolina have contributed to further protection and understanding of the species, including:

- Creation of the international Black-capped Petrel conservation group in 2008
- Production of the Conservation Action Plan for the Black-capped Petrel in 2010 and updated in 2021 (Goetz et al. 2012, Wheeler et al. 2021)
- Increased understanding of range and movements through tracking individuals with GPS/satellite transmitters (Jodice et al. 2015, Satgé et al. 2019 Satgé et al. 2023)

- Expanded monitoring efforts at known breeding sites to identify and reduce terrestrial threats (Wheeler et al. 2021)
  Increased public awareness and involvement of local communities to improve environmental conditions at breeding sites (Wheeler et al. 2021)

CONSERVATION RECOMMENDATIONS

- Protect foraging habitat for nonbreeding Black-capped Petrels feeding in South Carolina waters
- Establish systematic pelagic seabird surveys to monitor activity, movements, and quantity of Black-capped Petrels in South Carolina
- Get involved with the international Black-capped Petrel conservation group
- Review proposed offshore wind developments along the coast of South Carolina to include mitigations to counterbalance impacts on Black-capped Petrels

MEASURE OF SUCCESS:

As the above-mentioned action items are accomplished and yield valuable information, adaptive management procedures will be evaluated and implemented for this species.

Black Rail

Laterallus jamaicensis

Pair of Black Rails during courtship. Christy Hand, SCDNR.

Contributor (2013): Christine Hand (SCDNR)
Reviewed and Edited (2024): Christine Hand and Mikayla Thistle (SCDNR)

DESCRIPTION

Taxonomy and Basic Descriptions

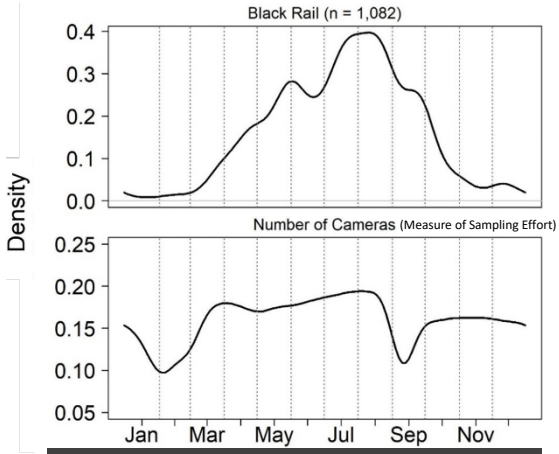
The Black Rail is the smallest North American rail measuring 10-15 cm (4 -6 in.) in length and 35 g (1.2 oz.) in weight (Eddleman *et al*. 1994). Adult rails have strikingly red irises, a dark gray to blackish head, gray neck and breast, rufous nape, and a black-and-white patterned back. Adult males have darker chins and breasts compared to females but are comparable in size (Eddleman *et al.* 1994). Chicks have dense black down, dark grey legs, brown eyes, and black beaks with a light pinkish band at the base. Juveniles are similar in appearance to adults but are duller overall (Sibley 2003). There are 5 subspecies, two of which nest in North America: the Eastern Black Rail (*L. jamaicensis jamaicensis*) and the California Black Rail (*L. jamaicensis coturniculus*). The Eastern Black Rail subspecies is found in along the Atlantic Coast, Gulf Coast, Colorado, and Midwestern region of the US (Eddleman *et al.* 1994).

Status

The Black Rail (Eastern subspecies) was federally listed as Threatened under the Endangered Species Act in 2020 (U.S. Fish & Wildlife Service (USFWS) 2020). In South Carolina, the Black Rail is a state "species of concern." The rail species present challenges in determining statuses due to a difficulty in detection as a result of their secretive nature and a general lack of information. IUCN lists Black Rails as Endangered, considers the Black Rail to be Tipping Point species, and placed the species on their Red Watch Lists due to their level of population threats (2024). Globally, the Black Rail is ranked as Vulnerable (G3) and the Eastern subspecies is ranked as Critically Imperiled (T1). In South Carolina, the Black Rail is ranked as Critically Imperiled (S1) and the Eastern subspecies has no ranking (NatureServe 2024). Breeding Bird Survey data are insufficient to estimate Black Rail population trends.

POPULATION SIZE AND DISTRIBUTION

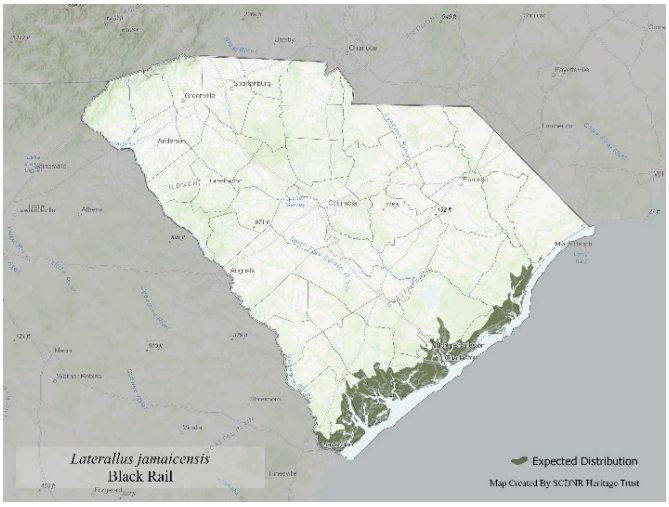
The historical breeding range of the Eastern Black Rail encompassed the Atlantic Coast from Connecticut to south Florida, the coastal plain of Texas, and inland states including Colorado, Kansas, Oklahoma, Minnesota, and Michigan (USFWS 2019). The Chesapeake Bay in the Mid-Atlantic region formerly was one of the most important strongholds for the species (Watts 2016). Particularly high and reliable numbers were consistently found in Maryland, Delaware, and New Jersey (Watts 2016, USFWS 2019). The Eastern Black Rail has experienced large population declines (by over 90% in the Mid-Atlantic since the early 1900s; Watts 2016) and range contractions. USFWS estimates that only 355-815 breeding pairs remain on the Atlantic Coast and approximately 1,299 individuals remained on the upper Texas coast prior to Hurricane



Harvey and other recent hurricanes (USFWS 2019). Without intervention to support population growth, USFWS predicts extirpation in 2068 (USFWS 2019). In South Carolina, USFWS (2019) and species experts estimated only 50 – 100 pairs persisted in 2016, prior to the recent storms and extreme flooding events that have occurred during vulnerable periods. Recent survey data suggest current numbers may be fewer than 50 pairs (C. Hand, personal observation).

Historically in South Carolina, Black Rails were considered to be a rare summer resident over much of the state (Sprunt and Chamberlain 1970). They have been observed in marshes in the coastal plain and in marshy meadows in scattered inland locations in South Carolina during the breeding season (LeGrand 1976, Watts 2016). Inland locations include an extensive marsh in Anderson County along Little Beaverdam Creek near its junction with Lake Hartwell, where a Black Rail was heard throughout the 1975 breeding season (LeGrand 1976). Mark Purcell reported seeing a Black Rail at Santee National Wildlife Refuge during the 2000's but details are unavailable. Declines in inland breeders were noted in 1976 in comparison to the beginning of the century (LeGrand 1976). No Black Rails were found in inland locations during surveys in 1991-1992 despite a concerted effort to find them (Cely *et al*. 1993). Historical and current records in the coastal plain are more numerous but also uncommon.

During statewide marsh bird surveys conducted by SCDNR during the 1991 and 1992 breeding seasons, Black Rails were detected 38 times at the following sites: Bear Island WMA (31), the Tom Yawkey Wildlife Center (5) and at the Santee Coastal Reserve (2). Extensive call-response surveys were conducted in South Carolina during 2014-2016 (Roach and Barrett 2015, Hand 2015, Hand 2016) and during 2024 (SCDNR, unpublished data). South Carolina breeding season surveys repeated 3–7 times per point per year produced detections at 32 of 283 points in 2015, 15 of 246 points in 2016, 13 of 48 points in 2017, 9 of 42 points in 2018, 9 of 54 points in 2019, 14 of 31 points in 2020, 8 of 51 points in 2021, 15 of 61 points in 2022, 13 of 88 points in 2023, and 12 of 149 points in 2024. The two SCDNR properties hosting the majority of the Black Rails detected during surveys from 1991 - 2024 have been resurveyed annually from 2017-2023 (Hand 2017a, Hand 2018a, Hand 2019, Hand 2020, Hand and Weitzel 2021, Hand 2022, and Hand 2023). All detections during 2024 occurred on these two properties.



South Carolina is recognized as one of four states with important remaining population centers in the Atlantic Coast Joint Venture geographic area (ACJV 2020). Small breeding populations are known to persist in the ACE Basin region and Santee Delta region, primarily on lands managed by the South Carolina Department of Natural Resources (Hand 2023). There was only one definitive nesting record prior to 2015, which occurred in 1903 (Wayne 1905, Post and Gauthreaux 1989). From 2015 – 2023, 72 broods of chicks have been documented (Hand 2023).

During the non-breeding season, Eastern Black Rails are generally thought to migrate to the southern portion of their breeding range (USFWS 2019). South Carolina provides habitat for Black Rails throughout the year (Sanders *et al*. 2021), but it is unclear if the Black Rails present during the winter are year-round residents, migrants from more northern areas of their range, or a combination of residents and migrants (C. Hand, personal observation). Currently, detections in South Carolina are substantially lower during the nonbreeding season. Previous high counts for the state (including 12 in Mount Pleasant on September 30, 1913, and 15-25 at Rochelle Plantation along the North Santee River on November 25, 1982 during a rice harvest; LeGrand 1983, Post and Gauthreaux 1989) occurred during the nonbreeding season when Black Rails were flushed as fields were cut during the harvest of hay, rice, or other grains. Rarely, Black Rails are still seen during the post-breeding season when vegetation is cut during the preparation of ponds and fields for wintering waterfowl.

Seasonality of detections of Eastern Black Rails (*Laterallus jamaicensis jamaicensis*) in Colleton County, South Carolina during 2018 – 2020. Density is based on the number of independent detections (detection events separated by 30 minutes) captured by camera traps and their respective time of year. Sanders *et al.* 2021

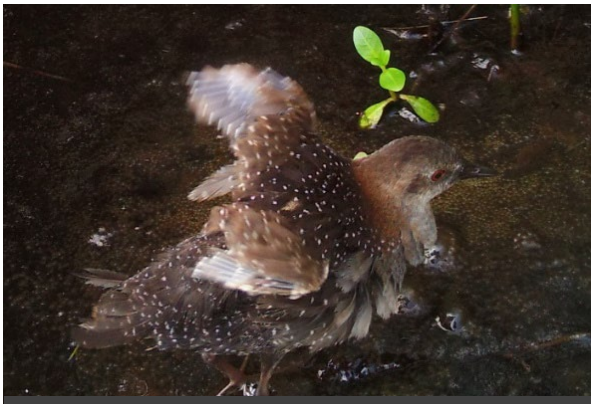
HABITAT AND NATURAL COMMUNITY REQUIREMENTS

As the smallest rail species in North America, with a tarsus (i.e., lower leg) length of less than an inch and particularly secretive habits, the Black Rail has very specific habitat requirements. Suitable habitat for Black Rails has four key habitat characteristics: 1) gently sloping or slightly uneven terrain that promotes a matrix of subtle depressions for forage (i.e., invertebrates and seeds) and ridges for nesting and refuge from flooding, 2) dense, clumping herbaceous vegetation providing both a canopy of overhead cover and openings or tunnels at the ground level allowing movement through the marsh without emerging into the open, 3) shallow brackish or fresh water that promotes moist soil conditions and depression pools (< 1 inch) at relatively consistent levels, but not stagnant, and 4) hydric wetland soil rich in organic material that retains moisture and supports desired plant communities and invertebrates (text excerpted from Hand *et al*. 2024).

In South Carolina, a handful of managed tidal impoundments in the coastal plain, as well as a few unimpounded tidal marshes, have consistently supported breeding Black Rails for decades (Hand 2023). The impoundments typically occupied by Black Rails were built using “dragline”

excavators to construct dikes around tidal marshes during the 20th century following the end of the rice era until the Clean Water Act of 1972 (Hand *et al*. 2024). This construction technique resulted in fields with uneven elevations including shallow depressions, subtle high areas, and elevational gradients adjacent to uplands. These impoundments are far less prevalent than the historical rice fields built by enslaved Africans during the 18th and 19th centuries (Hanks *et al*. 2021), which were relatively level to facilitate commodity-scale rice production. Tidal and inland historical rice fields are abundant throughout coastal South Carolina but rarely offer suitable physical characteristics for black rails unless topography is altered to create necessary elevational variations (Hand *et al*. 2024). Inland, Black Rails once were found in fields of hay or oats rather than the low, wet marshes and swamps preferred by other rail species (Sprunt and Chamberlain 1970).

Dominant vegetation in Black Rail habitat in South Carolina typically includes bunch grasses, sedges, rushes, and cattails. In particular, Black Rails are typically found in grasses such as sand cordgrass (*Spartina bakeri*) and saltmarsh cordgrass (*Spartina patens*) intermixed with species such as marsh fimbry (*Fimbristylis castanea*), chairmakers bulrush (*Schoenoplectus robustus*), black needlerush (*Juncus roemerianus)*, soft rush (*Juncus effusus*) and cattails (*Typha spp*.; Hand *et al*. 2020). Vegetation structure is more important than species composition and Black Rails will use diverse habitats across their range that meet water level, overhead cover, and food requirements. Vegetation composition provides clues about the microtopography and hydrology of the wetland. While non-clumping species can indicate high quality habitat when interspersed in small patches with clumping grasses, monocultures typically indicate water levels have been too deep and/or topography is too uniform.



Adult male Black Rail caring for three downy chicks (<1 week old). Young chicks are wobbly and have shorter legs compared to adults, so very shallow water depths are important. Photos: Christy Hand, SCDNR.

Cryptic nests are typically built in clumps of vegetation in elevated areas surrounded by a mix of small pools of very shallow water (1-3 cm; USFWS 2019) and areas with moist soil (Eddleman *et al.* 1994). Foraging habitat near nests sites is necessary because chicks begin foraging with assistance from their parents within a few days of hatching (Hand *et al.* 2021). Black Rails are believed to feed primarily on small invertebrates and seeds (Eddleman *et al.* 1994).

CHALLENGES

Decreasing habitat availability and quality likely plays a large role in population decline (Eddleman *et al*. 1994). Wetlands in the Southeastern United States represented 89% of the total wetland lost in the United States in the mid-1980s (Hefner *et al*. 1994). Rapid and expansive coastal development has created many challenges for Black Rails and other coastal species. In addition to direct habitat loss, development also alters the ways that remaining Black Rail habitat is managed.

Sea level rise and climate change are expected to be particularly detrimental to high marsh habitat. In addition to causing flooding during extreme high tides, higher low tides resulting from sea level rise prevent managers from letting out water from impoundments occupied by Black Rails. Increases in storm frequency and intensity may lower productivity if nests or foraging habitat are flooded. Flightless molt coincides with hurricane season (Hand *et al*. 2021) and the increasing severity and frequency of extreme rainfall events and period of drought are likely to reduce survival and productivity.

A flightless female Black Rail documented in a managed tidal impoundment in South Carolina. Christy Hand, SCDNR

Woody vegetation encroaches and shades out stands of desirable vegetation and clumping wetland plants become too dense over time and require a setback to reestablish ground-level tunnels. A variety of tools are available depending on the physical characteristics of the wetlands, time and funding, and overall management objectives for the property. Prescribed fire is an important tool but can result in the death of adults and chicks if precautions are not taken. Slow-burning (backing and flanking) fires that leave a mosaic of burned and unburned areas maintain suitable habitat for Black Rails. Ideally, prescribed burns should occur in late winter or early spring and be immediately followed by flooding to moist soil conditions. Maintaining saturated soil during prescribed fires may minimize the loss of desirable organic material, minimize detrimental effects on invertebrates, and ensure clumping grasses can regrow quickly. Best Management Practices for prescribed fire are provided in the U.S. Fish & Wildlife Service final listing published in the Federal Register (https://www.fws.gov/species-publication-action/threatened-species-status-eastern-black-rail-section-4d-rule-0) and South Carolina-specific details are available in Hand *et al*. (2024). Deep flooding during the nonbreeding season within impoundments also can be an effective tool to eliminate shrubs if the necessary infrastructure is in place (Hand and Weitzel 2021). In small areas, hand clearing and applying herbicide to cut stumps can be effective (Hand 2022).

Managed tidal impoundments provide essential habitat for a variety of waterbirds along the South Carolina coast. These impoundments also significantly contribute to the state's biodiversity. Traditional impoundment management practices prioritize management for wintering waterfowl and other species that benefit from deeper water and substantial fluctuations in water levels. With the exception of a few dragline impoundments where Black Rails have persisted under traditional management due to their unusual elevations and microtopography, traditional management rarely creates suitable nesting conditions for Black Rails. To optimize survival and productivity, it is necessary to prioritize management for Black Rails rather than attempting to manage for a variety of species simultaneously.

Ethical birding practices are particularly critical when seeking an observation of a rare species such as the Black Rail. As interest in birding and nature photography continues to increase, disturbance at popular birding spots has become a threat. Playback of Black Rail calls should not

be used to attempt to lure rails into view and the public should not walk into vegetation where Black Rails may be present. These actions have the potential to disturb birds, alter nest care, increase nest abandonment, trample nests or eggs, and may lead to increased predation (USFWS 2019).

Despite the many challenges faced by the species, some aspects of their ecology are encouraging. For example, SCDNR documented Black Rails successfully raising multiple broods within a breeding season (Hand 2020), and Black Rails can lay 6-8 eggs per clutch, which suggests the species has high reproductive potential if conditions are optimal throughout the breeding season. In addition, Black Rails are primarily found in managed wetlands in South Carolina, which offers more opportunities for habitat management compared to undeveloped tidal marshes.

CONSERVATION ACCOMPLISHMENTS

Color banded adult male Black Rail followed by a brood of chicks, Christy Hand, SCDNR

During the past decade, substantial conservation accomplishments have been made for the Eastern Black Rail in South Carolina and throughout their range. The USFWS has published a Species Status Assessment (USFWS 2019), which provides the basis for listing the species as Threatened under the federal Endangered Species Act (USFWS 2020). An updated Species Status Assessment incorporating new data will be published during 2026.

SCDNR, USFWS, and partners have implemented population monitoring using call-response surveys annually from 2014-2024 and participated in developing the range-wide Eastern Black Rail Call-Response Survey Protocol (Hand *et al*. 2023) to monitor for changes in distribution, status, and trends. Based on these survey data, SCDNR determined Black Rails primarily are breeding in dragline impoundments (Hand *et al*. 2024) and are very rarely found in historical rice fields during the breeding season, as was commonly believed (Roach and Barrett 2015).

Building upon research by a collaborator from Australia (Znidersic 2017), SCDNR adapted the use of motion-triggered camera traps (camera traps) to detect Black Rails, determine breeding phenology and breeding status (based on estimated hatch dates from 72 broods, Hand 2023), and determine flightless molt phenology and duration (Hand *et al.* 2019, Hand *et al.* 2021). SCDNR is now able to provide the following definition for these important periods: SCDNR defines the nesting and brooding period in South Carolina from April 1 to September 30 and the flightless molt period from August 1 to October 31 (Hand and Weitzel 2021; Hand *et al*. 2021). Black Rails have limited mobility and high food requirements during these periods; therefore, maintaining suitable habitat conditions increases their survival and reproductive success. These two periods of vulnerability offer the greatest opportunities to positively influence chick and adult survival. Land managers and regulators now prioritize water level management during these periods of elevated vulnerability with the goal of reducing adult mortality and increasing the survival of nests, chicks, and fledglings. Data collected by SCDNR using camera traps from 2015-2024 provided a new window into previously unknown aspects of Black Rail ecology and

vocalizations and will help to inform an update to the Cornell Lab of Ornithology's Birds of the World account for Black Rails (current edition: Eddleman *et al*. 1994). Using camera trap data, SCDNR determined Black Rails vocalize throughout the day and night and set crepuscular survey periods to coincide with peaks in activity. By conducting additional call-response surveys throughout the breeding and nonbreeding seasons, SCDNR determined Black Rails are present throughout the year in areas used for breeding, but numbers appear to be substantially lower during the winter (Sanders *et al*. 2021).

Autonomous recording units (ARUs) have the potential to increase detection probabilities and to allow intensive monitoring in areas of high management interest while reducing disturbance to Black Rails and their habitat and reducing personnel time. Beginning in 2015, SCDNR has been collecting acoustic recordings each year using ARUs. SCDNR co-leads the Eastern Black Rail Bioacoustics Team, a group of researchers from throughout the species range working to develop effective sampling techniques and processing workflows. SCDNR's dataset from wetlands occupied by Black Rails has been used to test and improve the capabilities of BirdNET (Kahl *et al*. 2021), a research platform using computer learning to identify bird calls within large acoustic datasets. BirdNET is now being used to identify Black Rail calls in past and current SCDNR ARU datasets to determine site occupancy and diel vocalization patterns.

SCDNR has researched habitat characteristics such as water depth/fluctuations and vegetation species and structure throughout the past decade using a variety of techniques. In collaboration with the Atlantic Coast Joint Venture (ACJV), the Conservation Media Team at the Cornell Lab of Ornithology, and SCDNR, Whiteout Solutions (https://whiteoutsolutions.com/) collected topobathymetric LiDAR & hyperspectral imagery data via unoccupied aerial systems (UAS) for the purpose of characterizing the microtopography and developing a method for modeling hydrology within Black Rail habitat using UAS-collected data and minimal field sampling. The ACJV is pursuing funding for a larger scale multi-state project.

Several resources providing guidance of habitat management for Black Rails have recently been published. USFWS released their *Eastern Black Rail Recovery Outline* (USFWS 2021) in 2021 and the full USFWS Recovery Plan is anticipated during 2024. The ACJV, which brings together public and private agencies, conservation groups, and other partners focused on the conservation of habitat for native birds, selected the Black Rail as one of their three flagship species in 2016. SCDNR collaborated throughout several years of work, and the ACJV finalized their *Black Rail Conservation Plan* (ACJV 2020) in 2020. SCDNR completed version 1.0 of the *Management Considerations and Recommendations for the Eastern Black Rail in South Carolina* during 2022 (Hand 2022) and worked with partners (USFWS, Nemours Wildlife Foundation, and Folk Land Management) to refine this document as a chapter in a booklet titled *Rice fields for wildlife: history, management recommendations and regulatory guidelines for South Carolina's managed tidal impoundments* (Folk *et al.* 2024) published by Nemours Wildlife Foundation and distributed to local property managers and landowners with managed tidal impoundments. In 2022, the Center for Conservation Biology published a report titled *Eastern Black Rail: Management Guidance* (Watts 2022) focused on management strategies for each population center in the Atlantic Coast Joint Venture geographic area.

To increase quantity and quality of habitat, SCDNR, the USFWS ACE Basin National Wildlife

Refuge, the U.S. Forest Service, and private landowners including the Nemours Wildlife Foundation have dedicated management units (impoundments) and begun intensively managing habitat specifically for Black Rails. In addition to implementing intensive water level management in dragline impoundments, South Carolina was the first state along the Atlantic coast to deploy irrigation systems with the goal of enhancing breeding habitat for Black Rails. Biologists in South Carolina began participating in ACJV Adaptive Management Project in 2022 after SCDNR received a Multi-state Competitive State Wildlife Grant focused on habitat creation through irrigation at the Tom Yawkey Wildlife Center and a grant through State of the Birds focused on optimizing reproductive success of Black Rails through habitat creation and management. Data from these projects will be used to inform future habitat management and creation projects throughout the subspecies range. To remove woody vegetation without temporarily making habitat unsuitable for the rails during the breeding season, Daniel Barrineau (SCDNR Wildlife Biologist) successfully deep flooded key impoundments during the winter. SCDNR also removed shrubs from nesting habitat using hand-cleared and very targeted herbicide treatments during the nonbreeding season.

Numerous outreach and public education activities have been conducted to raise awareness about the conservation needs and opportunities for Black Rails in South Carolina. During 2023, the South Carolina Black Rails working group was established with the mission of implementing "habitat management strategies relevant to South Carolina to advance Black Rail conservation by increasing habitat quantity and quality" (https://www.southcarolinablackrails.org/; Hand and Thistle 2023). During 2023, the Conservation Media Team at the Cornell Lab of Ornithology visited South Carolina to collect footage to create a short film to promote habitat management for Black Rails in the state (https://www.youtube.com/watch?v=e4m6xIl7ds8).

South Carolina Black Rails website.

The Post and Courier newspaper accompanied SCDNR in the field and featured a long-form story about Black Rail research and conservation on the front page of their September 10, 2020 edition ("Ghost Bird", https://www.postandcourier.com/longform/few-will-ever-see-scs-elusive-black-rail-will-climate-change-make-it-vanish-forever/article_fef70ae8-c1ea-11ea-a6dc-c795a69e5e82.html). SCDNR followed up with a blog post providing more detailed information about research and monitoring in South Carolina (Behind "Ghost Bird": Key Discoveries about the Elusive Black Rail https://www.southcarolinawild.org/2020/10/01/2020-9-28-behind-ghost-bird-key-discoveries-about-the-elusive-black-rail/).

Presentations about Black Rail ecology, management, and conservation were given for professional and public audiences including the Waterbird Society, ACE Basin Task Force, South Carolina Interagency Workshop, The Wildlife Society, South Carolina National Wildlife Refuges, Florida and North Carolina Black Rail Working Groups, Carolina Bird Club, and private landowner groups. In addition, USFWS and SCDNR participated in numerous site visits

and informal consultations with landowners and managers who are considering managing wetlands for Black Rails.

CONSERVATION RECOMMENDATIONS

- Overall
    - Implement Recovery Actions established by the *USFWS Recovery Outline for the Eastern Black Rail* (USFWS 2021) and future USFWS Recovery Plans as appropriate for South Carolina.

- Conduct Research to Inform Management Decisions
    - Continue to monitor the status of the Black Rail in South Carolina using standardized protocols provided by USFWS when available. Establish a long-term monitoring framework (e.g., frequency and extent of call-response surveys and sampling utilizing additional methods).
    - Identify potential inland habitat based on historical detections and current land use. Conduct sampling to determine if Black Rails are present and to quantify habitat characteristics. Determine if there are high potential opportunities to manage potential habitat for Black Rails farther from the coast.
    - Continue to collaborate with agencies throughout the range of the Eastern Black Rail to evaluate and improve monitoring methods and to establish standardized range-wide monitoring protocols. Ensure standardized protocols are appropriate for South Carolina by participating in protocol development teams. Standardized protocols for sampling habitat characteristics such as water depth and fluctuations, plant composition and structure, soil firmness, and soil composition are under development. Upcoming priorities include establishing standardized protocols for the use of autonomous acoustic recording units (ARUs), camera traps and evaluating the effectiveness of surveying for rails using thermal imaging from unoccupied aerial systems (UAS; Olsen *et al*. 2024) in South Carolina and determining optimal water depths and vegetation management schedules using data collected with UAS-based LiDAR.
    - Develop effective methods for sampling prey and seed abundance and availability to Black Rails.
    - Identify factors limiting productivity. Factors that should be considered include predation, invasive species (fire ants, feral cats, phragmites, etc.), prey availability, and nest flooding/unstable water levels.
    - Identify factors limiting adult survival and recruitment.

- Develop and Refine Habitat Management Strategies
    - Collaborate with biologists throughout the range of the Eastern Black Rail to develop and test habitat management strategies. Ensure South Carolina is represented in regional and national teams developing conservation and management plans.
    - Test and implement habitat management strategies including the strategies described in the *ACJV Black Rail Conservation Plan* (ACJV 2020) as appropriate. Contribute to the development of future conservation planning documents and

ensure recommendations relevant to South Carolina are included.
    - Develop, assess (through pilot studies), and refine habitat management strategies for dragline impoundments with suitable hydrology and topography.
    - Develop, assess (through pilot studies), and refine habitat management strategies for habitat creation strategies. Determine which site characteristics are necessary for successful habitat creation and management. Determine which techniques are effective for creating suitable conditions (e.g., re-grading and/or adding berms with machinery, irrigation from well or pond, soil amendments, and planting/seeding native plants with suitable structure.

- Implement Habitat Management Actions
    - Implement habitat management recommendations from *Management Considerations and Recommendations for the Eastern Black Rail in South Carolina* (Hand 2022, Hand *et al*. 2024). Excerpts from Hand *et al*. (2024) are included below. These recommendations apply specifically to South Carolina and are based on local knowledge and research. This information is also available through the South Carolina Black Rails working group website, which will be updated as our knowledge increases and we continue testing the recommended strategies (https://www.southcarolinablackrails.org/).
    - Targeted Impoundment Management: Dragline impoundments in coastal South Carolina provide the most immediate opportunities to rapidly incorporate management for Black Rails into existing management plans. A high level of personal commitment from individuals managing these wetlands is critical. The management of impoundments for Black Rails is difficult and time consuming because the rails require much narrower ranges of conditions compared to waterfowl, shorebirds, and wading birds. In wetlands where only a small amount of habitat is likely to be suitable and/or where management for other species is the priority, the incorporation of Black Rail-friendly management practices can still benefit rail conservation. Recommendations include 1) minimizing the magnitude of flooding during vulnerable periods (i.e., flightless molt and nesting and brood-rearing periods), 2) minimizing the duration of flooding during vulnerable periods, 3) minimizing or avoiding burning during vulnerable periods—especially during flightless molt, and 4) maintaining suitable grassy vegetation in high elevation areas of wetlands and in connected uplands. Clearing trees and shrubs from islands within wetlands may be sufficient to provide breeding habitat in wetlands that otherwise would be too deep.
    - Irrigation: Frequent, moderate rainfall often is necessary to create and maintain suitable conditions in both high tidal marsh and impounded habitat, however, rainfall is increasingly unpredictable (i.e., too much or too little). Electric and solar-powered irrigation can be used to supplement rainfall in grassy high marsh habitats such as dragline impoundments or former pastures that otherwise would frequently be too dry to provide suitable habitat. Irrigating this wet meadow habitat facilitates moist soil conditions by maintaining shallow pools of water in depressions while promoting water circulation.
    - Altering Topography and Hydrology: It may be possible to alter the topography and hydrology in wetlands or meadows that do not currently have compatible

characteristics. For example, material dug during quarter drain/canal cleanouts within historical rice fields may be used to create ridges or islands within impoundments that otherwise would be too deep during portions of the breeding season. Alternatively, cross-dikes can be installed to subdivide expansive impoundments to isolate areas with suitable topography and hydrology. New habitat should encompass a minimum of 2.5 continuous acres per breeding pair. Management of woody vegetation will be necessary to maintain newly created habitat and should be considered prior to construction.

- Vegetation Management: Managers should strive to maintain wet meadow conditions that favor clumping wetland plants (i.e., moist soil grasses, sedges, and forbs) while controlling for woody plant encroachment. To maintain suitable vegetation structure, it is necessary to actively manage for early successional habitat. Overly dry conditions can promote woody shrubs, particularly groundsel bush. Conversely, prolonged flooding may eliminate desirable clumping wetland plants (e.g., clump cordgrass, marsh fimbry) and establish monocultures of non-clumping wetland species (e.g., cattails, bulrushes, giant cordgrass). Black Rail management strategies require periodic vegetation management which should be conducted during nonbreeding seasons to maximize the amount of time habitat is available and minimize disturbance during breeding seasons
- Winter Flooding: Flooding during early November–February can be an effective method to kill shrubs and enrich the soil and associated invertebrate community. Due to infrastructure limitations (e.g., dike height), this method is not feasible in all impoundments. Traditionally, flooding during the spring and summer has been used to control vegetation; but flooding during these seasons diminishes or eliminates habitat when Black Rails are breeding. Care should be taken to avoid killing desirable vegetation with prolonged flooding. Managing water levels lower during March–October supports the growth of desirable vegetation (i.e., clump cordgrass and saltmarsh hay) while preventing monocultures of non-clumping species from forming.
- Mechanical Removal and/or Herbicide: When feasible, mechanical removal can be effective for managing small patches of habitat. This practice is most effective when followed-up by treating stumps with a wetland-approved broadleaf herbicide.
- Prescribed Fire: Stands of desirable vegetation may become too dense over time and require a setback to reestablish ground-level tunnels. Fire is an important tool for maintaining early successional grassland habitat but can result in the death of adults and chicks if precautions are not taken. Prescribed burns typically should occur in late winter or early spring and be immediately followed by flooding to moist soil conditions to promote desired plant growth and re-establish invertebrate communities. Maintaining saturated soil during prescribed fires may minimize the loss of desirable organic material, minimize detrimental effects on invertebrates, and ensure clumping grasses can regrow quickly. In addition, saturated soil may promote patchier burns, which are safer for Black Rails. Best Management Practices for prescribed fire must be followed and are provided in the U.S. Fish & Wildlife Service final listing published in the Federal Register (https://www.fws.gov/species-publication-action/threatened-species-status-

eastern-black-rail-section-4d-rule-0) and detailed below under Regulatory Information.
    - Wetland-Upland Interface Refugia: In addition to creating and maintaining breeding habitat, managing similar vegetation structure in adjacent higher elevation areas and connectivity between these habitats (i.e., the wetland-upland transition zone) can also benefit Black Rails as refugia during tropical storms and hurricanes.

- Support Outreach and Public Education
    - Continue and increase collaborations among partners within South Carolina and throughout the range of the Eastern Black Rail to effectively communicate about conservations opportunities to professional and public audiences, with a focus on providing information to landowners and managers with land with potential for management to benefit Black Rails. Coordinate with the ACE Basin Task Force.
    - Support the South Carolina Black Rails working group, which is a coalition of public and private organizations and individuals dedicated to promoting conservation for Black Rails in South Carolina by increasing habitat quantity and quality. As of 2024, working group members include wildlife management and conservation professionals from the South Carolina Department of Natural Resources, Nemours Wildlife Foundation, U.S. Fish & Wildlife Service (Charleston Ecological Services Office, Coastal Program, Partners for Fish and Wildlife Program, and Ernest F. Hollings ACE Basin National Wildlife Refuge), U.S. Forest Service, Atlantic Coast Joint Venture, Ducks Unlimited, American Bird Conservancy, Folk Land Management, and Audubon South Carolina.
    - Create accessible resources with impoundment management recommendations and recommendations for creating new non-tidal wet meadow habitat in pastures and other agricultural land.
    - Raise public awareness about status and conservation needs of the Black Rail.
    - When appropriate, advocate for Black Rail-friendly management on public and private properties. Assist property owners in securing cost-share funding for projects with high potential to contribute to the recovery of Black Rails.

MEASURES OF SUCCESS

The first measure of success would be to continue to implement long-term population monitoring studies which would yield information about distribution, population status, and trends. The next step is to increase quantity and quality of habitat by implementing the above-mentioned conservation recommendations. The ultimate measure of success is to increase populations to a sustainable level.

Black-throated Green Warbler (Wayne's race)

Setophaga virens wayneii

Contributor (2005): John Cely (SCDNR)
Reviewed and Edited (2012): John Gerwin (North Carolina Museum of Natural Sciences) and Anna Huckabee Smith (SCDNR)
Reviewed and Edited (2024): Amy Tegeler (SCDNR)

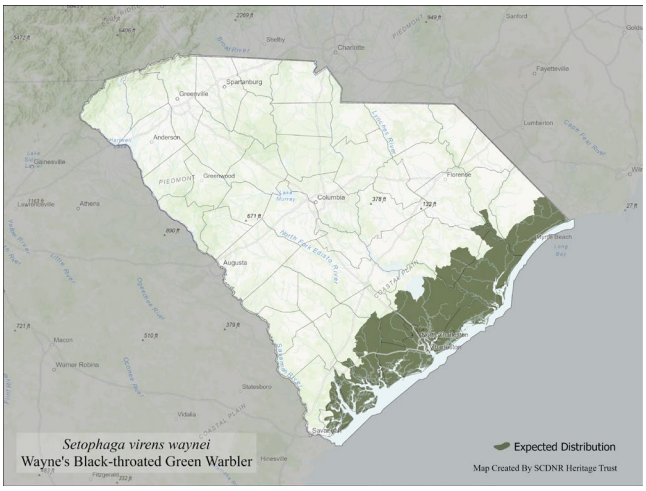
DESCRIPTION

Taxonomy and Basic Description

The Wayne's race of the Black-throated Green Warbler is recognized as highest priority in the SWAP. The more widespread nominate race was described by Gmelin in 1789, and is found in the Blue Ridge Ecoregion of South Carolina, whereas the subspecies known as "Wayne's" is confined to the Coastal Plain.

Black-throated Green Warbler males of all forms have a black throat with a bright yellow face while the females are duller in color (Morse and Poole 2020). The typical size of the nominate race is 11 to 12 cm (4.3-4.7 in.) (Morse and Poole 2020). Wayne's Black-throated Green Warbler is slightly smaller with a smaller bill (Morse and Poole 2020). Male Wayne's Black-throated Green Warblers also have slightly less extensive black bibs (Dias, pers. comm.). The coloration is olive on the back and crown with yellow on the head (Sauer et al. 2000). Black streaks are present on the sides while the wings have white bars (Sauer et al. 2000). The male has an additional black throat patch (Sauer et al. 2000). The breeding range, separated from the nominate race by more than 321.8 km (200 mi.) and a 609.6 m (2,000 ft.) elevational difference, consists of a narrow band of Atlantic white cedar (*Chamaecyparis thyoides*) stands, cypress (*Taxodium*) swamps, and other forested wetlands of the Outer Coastal Plain from southern Virginia to South Carolina.

Watts and Paxton (2002) noted that peak singing activity for Wayne's is around the end of April with a notable decrease after mid-May. This corresponds to its early spring arrival, usually the last 7 to 10 days of March in South Carolina.



Status

The Wayne's Black-throated Green Warbler is protected under the Migratory Bird Treaty Act. It is listed as a "species of special concern" by the South Carolina Department of Natural Resources (SCDNR). In addition, it and the nominate race are considered high priority landbirds by Partners in Flight (Partners in Flight Science Committee 2013). Wayne's is locally distributed

within a narrow belt of forested wetlands of the Outer Coastal Plain from southern Virginia to the Edisto River in South Carolina. Even within this narrow range, it is absent from some areas. The South Carolina Heritage Trust Program identifies the Wayne's race as imperiled to critically imperiled (S1S2B) in South Carolina. The nominate race is considered secure but the Wayne's race is considered critically imperiled (G5T1) globally. Population estimates and trends are not available for Wayne's Black-throated Green Warbler, but the nominate species has experienced a -4.58% population decrease from 1970 to 2014, and a -21.29% decrease from 2004 to 2014 (Panjabi et al. 2021).

The second-largest colony of Wayne's Black-throated Green Warblers in SC has dwindled to a few sporadic sightings. Other colonies have disappeared entirely since the mid-to-late 1990's (Dias, pers. comm.). Population levels in the Francis Marion National Forest and other areas that received heavy damage from Hurricane Hugo in 1989 did not begin a steep or noticeable decline until the mid to late 1990's. For example, the population in the drainage between the Wambaw Wilderness and the Little Wambaw Wilderness was South Carolina's second-largest population until 2000. Point counts conducted from mid-March to April of 1998 consistently yielded multiple singing males with a low count of 5 and a high count of 10. During surveys conducted between 2010 to 2014, a maximum of one or two singing males were counted; many surveys failed to identify any birds (Dias pers. comm.).

POPULATION SIZE AND DISTRIBUTION

The nominate race has a wide distribution which extends into Canada. The population is thought to be approximately 11,000 birds in South Carolina (Partners in Flight 2020). However, Wayne's race has one of the most restricted breeding distributions of any warbler in South Carolina or the Southeastern United States. It is rarely found further than 40 to 48 km (25 to 30 miles) inland from the coast. Prior to Hurricane Hugo, the habitat of the Francis Marion National Forest in Berkeley and Charleston Counties could have supported the largest population in South Carolina (Cely, pers. obs.). Even there, it was probably not common, based on 82-point counts conducted in the late 1970's. In these counts, Black-throated Green Warblers ranked 8th out of 12 breeding warblers (Hamel 1981). The Wayne's Black-throated Green Warbler has a spotty, and perhaps clumped, distribution within its limited range in the state. It is not known to occur in Horry County and much of northern Georgetown County. A population of unknown size and status occurs southwest of Charleston extending up, but not within, the Edisto River floodplain. Black-throated Green Warblers are not known to occur within the ACE Basin west of the Edisto. Population size and trends are unknown, although it is suspected of disappearing or declining from southeastern Virginia and parts of North Carolina (Watts and Paxton 2002) as well as areas devastated by Hurricane Hugo in South Carolina in 1989 (Cely pers. obs.). Wayne's Black-throated Green Warbler appear to winter in the Caribbean

Basin where additional threats to their populations may be occurring, but are unknown (NatureServe Explorer 2024).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The nominate race is typically found in coniferous stands of white pine/hemlock in the Blue Ridge Ecoregion of South Carolina with an apparent attraction for stage 3 to stage 4 oak-hickory stands that graded into coves that were devoid of hemlocks or white pines Huckabee pers. obs.). In contrast to the nominate Black-throated Green Warbler, the Wayne's race occurs along the Coastal Plain and prefers stands of deciduous or cypress trees.

In coastal South Carolina, Wayne's Black-throated Green Warblers avoid the big blackwater rivers, except for a stretch of Wambaw Creek near the South Santee River. They remain in areas around the slow-moving headwaters of blackwater creeks and the swamps and swamp borders that feed blackwater rivers and their tributaries. South Carolina colonies sometimes occur in isolated Cypress-Tupelo swamps amidst drier pine-hardwoods habitat.

In southern Virginia and coastal North Carolina, Wayne's Black-throated Green Warblers are closely associated with Atlantic white cedar. Where cedar is scarce or absent, such as coastal South Carolina, these birds are found primarily in non-alluvial forested wetlands or transitional zones between upland and wetland, where, as a canopy or subcanopy species, it uses blackgum (*Nyssa sylvatica*), laurel oak (*Quercus laurifolia*), sweetgum (*Liquidamber styraciflua*), bald cypress (*T. distichum*), "wet" loblolly pine (*Pinus taeda*), and red maple (*Acer rubrum*). It is rare to see this species without the presence of pond cypress, sweet gum, and black gum, and they are almost always located near water tupelo (*Nyssa aquatica*) (N. Dias, pers. comm.). Wayne's Black-throated Green Warblers are sometimes found in small or headwater riparian forests, but most observers suggest an association with forest stands growing in non-alluvial muck swamp. In Virginia and North Carolina, Watts and Paxton (2002) found higher than expected warbler use in survey plots containing loblolly pine, Atlantic white cedar, and bald cypress and less than expected use in those plots with pond pine *(P.serotina*) and hardwoods. This may help to explain the bird's absence in pond pine-dominated Carolina bays in Horry County. However, a 2021 study in NC found Wayne's Black-throated Green Warbler nests in loblolly bay, loblolly pine, red maple, and pond pine trees, all within swampy sites (Worm and Carpenter 2021). Wayne's Black-throated Green Warblers are not known to occur in large and medium outer coastal plain floodplain forests such as those associated with the Waccamaw, Great Pee Dee, Black, and Santee Rivers.

In the Francis Marion National Forest, Hamel (1981) noted most foraging and behavioral observations occurred between 10 and 17 m (32.8 and 55.7 ft.), similar to that of the pine warbler (*D. pinus*) and yellow-throated warbler (*D. dominica*). More than 50% of behavioral observations were made in laurel oak, blackgum, sweetgum, and water oak (*Q. nigra*). Red maple was used sparingly, and a subjective impression was that the species was found in forest stands with a high site index (Hamel 1981). Male Wayne's Black-throated Green Warblers favor sweet gum trees for singing perches, even with taller cypress or tupelo trees nearby (Dias pers comm.).

CHALLENGES

Based on its very restricted breeding range, apparent decline in parts of this range, and the fact that almost nothing is known about its breeding biology, status, and habitat use, the Wayne's Black-throated Green Warbler should be considered a high priority landbird species for research and survey efforts in South Carolina.

As a canopy/subcanopy species, short timber rotations may negatively affect the nominate race and subspecies (Cely pers. obs.; Sprunt 1953; Morse and Poole 2020). Alterations of hydrology and wetland drainage also pose potential problems. Additionally, Hurricane Hugo opened up many habitats to Brown-headed Cowbirds. The I'On Swamp Road in the Francis Marion National Forest used to have breeding Wayne's warblers without sightings of Brown-headed Cowbirds. Currently, the opposite is true—Brown-headed Cowbirds are often seen while very few Wayne's warblers are noted. However, effects of nest predation have not been studied in depth.

Like most Neotropical migrants, the Black-throated Green Warbler is probably area-sensitive and may require thousands of acres of suitable habitat in large blocks to sustain long-term population viability. No information is available on wintering grounds habitat use.

CONSERVATION ACCOMPLISHMENTS

Past surveys for Wayne's Black-throated Green Warbler were coordinated through the Cape Romain Bird Observatory (Dias pers. comm.). These studies have confirmed that Wayne's Black-throated Green Warbler is declining precipitously in South Carolina. Researchers tried to plot all known present breeding locations, develop a plant index at each site, and document the locations of suitable habitat on private lands, especially plantations.

Some private lands, especially those with easements or long timber rotations, may offer some protection as well. The protected Francis Marion National Forest probably has the main concentration of the species in South Carolina.

CONSERVATION RECOMMENDATIONS

- Investigate the possible benefits of Streamside Management Zones and buffers to Wayne's Black-throated Green Warblers, with particular attention to characterization of width, extent, and configuration.
- Complete intensive surveys to locate as many potential breeding populations of Wayne's Black-throated Green Warblers within the State as possible.
- Support adoption of Brown-headed Cowbird control measures near identified breeding locations of Wayne's Black-throated Green Warblers.
- Conduct in-depth investigations of Wayne's Black-throated Green Warbler breeding biology and habitat use once breeding populations have been identified. Locate nests and determine nesting success and nesting habitat, site fidelity, foraging behavior, and habitat use. At least two such study areas should be established, if possible, for comparative purposes.

- Develop a statistically valid monitoring protocol for Wayne's Black-throated Green Warblers.
- Determine wintering locations, migration corridors, and stopover sites for Wayne's Black-throated Green Warblers.
- Issue news releases and information to the public, constituent groups and conservation organizations. Biologists and researchers should work closely with landowners and the forest products industry to provide management data as it becomes available.
- Establish habitat protection measures for Wayne's Black-throated Green Warbler, including easements, Best Management Practices, and acquisition where feasible.

MEASURES OF SUCCESS

After determining habitat use, management guidelines should be provided to landowners and agencies. Adaptive management techniques should be utilized when opportunities arise. The development of a valid monitoring protocol for the Wayne's race will facilitate the periodic evaluation of population health and allow for appropriate corrective measures when declines occur.

DESCRIPTION

Taxonomy and Basic Description

This guild ranges from the diminutive Least Tern (wingspan of 50.8 cm or 20 in.) to the sizeable Brown Pelican (wingspan of 228.6 cm or 90 in.). Members represent 2 families and are grouped into a guild because they nest on small coastal islands in mixed colonies. The 2 families are: Pelecanidae (pelicans) and Laridae (gulls and terns).

Smallest of the North American terns, the Least Tern measures 21 to 23 cm (8.3 to 9.1 in.). This tern has a black cap with a white forehead. Least Terns are grey above and white below with two black outer primaries. The bill is yellow with a dark tip (Thompson et al. 2020).

Least Tern, Photo by USFWS

The Sandwich Tern is intermediate in size between the Royal and Common Terns. Sandwich Terns are sized 34 to 45 cm (13.4 to 17.7 in.) and weigh between 180 and 300 g (6.3 to 10.6 oz.). This tern is the only crested tern with a black bill, the tip of which is yellow. They are uniformly gray above, darker on their outer primaries, and have a white rump and tail. Underneath, Sandwich Terns are white with dark grayish edges under the primaries. The cap is entirely black with a spiky crest (Shealer et al. 2020).

Sandwich Tern, Photo by Erin Weeks/SCDNR

The Gull-billed Tern is another medium-sized tern measuring 33 to 38 cm (13 to 15 in.) (Molina et al. 2023). The Gull-billed Tern has a black bill and is similar in size to the Sandwich but has a stockier, gull-like build, longer legs, and a thicker, shorter bill. The upper wing of the Gull-billed Tern is uniform with a black line on the edge of the primaries, a gray rump, and a similar tail. Gull-billed Terns have black ear patches during the nonbreeding season (Molina et al.2023).

Gull-billed Tern, Photo by Felicia Sanders/SCDNR

Common Terns are medium-sized terns with a length of 31 to 35 cm (12.2 to 13.8 in.), including elongated outer tail feathers forming a 6 to 9 cm (2.4 to 3.5 in.) fork. These terns weigh between 110 and 145 g (43 to 57oz.). Adult breeding Common Terns are light gray above and below with a black cap, orangish-red legs, and an orange-red bill with black tip. There is extensive black on outer primaries that is obvious on the closed wing (Arnold et al. 2020)

Common Tern: Photo by USFWS

Forster's Terns are typically 33 to 36 cm (13 to 14 in.) long and weigh 130 to 190 g (4.6 to 7.0 oz.). Both sexes are mostly white during the breeding season with a black cap, pale gray wings, and a deeply forked tail. These terns have orange legs and variably black-tipped orange bills (McNicholl et al. 2020).

The Royal Tern is the largest crested tern with a length of 45 to 50 cm (18 to 20 in.) and a weight of 350 to 450 g (12 to 16 oz.). Both sexes of the Royal Tern have long, orange bills and forked tails. The breeding plumage of the Royal Tern is gray above and white below with a full black cap and shaggy crest. The rump is very pale gray with a white tail. The legs and feet are black and the eyes dark brown (Buckley et al. 2021).

Royal Terns: Photo by Felicia Sanders/SCDNR

The Black Skimmer is a slim bird with a black back and white belly. Males and females vary greatly in size with lengths between 40 and 50 cm (16 to 20 in.). Weight for females averages 265 g (9.3 oz.) while male weights average 365 g (12.9 oz.). The bill of the Black Skimmer is unique: half red and half black, long, and laterally flattened. The bill of the male Black Skimmer is larger than the bill of the female Black Skimmer (Gochfield et al. 2020).

Black Skimmers: Photo by Felicia Sanders/SCDNR

The Brown Pelican is one of two North American pelican species and is easily distinguished from its counterpart, the American White Pelican. American White Pelicans are larger with white bodies and black primaries. Brown Pelicans are gray to gray-brown with a black-brown belly. This coastal seabird is very large, measuring 100 to 137 cm (3.3 to 4.5 ft.) with a long bill (25 to 38 cm, 9.8 to 14.9 in.) and extensible gular pouch (Shields 2020).

Status

Least Terns are listed as South Carolina state threatened. Coastal populations have no official federal designation since they are common along the Gulf and Atlantic Coasts. Nevertheless, Least Terns are classified as threatened, endangered or a species of concern for most states because of the loss of nesting habitat (Thompson et al. 2020).

Brown Pelicans were formally listed as endangered throughout their range in 1970, but were removed from the list in Alabama, Florida, Georgia, South Carolina, North Carolina, and other areas of the Atlantic coast in 1985as both numbers and reproductive success recovered (Shields 2020). Gull-billed Terns and Black Skimmers are listed as South Carolina state species of concern.

POPULATION SIZE AND DISTRIBUTION

This guild of birds supports populations with thousands of nesting pairs. All of these birds are subject to loss of suitable nesting habitat, which can cause abrupt changes in numbers. Members of this guild are probably at much lower population levels than they were historically. Common and Forster's Terns are peripheral and occur in low numbers. Figures 1 through 6 show the minimum number of nests recorded for each species as part of the statewide seabird census, running from 1989 to present day. A more detailed status review through 1996 can be found in Wilkinson (1997) with Royal Tern, Sandwich Tern, and Brown Pelican trends found in Jodice et al. (2007) in figure 7.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Seabirds usually nest on isolated coastal islands that are high enough to avoid over-washing and too small to support mammalian predators. Most active nesting sites in the state are in Charleston County. Three of the islands with the multiple species of nesting seabirds are made from or augmented with dredge material. Due to erosion of natural sites from extreme high tides and storms these types of islands may be more common in the future. Nesting occurs in habitats ranging from bare sand and shell to low grass or shrub vegetation. The ends of larger barrier islands are used by several species. Nesting colonies serve as information exchange centers to facilitate location of prey that has a patchy and changing distribution

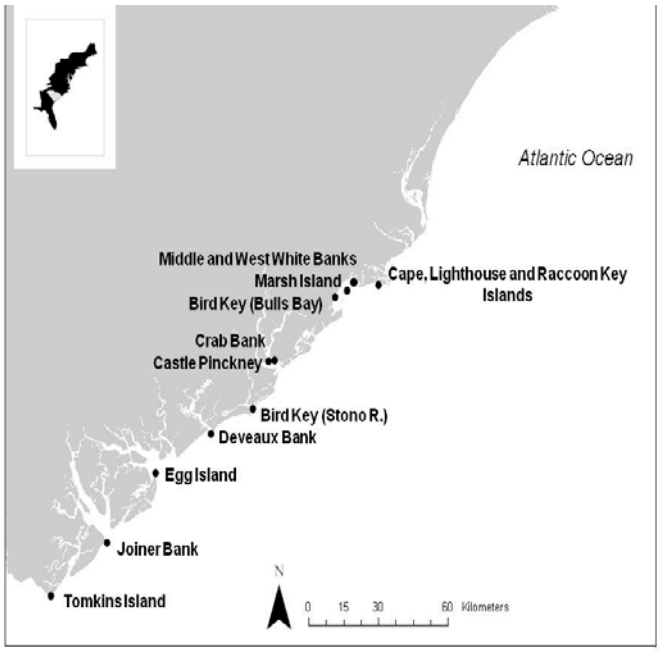

Figure 8: Locations of seabird colonies in South Carolina. These locations include sites that are currently active and sites that have had use in the past.

This guild is principally piscivorous and feeds in nearshore and estuarine waters of the state. During the nesting season, foraging is limited to areas within 16 to 24 km (10 to 15 mi.) of nesting sites. Terns typically plunge dive for food, while pelicans and skimmers have specialized foraging strategies. This guild also utilizes shrimp trawler by-catch.

CHALLENGES

Members of this guild share both nesting and foraging sites and are usually impacted by the following factors: loss of suitable nesting habitat; disturbance at nest and roost sites; predation, especially during nesting; soft tick infestation; loss of suitable roof nesting sites; oil spills; and loss of prey base.

Seabirds nest at sites that are prone to sudden and dramatic changes. Storms and hurricanes can alter or destroy nesting islands at any time. Loss of a single colony site can result in major, lasting impacts to statewide populations. Many of the islands currently in use by seabird colonies are owned by state or federal government agencies.

Soft tick infestation of a pelican nest. Photo by SCDNR

With ever increasing coastal development and associated boat use, protection of seabird colonies has become increasingly difficult. During the nesting season, several thousand nests can be negatively impacted by a single disturbance event such as a person entering a nesting colony during the heat of the day. Egg temperatures are significantly altered when the brooding parent is forced from the nest. Dogs that often

accompany their owners are a particular problem as they run through the colonies destroying eggs, killing or injuring chicks, and causing parent birds to leave chicks unattended and therefore vulnerable to aerial predators.

Predation by avian and mammalian predators significantly lowers nest success and can cause complete colony abandonment. Mammalian predators such as American mink, coyote and raccoon are frequently found on barrier islands, and trapping of these predators may be necessary to decrease loss of seabird, shorebird, and sea turtle nests. Great Horned Owls can cause colony abandonment and will prey on seabird adults and chicks. Nest abandonment associated with tick infestations has frequently affected Pelican rookeries in the state. These ticks (*Ornithodoros* spp.) feed mostly at night and complete a blood meal in a matter of hours; therefore, they are infrequently seen on the birds. Close examination of nests and chicks is required to detect the presence of ticks except when they are present in high densities. Infestations can involve thousands of ticks per nest and result in nest abandonment.

Least Terns have been able to maintain their nesting population by utilizing roofs with a pea-gravel substrate for nesting. A large proportion of the current population was hatched and has nested exclusively on roofs. In 2012 building codes changed in South Carolina to prohibit construction of gravel-covered flat roofs in hurricane prone coastal areas. The majority of gravel-covered roofs are old and have been refurbished with a poly-membrane resulting in a loss of 50% of suitable nesting roofs. Furthermore, although roof nesting sites can be productive, they frequently flood during thunderstorms, and may receive excessive disturbance from HVAC repair activities, and are susceptible to avian and rat predation.

CONSERVATION ACCOMPLISHMENTS

- South Carolina has the longest running seabird nesting trends dataset in the Southeast.

- Annually, 25 nesting sites on private and public lands are identified and posted with closed signs to minimize disturbance to colonial seabirds.

- Four SCDNR owned islands, with large colonies of nesting seabirds, continue to have Sanctuary Status as initially described and established by the SC Budget and Control Board on March 21, 2006. This Sanctuary Status allows management of the intertidal zone to benefit birds. Crab Bank and Bird Key-Stono are closed to boat landings and public access from March 15 – October 15. Deveaux Bank has closures to protect nesting and migratory birds. Tomkins Island is closed to public access year-round. Dogs and camping are prohibited year-round on these Sanctuary islands.

- Crab Bank Seabird Sanctuary was rebuilt in late 2021 with material taken from the Charleston Harbor Post 45 Deepening Project. The island is approximately a 32-acre sand bar at the mouth of Shem Creek. The first nesting season, in 2022, was successful for numerous seabird species including Black Skimmers and Least Terns.

- To avoid detrimental disturbance of walking through large colonies of Brown Pelicans, Royal Terns, and Sandwich Terns to obtain nest census data, aerial photos are obtained

from fixed-wing aircraft and/or drones. Nest counts are made from digital images using Image J software.

- New dog and camping restrictions on SCDNR owned barrier islands were passed. In 2023 an educational campaign, to make the public aware of the importance of undeveloped barrier islands to nesting birds, accompanied new signage with the beach rules and regulations.

- Beach stewarding programs were organized at several nesting sites with high probability of public disturbance. Beach stewards, consisting of volunteers and SCDNR staff, educate the public about nesting birds and facilitate reproductive success by minimizing disturbance.

- Created and implemented a web site with information on the status, management and natural history of seabirds in South Carolina. Additionally, the website promotes conservation of seabirds through partnerships and volunteer opportunities.

CONSERVATION RECOMMENDATIONS

- Protect birds during the nesting season with adequate and timely posting, stewarding and effective law enforcement.
- Establish or maintain suitable nesting islands at 48 km (30 mi.) intervals along the coast to maximize use of foraging habitat during the nesting season.
- Evaluate management actions and determine population trends using annual monitoring with complete ground or aerial counts.
- Continue cooperative efforts with the US Fish and Wildlife Service to census and manage nesting sites within Cape Romain National Wildlife Refuge.
- Monitor soft tick infestations and provide suitable treatment as needed.
- Conduct cooperative projects with the US Army Corps of Engineers to construct and maintain seabird-nesting sites under the authority of Section 204 of the Water Resources Development Act of 1992.
- Continue public education programs and partnerships on private and federal lands to promote conservation of seabirds.
- Develop oil spill contingency plans to protect nesting sites and provide rehabilitation of oiled birds.
- Maintain the fish prey-base for long-term success of these species.
- Continue to investigate management techniques that will improve reproductive success of these species.
- Continue to band seabirds to gather additional information on recruitment, dispersal, and migratory patterns.
- Participate in the development of monitoring protocol and data storage that can be used by the entire Southeast region. Support development of a Southeast Seabird Working Group.

MEASURES OF SUCCESS

This guild of birds is subject to rapid shifts in distribution and abundance and will require adaptive management to respond to these changes. Maintaining stable or increasing seabird populations regionally will represent a measure of success.

DESCRIPTION

Taxonomy and Basic Descriptions

Snowy Egrets, Glossy Ibis, Roseate Spoonbill, Great Egret, and Wood Stork by C. Hand, SCDNR

As the name suggests, colonial nesting wading birds nest in aggregations called colonies and feed by capturing prey while wading through or standing in shallow water. Colonial nesting wading birds are a taxonomically diverse group. Members of this guild belong to two orders: Pelecaniformes and Ciconiiformes. Pelecaniformes includes three families: Ardeidae (herons, bitterns and egrets), Threskiornithidae (ibises and spoonbills), and Pelecanidae (pelicans). Ciconiiformes includes one family: Ciconiidae (storks). Prior to the reclassification that occurred during 2010, all wading birds were classified as Ciconiiformes. Wading birds are medium to large birds that have long legs, necks and bills. Males and females look similar to each other. Immature birds often have different plumages than adults. These species typically nest and feed in wetland habitats. The double-crested Cormorant is a waterbird in the order Suliformes and the family Phalacrocoracidae that shares some habitat associations with wading birds and thus are included with this guild.

The Snowy Egret is a medium-sized heron that is approximately 56-66 cm (22-26 in) long and has a wingspan of about 100 cm (39 in). The Snowy Egret has white plumage, a thin black bill, black legs, yellow feet, and yellow bare skin around the lores. Breeding adults develop long flumes off the breast and back. The lores become red, pink, or orange during the early breeding season (Parsons and Master 2020).

Snowy Egret by R. Cammauf, NPS, Public Domain

Reddish Egret by Kristie Killam, USFWS, Public Domain

The Reddish Egret is also a medium-sized heron and is approximately 70-80 cm (28-31 in) long. The species has both a white and a dark color morph. Dark morph adults are gray with cinnamon-colored heads and necks. The bill is pink at the base and black towards the tip. The legs are blue on the sides and back and black on the front. Immature Reddish Egrets are gray to grayish tan. The white morph adults look similar to dark morph adults except their plumage is entirely white (Koczur et al. 2020).

The Little Blue Heron is similar in size to the Snowy Egret (length: 56-74 cm [22-29 in], wingspan: 100-105 cm [39-41 in]). Adults are slate blue with a purplish head and neck. The bill is dark gray with a black tip. The base of the bill can turn bright blue when breeding. The legs are gray to grayish green and turn black when breeding. Little Blue Heron chicks are white by day 7, and immature birds are white (Rodgers Jr. and Smith 2020).

Little Blue Heron by David Youngblood

Green Heron by David Youngblood

The Green Heron is small and compact (length 41- 46 cm [16-18 in]) with a relatively short neck and legs. It has a greenish black cap, dark grayish back and wings, reddish neck, and gray under-parts. The legs are yellow to orange-yellow, turning orange in the breeding season. The bill is dark with a yellow lower mandible (Davis Jr. and Kushlan 2020).

Yellow-crowned Night Heron by David Youngblood

The Yellow-crowned Night Heron is a medium-sized heron and is 55-70 cm (22-28 in) long. It is an overall gray with a yellow crown and white on its head and cheeks. Its legs are yellow-green and turn pink to scarlet during courtship. Juvenile Yellow-crowned Night Herons are mottled brown (Watts 2020).

Roseate Spoonbills by David Youngblood

The Roseate Spoonbill is a medium-sized pink wading bird that stands about 80 cm (31 in) tall and has a wingspan of 1.2 to 1.3 m (3.9-4.3 ft, Dumas 2020). The bill is long and flattens towards the tip, giving it a spoon-like appearance. The body is pale to light pink while the shoulders are a brighter pink-red. The legs are pink with some black and the feet are blackish. In adults, the bare head is a yellowish green. Juveniles have a feathered head and are pale pink.

Double-crested Cormorant, Wikimedia Commons

The Double-crested Cormorant is a large waterbird (length 70 to 90 cm [28-35 in], mass 1.2 to 2.5 kg [2.6-5.5 lbs]) with a small head on a long, kinked neck (Dorr et al. 2021). The beak is thin with a noticeable hook on the end. Adults of both sexes are dark brown-black, with a dull glossy sheen. The face and throat have a yellow-orange skin patch. During the breeding season adults develop a crest of black or white feathers behind the eye. Immatures are browner overall, with a paler upper breast and darker belly. Lesson first described the Double-crested Cormorant in 1831 (NatureServe 2024).

The terminology used to describe wading birds can be confusing. In North America, the term “wading bird” is used to refer to storks, herons, and egrets. In other areas of the world, shorebirds, such as oystercatchers and sandpipers, are often referred to as wading birds. The sites where groups of wading birds nest are referred to as colonies or rookeries. Sites where groups of wading birds rest during the day or overnight are called roosts, and groups of feeding wading birds are referred to as flocks or feeding aggregations.

Status

Members of this guild are of conservation concern because their reproductive strategy leaves them especially vulnerable to habitat degradation. Many wading bird species nest in large colonies; dozens of birds can nest in a single tree. Although this strategy affords benefits in terms of predator avoidance, it makes them especially vulnerable to habitat loss because the degradation of a small area (colony) can affect hundreds of breeding pairs of several different species. Food availability may be the limiting factor for many colonies in South Carolina. The loss of feeding habitat near a colony site can make the colony unsuitable even if the colony site itself is unaltered.

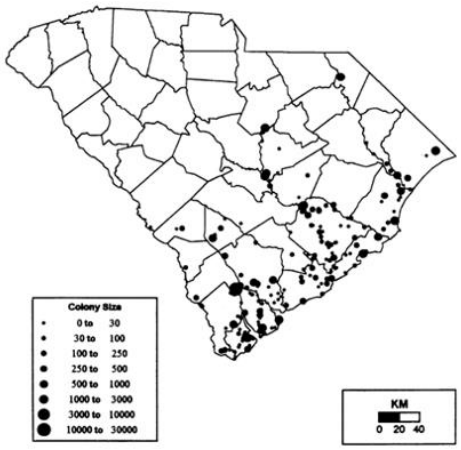
In addition to this vulnerability to habitat alterations, several members of this guild are of special concern due to declining population trends (Sauer et al. 2019). The Reddish Egret is listed as a Bird of Conservation Concern across the United States, while the Little Blue Heron is listed for other regions of the United States (USFWS 2021). The North American Waterbird Conservation Plan (Waterbird Conservation for the Americas) listed the Little Blue Heron and Snowy Egret as species of high concern; and the Reddish Egret, Roseate Spoonbill, and Yellow-crowned Night

Heron are listed as species of moderate concern (Kushlan et al. 2002). The Green Heron is listed as a species of low concern (Kushlan et al. 2002).

The Green Heron is considered a species of Least Concern by the International Union for the Conservation of Nature (IUCN, 2024). Globally, the Green Heron is ranked as Secure (G5) and in South Carolina, it is ranked as Apparently Secure (S4) (NatureServe 2024). However, Partners in Flight (PIF) considers the Green Heron to be a Common Bird in Steep Decline and a Species of Regional Concern for the Southeastern Coastal Plain, Piedmont, and Appalachian Mountain regions (2024). According to the North American Breeding Bird Survey (BBS) results from 1966-2019, Green Heron populations are declining by 1.35% each year in the United States and 1.30% in South Carolina (Sauer et al. 2019).

The Little Blue Heron is considered a species of Least Concern by the IUCN (2024). Globally, the Little Blue Heron is ranked as Secure (G5) and in South Carolina, it is ranked as Imperiled/Vulnerable (S2S3) (NatureServe 2024). PIF considers the Little Blue Heron to be a Common Bird in Steep Decline and a Species of Regional Concern for the Southeastern Coastal Plain (2024). According to the BBS results from 1966-2019, Little Blue Heron populations are declining by 1.25% each year in the United States and 3.39% in South Carolina (Sauer et al. 2019).

The Yellow-crowned Night Heron, Snowy Egret, and Roseate Spoonbill are considered species of Least Concern by the IUCN (2024). Globally, these species are ranked as Secure (G5) and in South Carolina, they are ranked as Imperiled (S2) (NatureServe 2024). PIF considers the Yellow-crowned Night Heron to be a Species of Regional Concern for the Southeastern Coastal Plain (2024). According to the BBS results from 1966-2019, Yellow-crowned Night Heron populations are declining by 0.23% each year in the United States and by 1.01% in the Southeastern Coastal Plain but are increasing by 1.51% in South Carolina (Sauer et al. 2019). Snowy Egret populations are increasing by 0.87% each year in the United States but are decreasing by 4.86% in South Carolina (Sauer et al. 2019). Roseate Spoonbill populations are increasing by 4.08% each year in the United States (Sauer et al. 2019). There is insufficient data to estimate population trends for Roseate Spoonbills in South Carolina.

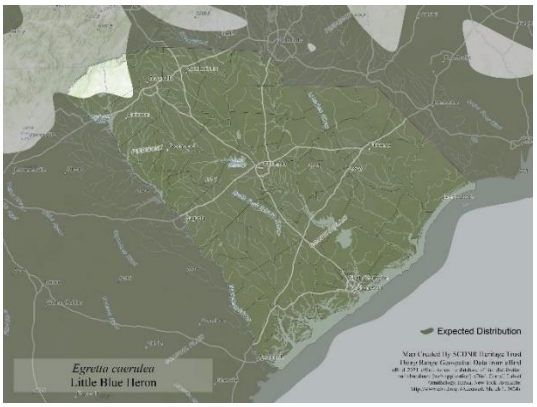


The Reddish Egret is considered by the IUCN to be Near Threatened (2024). Globally, the Reddish Egret is ranked as Apparently Secure (G4) and in South Carolina, it is ranked as Critically Imperiled (S1) (NatureServe 2024). PIF considers the Reddish Egret to be a Tipping Point Species and is on the Yellow Watch List, meaning the species has experienced “large long-term population loss but improved recent status (may be responding to current conservation efforts but still require recovery to healthier population levels)” (2024).

The Double-crested Cormorant is considered a species of Least Concern by the IUCN (2024). Globally, the Double-crested Cormorant is ranked as Secure (G5). In South Carolina, the breeding population is ranked as Critically Imperiled/Imperiled (S1S2B) and the nonbreeding population is ranked as Apparently Secure/Secure (S4S5N) (NatureServe 2024). According to the BBS results from 1966-2019, Double-crested Cormorant populations are increasing by 2.52% each year in the United States and 1.24% in South Carolina (Sauer et al. 2019). Double-crested Cormorants, like the wading birds listed in this account, are protected under the federal

Migratory Bird Treaty Act. However, the U.S. Fish and Wildlife Service also provides depredation and special permits for take of Double-crested Cormorants under certain circumstances.

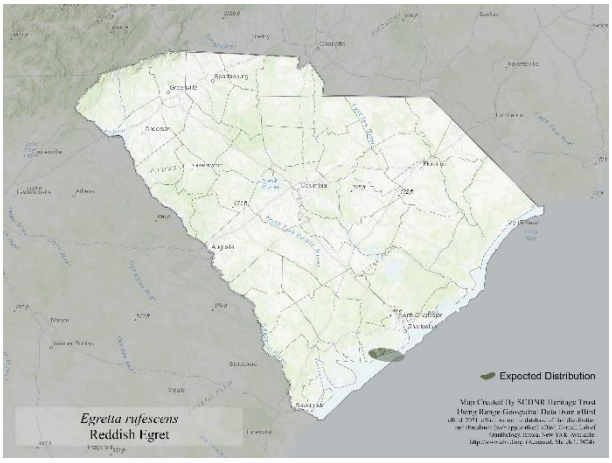
POPULATION SIZE AND DISTRIBUTION

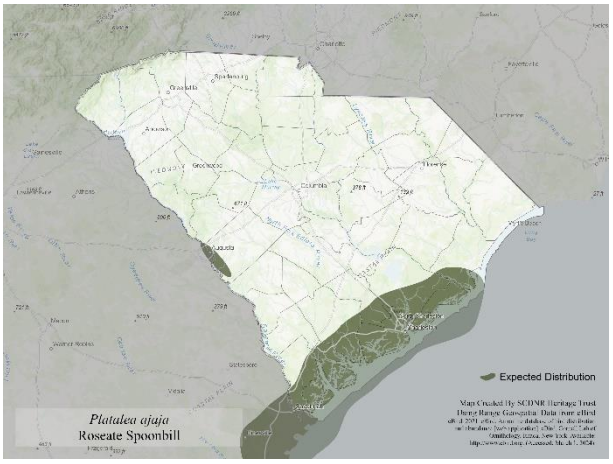


Complete ground censuses of nests in wading bird colonies in the Coastal Plain and Coastal Zone were conducted in 1988, 1989, 1994 and 1996. Counts of the total number of wading bird nests fluctuated among years, but high counts of 59,483 and 52,587 in 1989 and 1996 were representative of the population (Dodd and Murphy 1997). The fluctuations were primarily a result of one species: White Ibis. Nesting populations of members of this guild appeared to be stable between 1988 and 1996. Since that time, aerial estimates indicate the number of wading birds nesting in South Carolina has declined precipitously. This was particularly apparent during years of extended drought from 1999 through 2003.

Distribution of wading bird nesting locations (n=180) in South Carolina, 1996. (Figure from Dodd and Murphy 1997.)

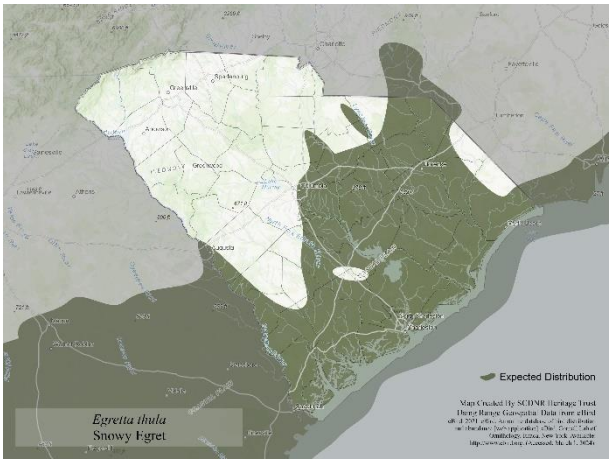
The Green Heron is distributed throughout the eastern and parts of the southwestern United States, the Pacific coast of the United States, southeast and southwestern Canada, Central America, and northern South America. The winter distribution tends to be more coastal. The range avoids dry areas and areas of high latitude and altitude (Davis Jr. et al. 2020). In South Carolina, the Green Heron can be found statewide during the breeding season but is restricted to the Coastal Plain and Coastal Zone in the non-breeding season (Davis Jr. et al. 2020). PIF estimates the global population size of Green Herons to be 1,200,000 individuals, with 770,000 in the United States and Canada (2024).



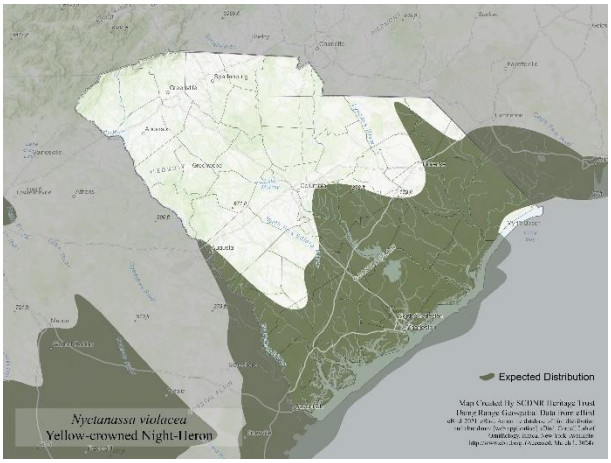


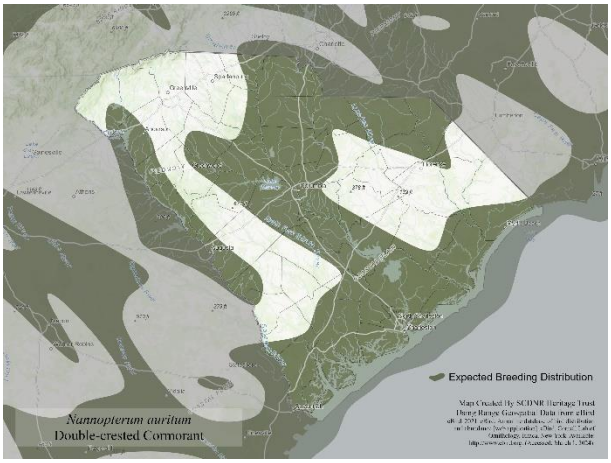
The Little Blue Heron breeds throughout Atlantic and Gulf Coast states, occasionally breeding further inland, the west coast of Mexico, the West Indies, and northern and central South America. Their nonbreeding range extends into Baja California and southern Central America. They can be found through the southeastern and south-central United States during migration (Rodgers Jr. and Smith 2020). The Little Blue Heron is distributed throughout all ecoregions of South Carolina except

for the Blue Ridge. PIF estimates the global population size of Little Blue Herons to be 1,100,000 individuals, with 270,000 in the United States (2024).



The Reddish Egret is distributed along coastal habitat in Florida and Gulf states, Central America, the Caribbean islands, and the northern coast of South America (Koczur et al. 2020). The Reddish Egret is regularly observed but uncommon in South Carolina. They are likely not regular breeders in the state. The first nesting activity in South Carolina was observed at Cape Romain National Wildlife Refuge in 2004 (Ferguson et al. 2005). PIF estimates the global population size of Reddish Egrets to be 15,000 individuals, with 2,400 in the United States (2024).

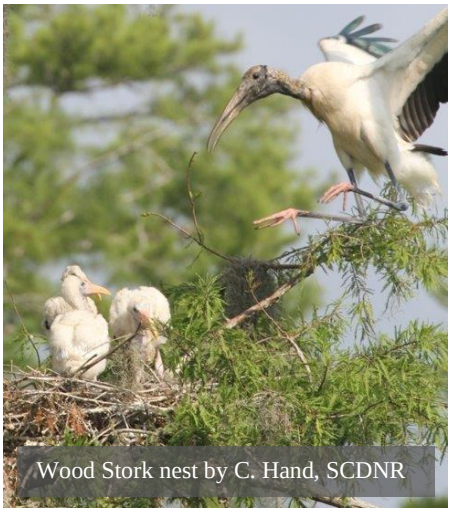




The Roseate Spoonbill is distributed from the southeastern United States, Central America, the West Indies, and South America, especially east of the Andes Mountains. In the United States, the Roseate Spoonbill primarily breeds and winters in coastal Texas, Louisiana, and South Florida (Dumas 2020). Occurrences elsewhere in the Southeast, including South Carolina, are generally immature individuals. In South Carolina, Roseate Spoonbills can be found in coastal wetlands south of Winyah Bay and occasionally inland along the Savannah River. PIF estimates the global population size of Roseate Spoonbills to be 170,000 individuals, with 11,000 in the United States (2024).

The Snowy Egret is distributed through much of South America, Central America, the United States, and into Nova Scotia, Canada. In the United States, Snowy Egrets breed along the Atlantic, Pacific, and Gulf Coasts. Breeding ranges extend inland in the South and Southwest, especially near rivers. Breeding populations can be disjunct (Parsons and Master 2020). PIF estimates the global population size of Snowy Egrets to be 2,100,000 individuals, with 220,000 in the United States and Canada (2024).

Yellow-crowned Night Herons feed primarily on crustaceans and their distribution is based on prey availability (Watts 2020). They range along the East Coast from Massachusetts to Florida, the Gulf Coast and up the Mississippi River and its tributaries, the Caribbean Islands, coastal Central America, and much of coastal South America. In the Unites States, there are also scattered breeding populations in the Appalachians and Midwest (Watts 2020). In South Carolina, Yellow-crowned Night Herons are found primarily in the Coastal Zone and Coastal Plain. PIF estimates the global population size of Yellow-crowned Night Herons to be 400,000 individuals, with 130,000 in the United States (2024).



Double-crested Cormorant populations have had large fluctuations in size during the 19th and 20th centuries, largely due to human-related processes including decreases due to contaminant residues (Weseloh et al. 1983) and direct mortality (Vermeer and Rankin 1984) and increases due to increases in fish prey (Hobson et al. 1989) and availability of suitable habitat on man-made lakes (Post 1988). The first confirmed nesting colony of Double-crested Cormorants in South Carolina were found on Lake Marion in 1985 (Seriff and Beirregaard 2018). Two additional sites were confirmed by the late 1990's (Seriff and Beirregaard 2018). The South Carolina breeding population was 60 pairs in 1986 and 186 pairs in 1989 (Post and Seals 1991). In 2017, the South Carolina Department of Natural Resources (SCDNR) documented 220 nesting pairs in the state. The Atlantic Coast is estimated to have 96,000 breeding pairs (Dorr et al. 2021).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Nesting sites are found in a variety of habitats. Colony sites for most guild members are found on islands in fresh and brackish water ponds. Water surrounding a nesting site deters mammalian predators while alligators frequently provide an additional deterrent. When suitable island sites are lacking, guild members may use vegetation around the edge of a pond for nesting. These sites are generally unsuccessful as a result of predation except for ponds in residential areas that are not affected by predators. Colonies are also sustained on estuarine islands that are free of

mammalian predators. Larger species prefer mature trees with large lateral limb structures while smaller species nest lower and prefer shrubby habitat.

Wood Stork nest by C. Hand, SCDNR

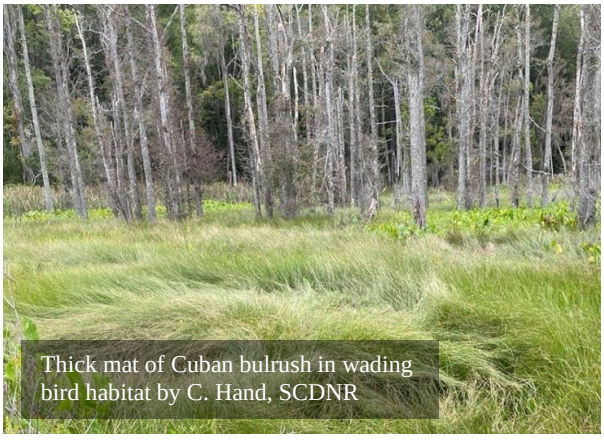
Double-crested Cormorants create nesting colonies in trees in or near water or on small rocky or sandy islands on waterways including ponds, lakes, managed impoundments, estuaries and open coastlines (Dorr et al. 2021). Colonies are established at locations that are safe from ground predators and close to feeding areas. Double-crested Cormorants may shift to ground nesting at those islands once the trees die (Dorr et al. 2021). They can also nest on mats of emergent vegetation in marshes (Dorr et al. 2021).

Wading birds feed primarily on fish, crabs, crayfish, insects, and amphibians and can be found feeding in a wide variety of aquatic habitats. Some species also feed opportunistically on small birds and mammals. Gradually receding water levels concentrate prey and facilitate feeding. Wading birds can be observed in large numbers foraging in managed impoundments during drawdown.

Wood Stork feeling for prey while egrets and herons search visually by C. Hand, SCDNR

Each species has its own feeding style. Roseate Spoonbills have specialized sensitive bills and are tactile feeders, which means that they use touch to locate prey. They require high prey densities in shallow water to feed efficiently. These species can feed even when visibility is low, such as in murky water and at night. They can feed efficiently in large groups, even when the water is stirred up, which allows them to take advantage of ephemeral food sources. Roseate Spoonbills wade through shallow water, while sweeping their bills back and forth through the water, to locate and capture prey. When their lower bill comes into contact with a fish, the individual reflexively snaps its bill shut to capture the prey. Most egrets and herons are visual hunters, which means that they locate prey visually before striking. They can capture a variety of types of prey in various situations but cannot forage efficiently when visibility is poor. These species perch at the edge of the water or wade out into shallow water to search for prey. Snowy Egrets and Reddish Egrets are very active feeders and pursue their prey.

Wading birds feeding in an impounded wetland by C. Hand, SCDNR



CHALLENGES

Loss of feeding, roosting, and breeding habitat is the biggest threat to colonial wading birds (Dodd and Murphy 1998). Over 50% of the wetlands in the contiguous United States were drained or converted to other uses between the 1780s and 1980s (Dahl 1990). Since the 1970s, the rate of wetland loss in the United States has been greatest in the Southeast. While South Carolina has been relatively successful in protecting its wetlands, significant losses have occurred in freshwater non-tidal wetlands. Some types of wetlands created to mitigate the loss of natural wetlands may be of lower ecological value to wading bird compared to diverse natural wetlands. The amount and quality of foraging habitat will ultimately determine the status of colonial wading bird populations.

Suitable nesting and roosting habitat is reduced by removal of vegetation during timber harvest and residential and commercial development. Shrub-type nesting and roosting habitat is lost through the removal of vegetation, mainly for aesthetic reasons, along the edge of ponds and impoundments.

Human disturbance is a problem for nesting colonial wading birds. Short-term disturbances such as airplanes, boats, vehicles, and human presence may cause the birds to fly from their nests, and can result in nest abandonment. Unattended eggs and chicks are vulnerable to depredation and to overheating. Disturbance at feeding areas can reduce the amount of prey that wading birds are able to consume and to feed to their young. Docks result in disturbance to feeding birds because of the increased boat traffic. The docks themselves are frequently used by the birds for foraging because fish concentrate in the shade of the docks.

Several types of environmental contaminants are problems for colonial wading birds. Petroleum from oil spills damages bird feathers and causes mortality. Chemicals such as DDT and PCBs are not currently widespread; however they do cause reduced reproductive success. Metals such as mercury and lead can concentrate and lead to reduced survivorship and reproductive success. Environmental contaminants also reduce availability of prey items. Nonpoint sources of pollution can reduce productivity of coastal marshes. Diseases such as cholera and botulism are particularly problematic for colonial wading birds. In the event of an outbreak of these diseases, they spread easily because the birds nest in such high densities.

Thick mat of Cuban bulrush in wading bird habitat by C. Hand, SCDNR

Other human-related causes of mortality include collisions with power lines and entanglement in fishing lines, gill nets, drift nets, and various forms of plastics (Dodd and Murphy 1998). Bird-flight diverters that make power lines more visible can be effective at reducing collisions by wading birds (Savereno *et al.* 1996).

The presence of invasive Cuban bulrush in rookeries is an emerging threat to wading bird colonies that warrants future study. Cuban

bulrush forms thick, buoyant mats that outcompete native aquatic plants and allow terrestrial predators such as racoons to access nesting sites. Thick mats of Cuban bulrush may also restrict alligator movement. Alligator presence attracts wading birds to nesting colonies (Burtner and Frederick 2017) as they reduce the number of mammalian predators. In turn, alligators benefit from consuming nestling carcasses (Nell and Frederick 2015).

CONSERVATION ACCOMPLISHMENTS

The Lacey Act of 1900 was the first major step toward protecting wading birds. The Lacey Act was passed, in part, in response to the millinery trade to regulate interstate and international trade of bird parts. Hundreds of thousands of herons and egrets, among other birds, were killed for their nuptial plumes, used in ladies hats and fashionable clothing (Ogden 1978). The Migratory Bird Treaty Act of 1918 made it illegal for a person to possess any migratory bird or part, with the exception of game birds during the proper season, as well as the possession of nests and eggs. Prior to these Acts, market hunting was responsible for population declines in many bird species.

SCDNR collected baseline data during statewide ground census counts in 1988, 1989, 1994 and 1996. Aerial surveys have been conducted annually since 1988 (with the exception of 2009 and 2010 when SCDNR did not employ a biologist to fill this role and in 2020 due to the COVID19 pandemic) to estimate the number of breeding individuals, breeding success, and distribution of wading bird colonies in South Carolina. SCDNR has documented over 300 wading bird nesting colonies since 1998, although not all colonies are active each year.

Surveys for breeding Double-crested Cormorant at historic breeding locations were completed in 2016 and 2017. They indicate the breeding population is small, but potentially increasing. Additionally, two dissertations were completed on Double-crested Cormorants in South Carolina (Kelley 2008, Sheehan 2013).

SCDNR has partnered with the USFWS Coastal Program, SCE&G, private landowners and other partners to improve habitat for wading birds. Collaborative projects include managing aquatic vegetation at rookeries using herbicide applications and the installation of bird-flight diverters on the power line adjacent to a rookery at Donnelley Wildlife Management Area to reduce the likelihood of collisions.

CONSERVATION RECOMMENDATIONS

- Conduct Research and Inform Permitting Agencies
    - Annually survey colonies containing federally listed birds.
    - Continue aerial surveys of nesting colonies to estimate the number of breeding individuals, breeding success, and distribution of wading bird in South Carolina.
    - Coordinate with biologists in the Southeastern Coastal Plain to develop plans to monitor wading birds on a regional scale.
    - Monitor individual nests at a subset of colonies to determine productivity.
    - Identify important foraging areas near nesting colonies, and determine how far from the colonies different species travel to forage.

  - Determine the effects of human activity on wading bird foraging efficiencies as well as the importance of roost sites and their relationship to available foraging habitat.
  - Monitor the effects of invasive Cuban bulrush and Cuban bulrush removal on wading bird nesting success
  - Complete intensive surveys to locate breeding Double-crested Cormorant colonies to better estimate the number of breeding pairs.
  - Determine distribution and survival of breeding Double-crested Cormorants during the nonbreeding season.
- Partner with Industry, Developers, Permitting Agencies and Private Property Owners/Managers to Protect Nesting and Feeding Habitat
  - Provide technical assistance and/or financial incentives to property owners for projects that will significantly benefit wading bird conservation. Control aquatic vegetation in large rookeries to ensure that alligators can move through the nesting area and deter mammalian predators from depredating eggs and chicks.
  - Determine Best Management Practices for multi-species management of impounded marsh habitat. Integrate management for colonial wading birds into traditional waterfowl management of currently impounded wetlands by timing draw-downs during key feeding periods (post-fledging).
  - Partner with industry and permitting agencies to prevent the destruction of important wading bird breeding, feeding, and roosting sites.
  - Work with permitting agencies to encouraged the creation of wetlands that are appropriate for wading birds when wetland mitigation is required. To create wetland habitat for waterbirds, water depth, water level fluctuation, vegetation, salinity, topography, food type, food accessibility should be considered (Ma et al. 2010). Short hydroperiod wetlands are important for tactile foragers. Deeper wetlands with islands and/or trees surrounded by water provide nesting habitat. Nesting and feeding habitat should be created in close proximity.
  - Determine and encourage the use of Best Management Practices for residential and commercial development activities near nesting and feeding sites.
    - Maintain vegetated visual buffers around nesting colonies and feeding areas to protect birds from human disturbance.
    - Include islands with suitable nesting habitat when constructing new ponds.
    - Leave shrubs around the edges of ponds to provide nesting and foraging habitat and for bank stabilization.
    - Minimize fertilizer, herbicide, and pesticide runoff into wetlands.
  - Document water quality issues at colony sites, and partner with appropriate permitting agencies to reduce the input of chemical contaminants and untreated wastewater into wetlands.
  - Place landfills, power lines, and towers away from colonies and wetland areas. Install bird-flight diverters and space power lines widely at sites used by wading birds where it is not feasible to bury lines.
  - Acquire, or assist conservation organizations to acquire, and manage important nesting and feeding sites to benefit wading birds.
- Support Outreach and Public Education

- Provide information about wading birds in South Carolina to the public via the SCDNR website and news releases.
- Provide increased opportunities for the public to view and appreciate wading birds while preventing disturbance to nesting and foraging birds (i.e. the overlook at Pinckney Island National Wildlife Refuge).
- Install educational kiosks and signs at sites where the public can view wading birds.

MEASURES OF SUCCESS

Protecting important habitat as outlined above should provide stable resources and enable populations to rebound. Wading bird nesting colonies should be distributed widely across Coastal Plain counties. The ultimate measure of success would be to document stable to increasing population trends of colonial wading birds.

Cory's Shearwater

Calonectris Diomedea borealis

Photo by Irvin Pitts.

Contributor (2024): Cami Duquet (SCDNR)

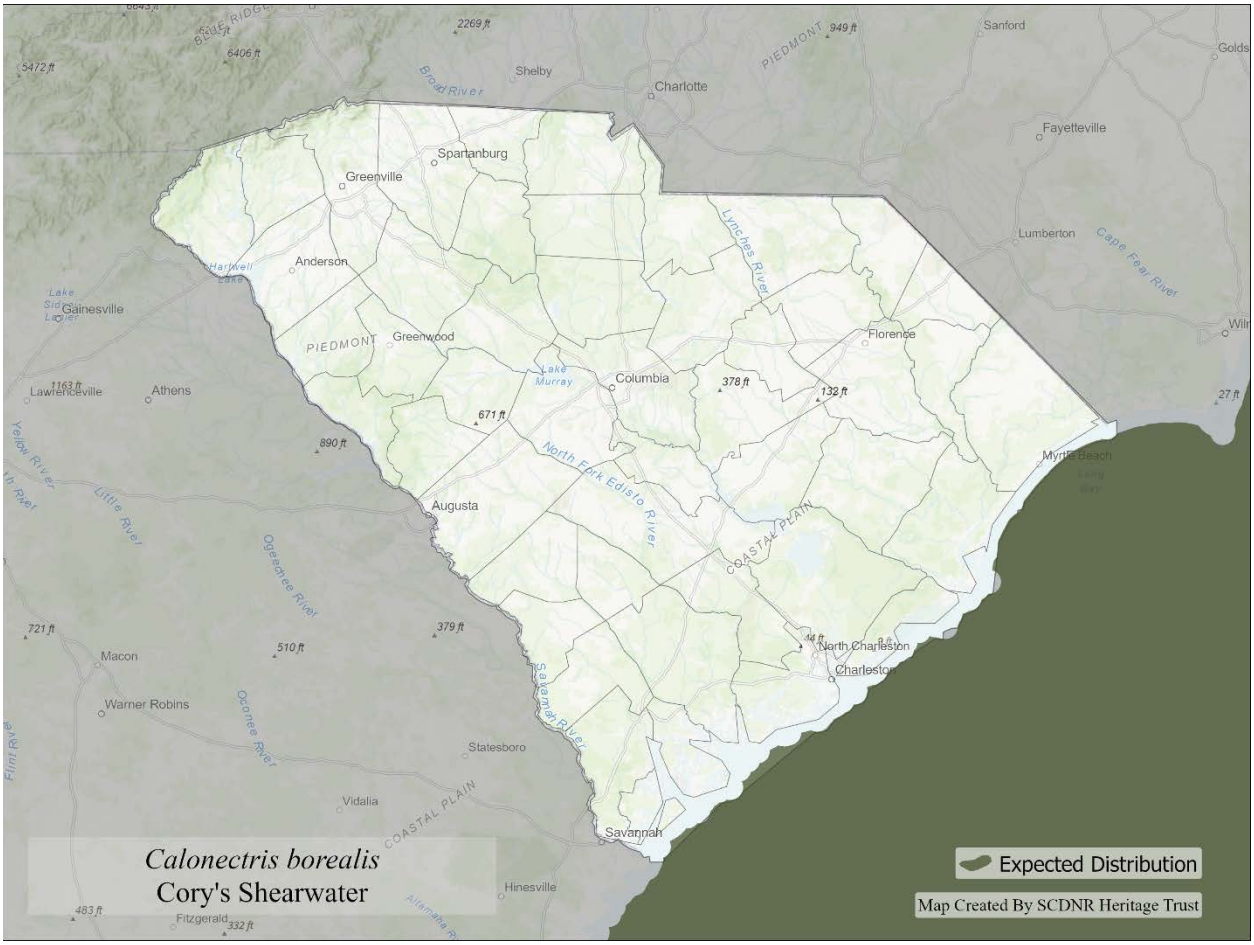
DESCRIPTION

Taxonomy and Basic Description

The Cory's Shearwater is a large pelagic seabird in the Shearwater *procellariidae* family. They have a distinguishable tube shape bill that is a pale pinkish yellow in color with irregular black coloring near the tip. They have a mostly gray-brown upper body with clean white underparts (del Hoyo et al. 2020). It has a long glide flight with bowed wings that are angled back slightly.

Historically, three subspecies of Cory's Shearwater were listed; *C. d. borealis, C. d. scopolis,* and *C.d. diomedea,* however, although closely related, the three were deemed to be different species based on genetic, morphological, and ecological differences. The Cory's Shearwater name was transferred to *Calonectris borealis* while the other two are now classified as Scopoli's Shearwater, (*C. Diomedea*), the nominate species, and Cape Verde Shearwater (*C. edwardsii*).

Status



The Cory's Shearwater was most recently assessed for the IUCN Red List of Threatened Species in 2018 and is currently listed as *Least Concern*. Although the population trend is somewhat unknown, it does not meet the threshold for *Vulnerable* due to its extremely large range and large population size (BirdLife International 2024).

POPULATION SIZE AND DISTRIBUTION

Total population is estimated around 600,000 birds (Brooke 2004) with a single survey recording 365,729 in 1996 around the Azores (Monteiro et al. 1998). Recent studies suggest that the population may be declining due to mortality events of young birds from introduced mammals, poachers, and urban lights (Fontaine et al. 2011).

The Cory's Shearwater is a trans-equatorial migrant and therefore has a wide range over the Atlantic Ocean as well as into the Southwest Indian Ocean. Its wintering sites include the Eastern Atlantic off both North America and South America, as well as the south-western Atlantic off the coast of South Africa (del Hoyo et al. 2020). The largest numbers of Cory's Shearwater cross the Atlantic in mid-summer post breeding, then move up the Northeastern United States coast in the fall and congregate off the New England and Canadian Maritime region. A recent study shows that more birds may be increasingly using waters of Nova Scotia with high numbers reported in 2016 and 2017 (Gjerdrum, C et al. 2018).

As a pelagic species, it is rare to uncommon to observe Cory's Shearwater on land in South Carolina and if so, they are usually associated with a strong storm or a hurricane blowing them off their course. The first recorded sighting of the species in South Carolina from land was of a deceased bird found on Isle of Palms, post tropical hurricane in August of 1940 (Dingle 1941). Most recently a live Cory's Shearwater was found on Hilton Head Island, post hurricane-Irma in 2017 (High 2017). Live sightings in South Carolina waters have been observed as early as the 1970s. In July 1973, Dennis Forsythe observed 2 Cory's Shearwater 15km east of Charleston and suggested that the species may be more widely distributed in the western Atlantic than previously thought (Forsythe 1980). Ebird shows 251 reported sightings in South Carolina waters to date, all occurring between the months of March and November.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

During the nonbreeding season (May to November) when Cory's Shearwaters are known to forage off South Carolina waters, they are often observed in groups with other Shearwaters and pelagic birds. Sightings and surveys show they are mostly associated with areas over the continental shelf as well as areas with abundant sargassum, where their primary food source small pelagic fish, tend to populate (Moser and Lee, 2012). Stomach content of Cory's Shearwater off the coast of Brazil during non-breeding season showed cephalopods present in 97% of cases and fish in 33% of cases (Kruger et al. 2009).

CHALLENGES

The pelagic nature of these birds makes them difficult to study. Research of Cory's Shearwaters has not been undertaken in South Carolina; therefore trends, movements, and numbers of the species frequenting South Carolina waters are not well understood.

However, research in other parts of their range may inform how the species will respond to similar threats they may face on the South Carolina coast. Such identified threats include incidental catch from fisheries, offshore developments such as wind farms, and climate change.

Shearwaters were found to be one of the most captured seabirds in Newfoundland and Labrador fisheries in Canada, primarily from gillnet fishery and bottom-set long lines. As a result, migrating Shearwater populations, including Cory's Shearwater, will likely experience sequential mortality in numerous fisheries due to their extensive migrations exposing them to fisheries interactions (Kulka et al. 2008).

Numerous studies have found clear evidence of Shearwaters and other seabirds being attracted to offshore structures, due to the abundance in prey items as caused by the structures acting as artificial reefs. Foundations of offshore wind turbines may similarly act as artificial reefs attracting pelagic seabirds, including Cory's Shearwaters, to feed on the fish populating in and around the structures which can result in collision (Baird 1990).

Additionally, Cory's Shearwaters are sensitive to climatic factors affecting the sea surface temperatures which affects food availability and therefore negatively impacts survival on nonbreeding grounds. These changes in sea surface temperatures are expected to worsen with climate change (Ramos et al. 2012).

CONSERVATION ACCOMPLISHMENTS

No conservation initiatives have been set specifically for the Cory's Shearwater in South Carolina. Reports of sightings through Ebird have provided data showing their presence in South Carolina waters.

CONSERVATION RECOMMENDATIONS

- Conduct systematic surveys of pelagic seabirds in South Carolina waters, including Cory's Shearwater, to gain better understanding of range, seasonality, movements, and numbers present
- Implement reporting of bycatch of pelagic seabird species from fisheries operating in South Carolina
- Protect foraging habitat where Cory's Shearwater feed from offshore development

MEASURE OF SUCCESS

As the above-mentioned action items are accomplished and yield valuable information, adaptive management procedures will be evaluated and implemented for this bird species.

Forested Wetlands Birds Guild

Prothonotary Warbler *Protonotaria citrea*
Rusty Blackbird *Euphagus carolinus*

NOTE: The Swallow-tailed Kite is discussed in its own species account.

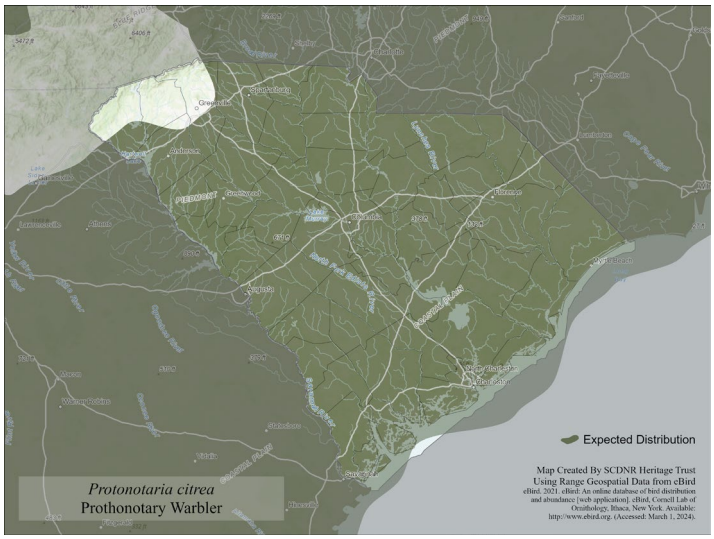
Contributor (2005): Craig Watson (USFWS)
Reviewed and Edited (2012): John Kilgo (USFWS); (2013) Lisa Smith (SCDNR)
Reviewed and Edited (2024): Matt Johnson (Audubon SC); Sherri Fields (Audubon SC); Amy Tegeler (SCDNR)

DESCRIPTION

Taxonomy and Basic Descriptions

These birds are grouped together because they either nest or winter primarily in forested wetlands in South Carolina.

The Prothonotary Warbler is a striking bird averaging 14 cm (5.5 in.) in length and 15 g (0.56 oz.) in weight. Adult male Prothonotary Warblers are bright yellow on their head, throat, breast, and nape; they have gray wings and an olive back. Females are similar to males but more muted in color, with more olive-green on the head and nape. Immature birds are similar to adult females.



The Rusty Blackbird is brown to black overall with a length of 23 to 25 cm (9.1 to 9.8 in.). Its bill is narrow and shorter than its head with a slightly rounded tail nearly as long as its wing. During the breeding season, the males gain a bluish-green gloss to its upper feathers (Avery 1995). Its fall and early winter plumage is characterized by fringe of rusty brown coloring on their otherwise dark feathers.

Status

None of these species are officially recognized as threatened or endangered, but all are either experiencing declines or declines are suspected. The Prothonotary Warbler is recognized by Partners in Flight (PIF) as a Watch List species that is declining and have moderate to high threats (Rosenberg et al. 2016). These same species are also listed as a species of conservation concern by the U.S. Fish & Wildlife Service (CITE). The Prothonotary Warbler are the highest ranked species in the southeastern Coastal Plain. The Prothonotary Warbler is considered a moderate priority species in forested wetlands by PIF and is in need of conservation attention (Hunter et al. 2001). The Prothonotary Warbler is ranked vulnerable (S3S4; NatureServe 2005). The Global IUCN status for Rusty Blackbirds is Red List (Vulnerable). It is not listed by the U.S. Fish and Wildlife Service. Partners in Flight (2024) rank this as a Conservation Concern as a Common Bird in Steep Decline. The Rusty Blackbird is ranked as S3N in the State (NatureServe 2005).

POPULATION SIZE AND DISTRIBUTION

The Prothonotary Warbler is a common breeder throughout most of South Carolina in forested wetlands, though density is higher in the coastal plain than the midlands and piedmont. This species is a very rare breeder in the Blue Ridge escarpment. The Breeding Bird Survey (BBS) indicates a 0.1% rate of decline per year for South Carolina, and a decline of 0.9% survey-wide from 1966-2010 (Sauer et al. 2012).

Rusty Blackbird populations have declined by 89% overall in recent decades (Partners in Flight, 2024). In South Carolina, the Rusty Blackbird is a fairly common winter visitor to the Piedmont and Coastal Plain, with lesser numbers occurring in the Mountains. Rusty Blackbirds breed in northern forests and migrate southward in mid-September, arriving in southeastern wintering grounds in late November. They will remain on wintering grounds until late March or early April when they begin their northward migration.

Rusty Blackbirds were commonly encountered on the Christmas Bird Count routes until approximately 1970 when the species started a decline that has not ended (National Audubon 2002). It is speculated that the steep population declines observed in the 1970's may be due to blackbird control programs. Obtaining detailed knowledge of the species has been complicated due to difficulty in navigating or accessing their preferred forested wetland habitat.

Table 1: US and Canada, and Bird Conservation Region population estimates (PIF 2020) expressed as individual number of birds. Estimated years until another 50% of the North America population is lost (Rosenberg et al. 2016).

Species	US/Canada Population Estimate	Years Until 50% Population Loss Estimate	SE Coastal Plain BCR	Appalachian Mountain BCR	Piedmont BCR
Prothonotary Warbler	2,100,000	> 50	47,000	Unknown	1,900
Rusty Blackbird	Unknown	19	Unknown	Unknown	Unknown

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Prothonotary Warbler requires the presence of water in wooded areas. This is the only species of warbler in the eastern United States that nests in cavities, so appropriate habitat must contain suitable cavity nest sites. Nest cavities are usually placed over or near large, slow-moving water bodies, including seasonally flooded bottomland hardwood forest, bald cypress swamps, and large rivers or lakes. Nests are usually located close to water height, usually within five meters (Petit 2020). Nests are usually placed in secondary cavities or in hollow branches or cypress knees. Prothonotary Warblers readily use artificial cavities, including a variety of different next box types (Petit 2020).

The Rusty Blackbird is a wetland obligate for its entire life history. In South Carolina, the rusty blackbird is found wintering in swamps and bottomland hardwoods, sometimes associated with other blackbird species such as Red-winged Blackbirds and Common Grackles (Cornell Lab of Ornithology, 2024) This species is primarily found in damp, wooded places, such as swamps and wet thickets but will forage in croplands and lawns with other blackbirds (Hamel 1992). Rusty Blackbirds can spend over a quarter of their annual life cycle migrating. Habitat types such as dogwood-willow swamp, low-lying forest patches, and area of habitat complexity were found to be preferred for foraging in fall and spring. Spring migrants selected habitat edges with this habitat while fall migrants avoided areas with dense grass, forbs, and herbaceous shrub cover. Migrating Rusty Blackbirds have also been found to roost in dense stands of emergent *Phragmites* or *Typha* marsh, suggesting that the best stopover or staging sites include a mixture of different wetland habitat types (Wright et al., 2020). [5] Rusty Blackbirds have also been described in suburban landscapes within the Georgia and South Carolina Piedmont Plateau in the winter, with flocks observed in suburban areas that provide forested or wetland habitats (Wohner et al., 2018).

CHALLENGES

By far, the loss and fragmentation of forested wetlands on both the breeding and wintering grounds are the most significant challenges to successful conservation of these species. These impacts stem from urbanization, residential and commercial development, power lines, agricultural practices, forest management practices, and surface water management (Audubon

2024). Forested wetlands have been extensively drained and converted throughout the United States; most of the remaining intact-forested wetlands outside of the Mississippi Alluvial Valley occur in the Southeastern United States. Conservation of these remaining forested wetlands should be a top priority for any conservation entity. In some cases, a fragmented landscape will not be able to support minimum viable populations. Additionally, while available habitat in South Carolina for many of these species could be maintained under climate vulnerability scenarios of 1.5 – 2.0-degree warming (Wilsey et al., 2019),[9] concerted efforts to maintain and restore suitable habitat on wintering grounds found in the state are important for species recovery.

CONSERVATION ACCOMPLISHMENTS

A primary objective of the South Atlantic Migratory Bird Initiative has been to delineate focus areas in which public lands serve as the anchors. These focus areas have been important in garnering North American Waterfowl Conservation Act (NAWCA) grants for significant land acquisition and enhancement projects in the state with an emphasis on wetlands (Watson and McWilliams 2005). An international working group was formed to shed light on the Rusty Blackbird, in order to coordinate efforts including sponsoring workshops, symposium, and bioblitzs. The Wildlife Society Conference held in 2020 included presentations on research associated with the species (The Wildlife Society, 2020)[10] and a 2020 Management Plan has been developed for Rusty Blackbirds in Newfoundland and Labrador focused on the breeding territory (Wildlife Division, 2020).[11] Prothonotary Warbler Accomplishments include

- The Prothonotary Warbler Working Group formed in 2014 with the goal of using research-based methodologies to better understand gaps in knowledge around the full life cycle conservation of this species (https://prowwg.wixsite.com/home).
- Since the formation of this working group, papers looking at migratory connectivity (Wolfe and Johnson, 2015, Tonra et al., 2019) and stable isotope analysis (Reese et al, 2019).
- More research is needed using advanced tracing technologies to provide more refined information on migratory stopover sites and wintering ground locations.

CONSERVATION RECOMMENDATIONS

- Continue conservation and restoration of forested wetland habitats including pocosins and Carolina bays. Care should be taken to increase block/patch sizes in order to decrease the amount of small, isolated forest patches across the landscape so that minimum viable populations are sustained.
- Promote conservation easements on private lands, specifically developing and pursuing reforestation programs.
- Reduce the effects of habitat fragmentation by minimizing the frequency that roads and power line rights-of-way bisect contiguous forested tracts.
- Develop and implement forest management practices that produce large, mature forests with tall, closed canopies and high tree density with a mosaic of understories.
- Develop Best Management Practices to balance the habitat needs of priority forested wetland species. Identify silvicultural activities that mimic the historical mosaic of young and old forests created by catastrophic events.

- Protect Streamside Management Zones and identify optimal sizes.
- Restore canebrake habitats in the understory of forested wetlands.
- Preserve and improve water quality to ensure aquatic insect biomass and diversity.
- Conduct surveys and studies to collect information on the distribution and life history characteristics of Rusty Blackbirds in South Carolina.
- Follow green tree reservoir management guidelines to ensure timber survival and production of desired food.
- Develop and implement monitoring programs to better assess breeding and wintering bird population sizes. Management and surveillance monitoring techniques will need to be assessed to quantify short- and long-term population responses in order to answer specific monitoring questions. Measures will need to be developed to integrate state monitoring results into regional- and national-level databases in order to identify if continental goals are being reached.
- Continue use of the Breeding Bird Survey as a surveillance monitoring technique and consider modifications to make the survey more robust across the state.
- Continue use of the Christmas Bird Count to identify population trends of wintering species.

MEASURES OF SUCCESS

Conserving and restoring forested wetland acreages throughout the state will greatly benefit a wide range of taxa. Collecting monitoring data based on habitat restoration and management objectives should result in measurable population responses at the local level. Other bird species that are likely to be positively affected by forested wetland management and restoration include: Swallow-tailed Kite (*Elanoides forficatus*), Cerulean Warbler (*Dendroica cerulea*), Black-throated Green Warbler (*Dendroica virens*), Black-billed and Yellow-billed Cuckoos (*Coccyzus erythropthalmus* and *americanus*), Worm-eating Warbler (*Helmitheros vermivorus*), Hooded Warbler (*Wilsonia citrina*), White-eyed Vireo (*Vireo griseus*), Carolina Wren (*Thryothorus ludovicianus*), Red-bellied Woodpecker (*Melanerpes erythrocephalus*), and Yellow-throated Vireo (*Vireo flavifrons*; Rich et al. 2004).

DESCRIPTION

Taxonomy and Basic Description

The Bobolink is medium-sized with a length of 15.2 to 20.5 cm and males weigh 34 to 56 g while females weigh 29-49 g (Renfrew et al. 2020). Breeding males have a black breast and black and white back. The head is black with a noticeable yellowish tan patch on the back of the neck (Sibley 2000). Nonbreeding males and females have a brown breast with faint streaking on the flanks. They have a dark eyeline and a pink bill (Sibley 2000). Linnaeus first described the Bobolink in 1758 (NatureServe 2014).

The Common Ground Dove is one of the smallest doves, measuring roughly 17 cm (0.39 in.) and weighing 30 g (1.06 oz.) (Sibley 2000). Typically, this is a stocky dove with a scaled effect on its head and breast and a short tail. Bright chestnut primaries and wing linings are visible in flight (NGS 1999). Linnaeus first described the Common Ground Dove in 1758 (NatureServe 2014).

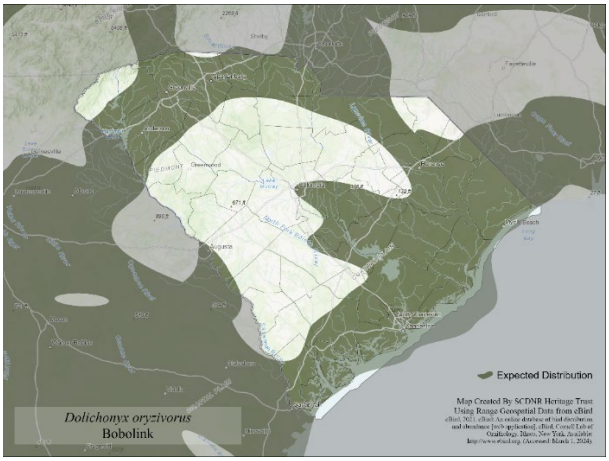
The Dickcissel is sparrow-like. Breeding males have a yellow breast with a black V on the throat, and reddish-brown wings (Sibley 2000). Females have a pale yellow breast and lack the black V (Sibley 2000). They weigh 23 to 29 g and have a total length of 14 to 16 cm (Sousa et al. 2022). The Dickcissel was first described by Gmelin in 1789 (NatureServe 2014).

Linnaeus, in 1758, first described the Eastern Meadowlark (NatureServe 2014). This distinctive species has a black, V-shaped breast band on yellow underparts. The upperparts are dark brown with dusky brown feather tips (NGS 1999). This species is 24 cm (9.45 in.) in length and 90 g (3.17 oz.) in weight (Sibley 2000).

The Field Sparrow is in the genus *Spizella* which represents small, long-tailed sparrows. Field Sparrows have a gray face with a reddish crown, a distinct whitish eye ring, and a bright pink bill (NGS 1999). The overall size of field sparrows is 15 cm (5.9 in.) in length and 12.5 g (0.44 oz.) in weight (Sibley 2000). Wilson first described Field Sparrows in 1810 (NatureServe 2014).

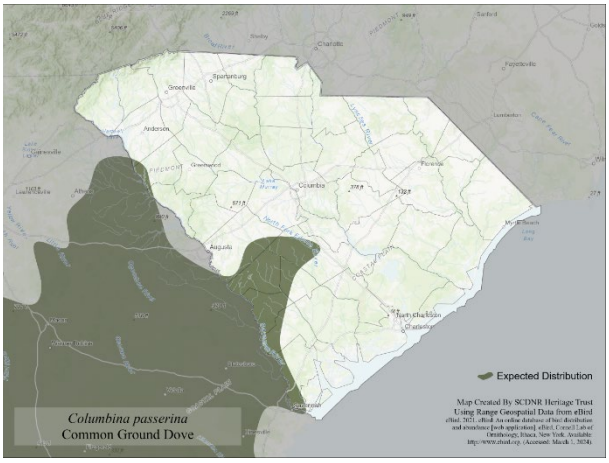
Gmelin first described the Grasshopper sparrow in 1789 (NatureServe 2014). This ground-dwelling species is very secretive. It has a buff-colored breast and sides, usually without streaking; a white eye-ring; and a dark crown with a pale central stripe (NGS 1999). Overall, this sparrow is small and chunky with a length of 13 cm (5.1 in.) and weight of 13 g (0.46 oz.). Grasshopper Sparrows have short tails, long bills and a flat head (Sibley 2000).

The Horned Lark is sparrow-like. Males have a brown back and pale brown breast. They have a black chest band and mask with some yellow on the head and throat (Sibley 2000). Females are paler than males and lack the black mask (Sibley 2000). The Horned Lark was first described by Linnaeus in 1758 (NatureServe 2014).



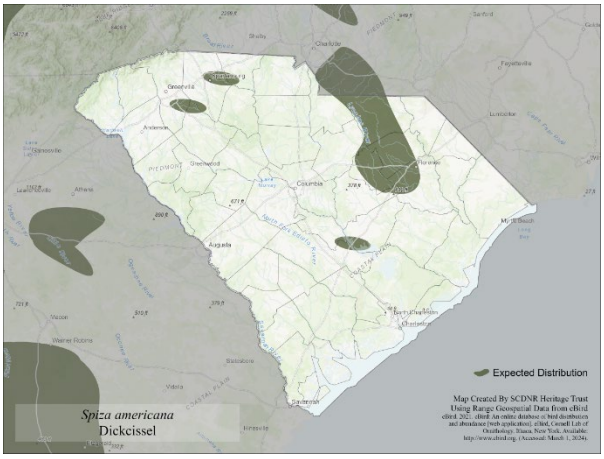
The Loggerhead Shrike is a predatory songbird with a strong, hooked bill used to kill and dismember prey (Sibley 2000). Its head and back are bluish-gray with underparts that are white with faint barring. A broad mask of black extends above the eye and thinly across the top of the bill (NGS 1999). This species is approximately 23 cm (9.1 in.) long and weighs 48 g (1.69 oz.) (Sibley 2003). Linnaeus first described the Loggerhead Shrike in 1766 (NatureServe 2014).

Status



Birds that use grasslands have shown some of the steepest population declines of any bird group in North America (North American Bird Conservation Initiative 2022). Loggerhead Shrike and Field Sparrow are endemic to North America and were listed among the common birds in steep decline, having lost an estimated 74% and 62% of their populations, respectively, over the last 40 years. Although not endemic to North America Horned Lark has experienced a 65% population loss, Grasshopper Sparrow a 68% loss, Dickcissel a 14% loss, Bobolink a 60% loss and Eastern Meadowlark a 77% loss over the last 40 years (Rosenberg et al. 2016). Estimates for number of years until another 50% of each species North American populations are lost are in Table 1 (Rosenberg et al. 2016). Bobolink is included in the PIF Orange Watch List, while Field

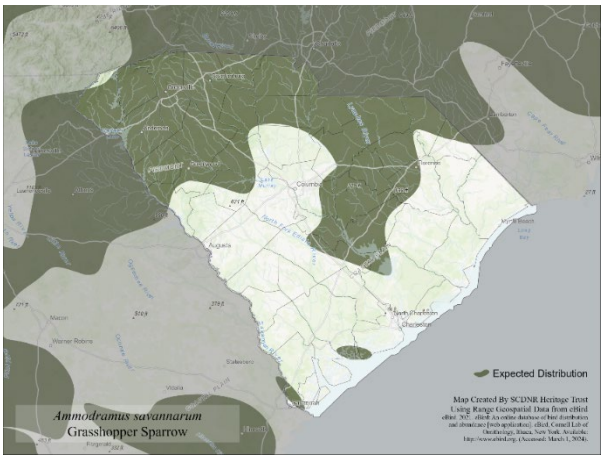
Sparrow, Loggerhead Shrike, and Eastern Meadowlark are important to consider for conservation within the bird conservation regions in South Carolina (Rosenberg et al. 2016). The PIF Watch List is comprised of species that have multiple reasons for conservation concern across their entire range and species are selected according to the PIF scoring process. At the state level, the Common Ground Dove is listed as a threatened species in need of management.



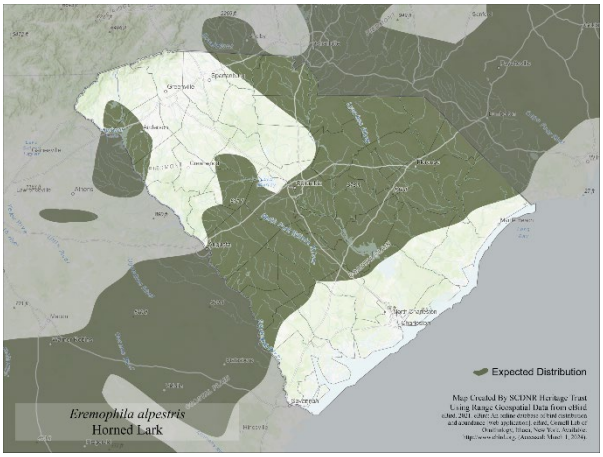
POPULATION SIZE AND DISTRIBUTION

The Bobolink is a passage migrant through South Carolina. Generally, spring migration occurs from mid-April to mid-May and fall migration from late August to mid-October (Seriff and Beirregaard 2018). Bobolinks nest in northern U.S. states and Canada and winter in South America (Renfrew et al. 2020). During the 1800's and early 1900's Bobolink were abundant, and often considered a pest (Seriff and Beirregaard 2018). They were often called "Ricebirds" due to large numbers foraging in rice fields (Seriff and Beirregaard 2018). They were also used as food (Seriff and Beirregaard 2018). However, the population has continued to decline (Renfrew et al. 2020).

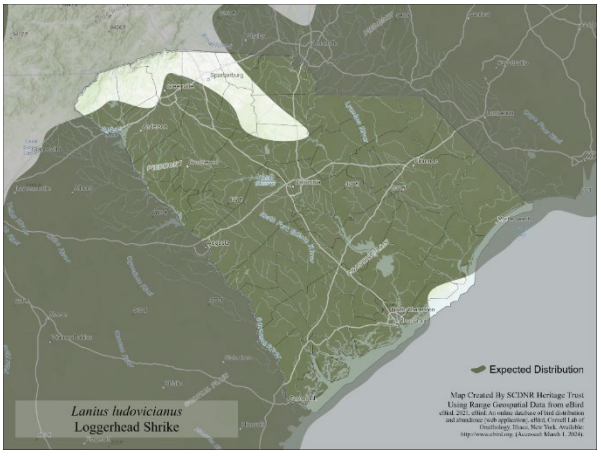
The Common Ground Dove is a state resident of South Carolina; most individuals are concentrated along the Outer Coastal Plain. This bird is present in smaller numbers as far inland as the Fall Line within the Sandhills Ecoregion. Data for South Carolina indicates a decrease of 0.3% in the population of Common Ground Doves from 1966 to 2022 (Sauer et al. 2021).



The Dickcissel is a sporadic breeder in South Carolina with very rare winter occurrences (Seriff and Beirregaard 2018). In the 1800's it is believed to have been more abundant along the Atlantic states, but by the early 1900's it had become a rare breeder (Seriff and Beirregaard 2018). South Carolina has experienced an annual rate of decline of 0.6% from 1966 through 2022 (Sauer et al. 2021).



The Eastern Meadowlark is another permanent resident of South Carolina. Most individuals of this species are concentrated in the Piedmont BCR. The Eastern Meadowlark is also exhibiting long-term population declines throughout much of its range; in South Carolina, it has experienced a 4.1% annual rate of decrease from 1966 through 2022 (Sauer et al. 2021).



The Field Sparrow has a similar distribution to that of the Grasshopper Sparrow, but it is more abundant in South Carolina. However, data from the Breeding Bird Survey indicates a long-term decline of 4.6% in South Carolina for the period from 1966 through 2022 (Sauer et al. 2021).

The Grasshopper Sparrow is a summer resident of South Carolina; it also winters in this state, but in fewer numbers. Although breeding occurs throughout the Piedmont and within the Southeastern Coastal Plain, most breeding Grasshopper Sparrows are located in the "orchard-pasture belt" of the Upper Piedmont (Cely 2003). Breeding Bird Survey data indicates a long-term decline of 4.7% in South Carolina for the period from 1966 through 2022 (Sauer et al. 2021).

The Horned Lark is a resident in South Carolina. It is believed to be more common in the winter as birds come down from more northern states (Seriff and Beirregaard 2018). The first confirmed breeding record in South Carolina was in 1950 (Seriff and Beirregaard 2018). The winter population has noticeably decreased (Seriff and Beirregaard 2018). However, the small South Carolina breeding population has experienced an annual rate of increase of 1.7% from 1966 through 2022 (Sauer et al. 2021).

The Loggerhead Shrike is a resident found statewide, except at higher elevations. It is most abundant in the Coastal Plain, especially within the "farm belt" of the Inner Coastal Plain. Breeding Bird Survey data has demonstrated declines over significant portions of its range in the East, especially within the Piedmont Bird Conservation Region (BCR). South Carolina has experienced an annual rate of decline of 4.2% from 1966 through 2022 (Sauer et al. 2021).

Population sizes were estimated for South Carolina and (PIF 2020) and North America (Panjabi 2021, Table 1).

Species	South Carolina Population Estimate	US/Canada Population Estimate	Years Until 50% Population Loss Estimate
Bobolink		10,000,000	48
Common Ground Dove	12,000	2,000,000	>50
Dickcissel	2,500	28,000,000	>50
Loggerhead shrike	43,000	4,600,000	24
Grasshopper Sparrow	67,000	33,000,000	>50
Horned Lark	11,000	100,000,000	40
Field Sparrow	140,000	9,300,000	36
Eastern Meadowlark	170,000	24,000,000	23

Table 1: South Carolina population estimates, and US and Canada population estimates (PIF 2020) expressed as individual number of birds. Estimated years until another 50% of the North America population is lost (Rosenberg et al. 2016).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Bobolink use large open fields with a mixture of grasses and legumes, including hayfields and meadows, for breeding. After breeding they also use freshwater marshes and coastal areas to molt before migrating (Renfrew et al. 2020). Bobolink are passage migrants through South Carolina. Historically they fed on cultivated rice, corn, small grains and hay fields during migration, and it is believed to be similar today (Renfrew et al. 2020).

Common Ground Doves are found at greatest densities within coastal scrub/dune fields. This bird feeds heavily on weed seeds and requires a mix of bare ground and grassy areas for foraging but favors sandy soil. Common Ground Doves will nest on the ground; however, they more typically use shrubs or small trees along a woodland edge for nesting sites (Hamel 1992). These doves have also been seen nesting in the crowns of palmettos (*Sabal* spp.). Inner Coastal Plain habitats utilized by ground doves consist of recent clearcuts, peach orchards and farmland (Hamel 1992).

Dickcissel is an obligate grassland specialist. They nest in grasslands with 90-100% cover, vegetation that is 25-150cm tall, 5-15cm letter depth, and elevated song perches (Sousa et al. 2022). This habitat is typically found in native prairies, restored grasslands, hayfields, fallow fields, lightly grazed pastures, no-till crop fields, and linear grassy strips such as fencerows, stream sides, and roadsides (Sousa et al. 2022). A high proportion of forbes, especially legumes, is important because it provides song perches, nesting cover, nest support and invertebrate prey (Sousa et al. 2022). Proximity to wooded areas reduces habitat suitability (Sousa et al. 2022). During nonbreeding use agricultural fields, open grasslands, and fallow fields near water (Sousa et al. 2022).

Eastern Meadowlarks create well-concealed nests on the ground in clumps of grass 0.6 m (1.97 ft.) in height (Hamel 1992). Typically, this species nests and forages for insects or seeds in fields, orchards, pastures, roadsides and golf course roughs. Eastern Meadowlarks may require

landscapes dominated by agriculture and grasslands to maintain long-term population viability (Lanyon 1995).

The Field Sparrow is more tolerant of brush, hedgerows, briar tangles, plum thickets, and generally thicker stands of grass and herbaceous material than the Grasshopper Sparrow. Field sparrow nests are typically placed on the ground, but shrubs and small trees will also sometimes be used. This species forages by gleaning seeds from the ground, but its diet can also include insects (Hamel 1992). Field Sparrows benefit from management of grasslands and scrub/shrub habitats.

The Grasshopper Sparrow favors grassy fields for nesting; it is less numerous in weedy fields, pastures, and grain fields (Hamel 1992). Nest sites are usually found in vegetation approximately 0.3 m (0.98 ft.) high (Hamel 1992). Grasshopper Sparrow wintering habitat is composed of broomsedge (*Andropogon* spp*.)* fields, other open fields, and open Pine Savannas. The diet of this bird consists of primarily insects but can include seeds.

Horned Lark use open areas, and prefer bare ground to grasses taller than a few centimeters (Beason 2020). In agricultural areas they use bare ground, row crop stubble and heavily grazed areas. They also utilize mowed areas such as airport airstrips and sand beaches and dunes (Beason 2020). During nonbreeding they use similar habitats, but with increased use of areas such as feedlots and dunes (Beason 2020).

Loggerhead Shrikes use open lands consisting of expanses of short grass, old fields, orchards, grassy roadsides, cultivated fields, and pasture. This bird nests in hedgerows, shrubs, and trees—notably red cedar (*Juniperus virginiana*)—but also loblolly pine (*Pinus taeda*) and live oak (*Quercus virginiana*). Nest trees and shrubs are typically in the open. Loggerhead Shrikes hunt from powerlines, exposed tree limbs, fence posts, and other conspicuous perches. Thorn trees, barbwire, or other sharp objects are necessary within the habitat as the Loggerhead Shrike uses these to impale and cache prey. The Loggerhead Shrike feeds mainly on large insects and small rodents though it will, at times, take smaller birds.

The following species are PIF species on the continental watchlist and/or of regional concern that will benefit from increased amounts of grassland habitat on the landscape: Short-eared Owl (*Asio flammeus*), Eastern Kingbird (*Tyrannus tyrannus*), Henslow's Sparrow (*Ammodramus henslowii*), and Le Conte's Sparrow (*Ammodramus leconteii*)

CHALLENGES

Vegetative succession and permanent loss of early-successional habitat through urban development and intensified agriculture are primary factors resulting in the long-term population declines experienced by these species (Lanyon 1995; Ehrlich 1992; Colvin 1985). Although habitat protection will assist in protecting these early-successional species, that alone is not expected to increase populations of the birds included in the grassland guild. In order to increase populations, active management of early-successional habitat, such as burning, grazing, mowing, disking, and other means to retard plant succession, must be emphasized.

In general, intensive agricultural practices may reduce habitat suitability for grassland bird species. Mowing and haying, as well as the timing of these activities, undoubtedly destroy many nests. The use of pesticides may result in lower insect and rodent availability, thereby reducing foraging opportunities for these birds. Also, in some cases, existing Farm Bill programs may create sinks for wildlife. For example, planting sod-farming grass can preclude nesting and foraging activities for these species, as well as Northern Bobwhite quail. Active management for early-successional habitat is necessary to reverse population declines for grassland birds. The positive side of this problem is that early-successional management is straightforward; it can be accomplished in a short period compared to growing a 60-year old forest from seed; and the response time for grassland bird populations should be short. Monitoring and documenting the response of grassland birds to Farm Bill programs will allow for improving landowner recommendations (Hunter et al. 2001). Additionally, Dickcissel are targeted by illegal poisoning on their wintering grounds because they are considered a pest on grain crops (Sousa et al. 2022).

The decline of Common Ground Doves could be due to several factors in addition to habitat alteration and loss, especially excess predation by cats, raccoons, and other predators on developed barrier islands and inland habitats (NatureServe 2005). In some states, declines are also attributed to loss of birds due to misidentification during Mourning Dove (*Zenaida macroura*) hunting seasons (NatureServe 2005)

There are other, apparently less significant problems for grassland bird species. Birds are killed by flying into communication towers and turbines on wind farms. In a report reviewing studies of bird mortality at communication towers in the eastern portion of the US, 230 species of birds (184,797 individuals) were killed. Of these, 17.8% were warblers, 10% were sparrows, and 9.5% were waterfowl (Shire et al. 2000). Also, nest parasitism by Brown-headed Cowbirds is common; rates for this type of predation vary geographically. However, nest predation is a major cause of grassland bird population declines (NatureServe 2005; Carey et al. 1994). In some areas, roadsides may represent the best quality and highest quantity of nesting habitat, but the potential for vehicle collisions and invasion by exotic plant species may be high. For example, kudzu (*Pueraria lobota)* grows at an average rate of one foot per day (18 m or 60 ft. during a growing season) enveloping and eventually killing all vegetation in its path, thus destroying nest and foraging sites (Mississippi State University 2005)

Additionally, lack of survey and monitoring programs to supplement Breeding Bird Surveys and other existing programs can result in inaccurate population estimates and trends. A number of specific protocols need to be developed for individuals in this suite of species in order to adequately determine population declines. Additional monitoring efforts and coordination will increase the efficacy of management actions in the future (Coordinated Bird Monitoring 1).

CONSERVATION ACCOMPLISHMENTS

The development and implementation of agricultural incentive programs with focused environmental benefits for wildlife have provided significant benefits to said wildlife in the State and Nation. In fiscal year 2004, NRCS and its partners invested $2.8 billion in conservation nationally (Knight 2005). Implementation of conservation and monitoring objectives developed for the popular Northern Bobwhite quail (*Colinus virginianus*) will positively impact the suite of

grassland species (Dimmick et al. 2002). [NOTE: See the species account for the Northern Bobwhite for specific details of the NBCI's guidance document.]

A number of contributions have occurred at the state and species level: A two-year study of Loggerhead Shrike habitat and nesting productivity was conducted in the Coastal Plain (Cely and Corontzes 1988) and SCDNR funded 2 graduate projects exploring Loggerhead Shrike habitat, nesting success and survivorship (Froehly et al. 2019, Froehly et al. 2020, Krauser and Hill 2023). Also, a one-season survey to determine locations of significant Common Ground Dove populations was conducted in the State (Cely and Glover 2000) and SCDNR staff are in the process of trying to create Common Ground Dove habitat models using eBird data.

CONSERVATION RECOMMENDATIONS

- Research the possible creation of cost-share or incentive-based programs to promote the retention of early-successional habitats. Identify potential partners such as the Natural Resources Conservation Service to help assess the efficacy of such measures.
- Continue to participate in existing efforts to develop and implement agricultural incentives that are beneficial for wildlife. Integrate monitoring objectives and funding mechanisms to support such programs where appropriate. Also, continue to develop program delivery mechanisms.
- Develop partnerships and infrastructure to integrate bird conservation efforts into private land management activities. Pursue private and federal grant programs to implement management objectives.
- Establish Loggerhead Shrike posts in locations where perch sites are limited.
- In grassland bird habitat devoid of site-appropriate herbaceous species or with depauperate seed banks, establish seed sources through propagation from local sources.
- Prevent the spread of existing invasive and non-native grasses in wild areas, eliminating them, where possible.
- Acquire more complete information on the habitat needs of each grassland bird species to determine the best management guidelines. Promote the development and dissemination of best management practices for grassland species utilizing agricultural lands.
- Educate landowners about the use of seed mixtures that benefit wildlife in early succession habitats.
- Identify habitat requirements and dispersal rates for Common Ground Doves.
- Develop and implement monitoring programs to better assess breeding and wintering bird population sizes. Assess management and surveillance monitoring techniques to quantify short- and long-term population responses. Develop measures to integrate state monitoring results into regional and national level databases.
- Continue using the Breeding Bird Survey as a surveillance monitoring technique, and consider modifications to make the survey more robust across the state.
- Derive quantitative population-based habitat objectives for priority grassland birds, and test assumptions (identify habitat-specific densities, limiting factors) in order to model habitat requirements necessary to meet population objectives.
- Continue participation in the Atlantic Coast Joint Venture at the management board and science committee levels.

- Continue participation in Partner's In Flight, other bird initiatives, and the North American Bird Conservation Initiative.
- Promote the participation of volunteers and employees to collect survey and monitoring data for grassland bird species.
- Reduce communication tower collisions through design modifications.
- Reduce loss of grassland habitat through solar farm development by encouraging use of wildlife friendly solar BMP's.

MEASURES OF SUCCESS

The landbirds featured here are high-priority representatives of this group for South Carolina and populations should respond positively to focused management practices. The recovery of priority species, primarily through habitat restoration and management, should benefit the many other lesser priority birds that also use grasslands. Monitoring programs with specific objectives should indicate if populations are responding to an increase in the quantity and quality of grassland habitat across the state.

Calculation of habitat objectives will indicate if population objectives determined at the continental level are attainable for the State, and if changes in objectives are necessary. In some cases, it may be unrealistic to achieve PIF continental population objectives due to significant and permanent habitat loss. In other cases, South Carolina will be a source for some populations and will contribute to overall continental population goals.

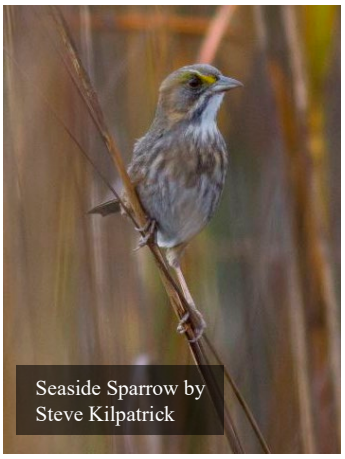
Seaside Sparrow (MacGillivray's)

Ammospiza maritimus macgillivraii



Contributors (2005): John E. Cely (SCDNR) and Dennis M. Forsythe (The Citadel)

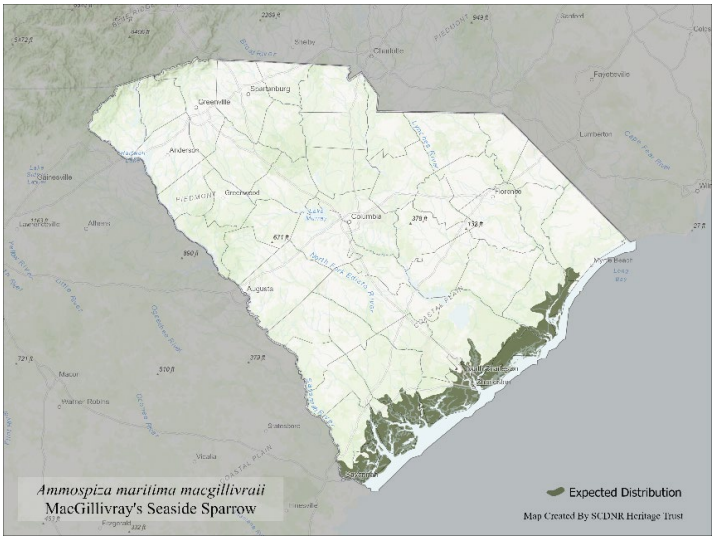
DESCRIPTION

Taxonomy and Basic Description

The Seaside Sparrow (*Ammospiza maritimus*, formerly *Ammodramus maritimus*) is a small passerine whose range extends along the Atlantic coast and Gulf of Mexico. There are seven extant subspecies of the Seaside Sparrow. Although other migratory subspecies, such as *Ammospiza maritimus maritimus,* may winter in South Carolina, the MacGillivray's Seaside Sparrow (*Ammospiza maritimus macgillivraii*) is the only species believed to breed in the state.

The Seaside Sparrow is olive-gray to olive-brown, has a relatively long conical bill and a short, sharp tail. The back and breast are streaked, but the streaking is not always visible. The Seaside Sparrow has a unique facial pattern. It has a yellow supraloral spot that blends to olive-green over the eye, a gray supercilium, crown stripe, and moustachial stripe, and a white chin and throat. The malar stripe is pale and buffy. Coloration is similar between the sexes. Seaside Sparrows are about 13 to 15 cm (5 to 6 in.) in length (Greenlaw et al. 2022). Males (22.8 ± 1.2 g [0.80 ± 0.04 oz]) are on average slightly larger than females (22.2 ± 1.6 g [0.78 ± 0.06 oz], Hunter 2016).

Seaside Sparrow by Steve Kilpatrick



Status

The Seaside Sparrow is considered a species of Least Concern by the IUCN (2024). Globally, the Seaside Sparrow is ranked as Secure (G5) but the MacGillivray's subspecies is ranked as Vulnerable (T3). In South Carolina, MacGillivray's Seaside Sparrow is ranked as Imperiled (S2) (NatureServe 2024). Partners in Flight considers the Seaside Sparrow to be a Yellow Watch List species range-wide and a Species of Regional Concern and Regional Stewardship species for the Southeastern Coastal Plain (2024). Although not specific to the MacGillivray's subspecies, Breeding Bird Survey results from 1966-2019 indicate that Seaside Sparrow populations are increasing by 0.70% each year in the United States; however, populations in the Southeastern Coastal Plain are declining by 1.86% (Sauer et al. 2019). The Seaside Sparrow is designated as a high priority species by South Atlantic Migratory Bird Initiative. In 2010, the USFWS received a petition to list the MacGillivray's Seaside Sparrow as endangered or threatened under the Endangered Species Act. However, after review of a 12-month finding in 2018, known stressors to the subspecies were not considered sufficient for listing. Populations in South Carolina were found to be likely stable (USFWS 2018). A Florida subspecies, the Dusky Seaside Sparrow (*A.*

m. nigrescens) is now extinct, while the Cape Sable Seaside Sparrow (*A. m. mirabilis*) is critically endangered.

POPULATION SIZE AND DISTRIBUTION

The MacGillivray's Seaside Sparrow range included in the 2018 Species Status Assessment includes coastal counties from Georgetown, SC to Duval, FL. During the 20th century, the accepted northern boundary for the MacGillivray's Seaside Sparrow was Dare County, NC. However, recent genetic analysis suggests that this range may need to be revised. Sampled Seaside Sparrows in a Charleston, SC population were found to be genetically different from populations spanning from Florida to Georgia and northern South Carolina to Connecticut, with admixture evident in South Carolina populations north and south of Charleston (Roeder et al. 2021). Additional genetic analysis by Davis et al. identified a transition in the Atlantic Coast Seaside Sparrows genetic structure occurring near northern South Carolina; however, their analysis showed stronger support for only two intergrading groups (northern and southern) with some support for a third genetic group (Charleston, 2021).

The MacGillivray's Seaside Sparrow occupies a very narrow strip of salt and brackish marsh along the Outer Coastal Plain "tidewater region". In South Carolina, the species has also been found nesting in coastal marshes as far inland as the town of Hanahan near Goose Creek. Although they are non-migratory, MacGillivray's Seaside Sparrows will move locally between breeding and non-breeding seasons (USFWS 2018). Little is known about winter distribution. Winter numbers are augmented by migrants from northern populations. Typically, the breeding birds belong to the dark subspecies *A. m. macgillivraii* while additional wintering birds belong to the lighter subspecies *A. m. maritimus.*

The population size of MacGillivray's Seaside Sparrow is estimated to be 32,800 individuals (USFWS 2018). The 2018 USFWS Species Status Assessment outlines four populations for the subspecies, three of which are in South Carolina – North Inlet-Bulls Island, Headquarters Island, Ace Basin, and Georgia-Florida. The species is thought to be extirpated from Volusia, Flagler, St. Johns, and part of Duval Counties in Florida.

SCDNR and collaborators at Coastal Carolina University completed a study in 2014-2015 in order to understand the breeding distribution of MacGillivray's Seaside Sparrow in South Carolina. Tidal marshes throughout the state as well as historically occupied marshes were surveyed. At Yawkey Wildlife Center, Santee Coastal Reserve, and Cape Romain NWR, MacGillivray's Seaside Sparrows were found to be widespread but they were only found at dense concentrations at a few sites (Tegeler et al. 2015, Hill and Laskaris 2015). Results from

this study were used to inform the MacGillivray's Seaside Sparrow Species Status Assessment in 2018.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Melanie Gaddy, iNaturalist, Public Domain

The Seaside Sparrow is found exclusively in salt and brackish marshes. Low marsh habitat is dominated by smooth cordgrass and black needlerush and high marsh habitat is dominated by black needlerush, saltgrass, and glasswort (USFWS 2018). In South Carolina, MacGillivray's Seaside Sparrow breed in areas of lower elevation within high marsh that are flooded only twice a month. They also use managed impoundments (Tegeler et al. 2015, USFWS 2018). Significant populations occur in black needle-rush marshes at the Tom Yawkey Wildlife Center, Cape Romain National Wildlife Refuge, and other areas featuring extensive coastal marsh. In Georgia and Florida, MacGillivray's Seaside Sparrow breed in areas of higher elevation within low marsh (USFWS 2018). In order to avoid extreme tidal fluctuations, Seaside Sparrows move up the estuaries to nest (Post and Gauthreaux 1989). In South Carolina, birds breed in marshes upriver and move to saltier coastal marshes in the wintertime (Hill & Laskaris 2015). Predation is the leading cause of nest failure. MacGillivray's Seaside Sparrows use habitat far from upland to avoid areas with higher predator density (USFWS 2018). Nest placement must balance the risk of tidal flooding and predation (Hunter et al. 2016). Vegetation must be dense to prevent nest predation yet must allow movement.

MacGillivray's Seaside Sparrows forage in open stands of vegetation, shallow pools, pannes, and edges of tidal creeks (Greenlaw et al. 2022). Most commonly they probe and glean from the ground so maintaining open ground is important for foraging habitat. Their diet consists of small invertebrates and seeds (Greenlaw et al. 2022).

CHALLENGES

While the Seaside Sparrow has one of the most restricted breeding ranges of any passerine, its habitat has one of the most stringent regulatory protections of any type in the country. Prior to the enactment of tidelands protection such as the Clean Water Act, some Seaside Sparrow populations had been severely impacted by salt marsh ditching for mosquito control and impoundment creation for rice cultivation and wildlife management, particularly for waterfowl. These changes greatly alter the natural hydrology and vegetation of the marshes, often making them unsuitable for Seaside Sparrows. Although MacGillivray's Seaside Sparrow will use some impounded habitat, especially impoundments large enough to have sufficient topographic variability so that patches of suitable habitat remain, the creation of impoundments largely reduced habitat availability in South Carolina.

Major threats to MacGillivray's Seaside Sparrow include predation, flooding, and extreme weather (USFWS 2018). The largest challenge to Seaside Sparrow populations over the next

century may come from impacts of sea level rise on salt marsh habitat. Saltmarsh habitat will likely decline with sea-level rise, as accretion may not keep up with the rate of sea-level rise and coastal development may prevent marsh migration inland (Mitsch and Gosselink 2015, Crosby et al. 2016). In addition, increased severity of tidal flooding is expected to increase rates of nest failure. Nest loss due to sea-level rise and storm surge is likely affect the viability of Seaside Sparrow and other salt marsh species (USFWS 2018). Although MacGillivray's Seaside Sparrows accommodate for tidal fluctuation in nest placement, nests placed higher experience higher rates of predation (USFWS 2018).

CONSERVATION ACCOMPLISHMENTS

Many protected lands in South Carolina, including National Wildlife Refuges and Wildlife Management Areas, provide habitat for MacGillivray's Seaside Sparrow. Almost all marsh in the North-Inlet-Bulls Island Population is protected. The ACE Basin remains largely undeveloped and MacGillivray's Seaside Sparrow habitat is within the 38,292 ha ACE Basin National Estuarine Reserve. Management of marshes and impoundments on these properties can improve habitat for MacGillivray's Seaside Sparrow. Prescribed fire is often used to mimic historic fire regimes and reset vegetation structure. Seaside Sparrow use generally increases 3-4 years after burning.

Research completed in the past decade has clarified the distribution, habitat use, and breeding ecology of MacGillivray's Seaside Sparrow in South Carolina. Although there is still much to be learned about this species, this research can inform conservation activities. For example, because it is now known that MacGillivray's Seaside Sparrows tend to breed in dense clusters in South Carolina, marshes being used for breeding can be targeted for protection and management.

CONSERVATION RECOMMENDATIONS

- Maintain current regulations and statutes protecting tidal wetlands.
- Where possible, restore ditched and altered marshes.
- Control predators, such as rice rats, in areas experiencing high rates of MacGillivray's Seaside Sparrow nest predation.
- Support efforts to collect basic information on demographics, nesting, habitat, site fidelity, predation, and other biological parameters. Initiate a range-wide monitoring program.
- Inform the public and constituents about research, survey results, and habitat needs, as this species is little known to the general public.
- Acquire lands that are suitable for facilitated marsh migration.
- Manage select impoundments near natural marsh and MacGillivray's Seaside Sparrow hotspots specifically for the species. Mimic hydrology and restore low elevation high marsh vegetation.
- Initiate research project to determine wintering grounds of MacGillivray's Seaside Sparrow in South Carolina.

MEASURES OF SUCCESS

Stabilization or increases in populations would be considered successes, as well as preventing extirpation from high density clusters. This may be accomplished through establishing a state-wide monitoring program and habitat protection.

DESCRIPTION

Taxonomy and Basic Descriptions

The members of the marsh birds guild vary widely in appearance, size, and habits. Guild members included in this account are in three orders, although other orders not included in this account may use marsh habitat during some or all life history stages. The order Gruiformes includes the families Rallidae (rails) and Gruidae (cranes). The family Ardeidae (herons, egrets, and bitterns) is included in the order Pelicaniformes. The order Passeriformes includes all perching birds, including those of the families Passerellidae (new world sparrows) and Troglodytidae (wrens) included in this account.

Yellow Rail by USFWS

The Yellow Rail is a small marsh bird averaging 18.4 cm (7.2 in) in length and 50 g (1.8 oz) in weight. The adult has a short yellow bill, short tail, buffy yellow chest and face, dark crown and eye stripe, and a yellow and black streaked back. The juvenile is similar to the adult but has a darker bill and more speckling, especially on the neck and head (Sibley 2003).

King Rail by David Youngblood

The King Rail is the largest North American rail. It averages 38.1 cm (15.0 in) in length and 360 g (13 oz) in weight. The adult male has a brown streaked back, deep orange neck and breast, and a black and white striped flank. The adult female is smaller and drabber than the male. The juvenile is similar to the adult but has a whitish breast with dark speckling (Sibley 2003).

The Least Bittern is the smallest heron in the Americas, averaging 33 cm (13 in) in length and 80 g (2.8 oz) in weight.

The adult has a dark brown to blackish back and crown, an orange-brown neck and sides, and a white and orange striped neck and chest. The juvenile is similar to the adult but is paler with a brown crown (Sibley 2003).

Least Bittern by David Youngblood

Nelson's Sparrow by Kimberly Emerson, USFWS, Public Domain

The Nelson's Sparrow is a small short-tailed sparrow averaging 11 to 13 cm (4.3 to 5.1 in.) long and weighing 17 to 21 g (0.6 to 0.7 oz.). It has a dark brown to olive back that has four grayish or white stripes. The underparts are white or pale yellow and the breast and flanks have faint streaking. Nelson's Sparrows are typically identified by their bright yellow-orange supercilium stripe that batches the breast color, gray check patch, and brownish post-ocular stripe (Shriver et al. 2020). Juveniles are similar to adults but have a blackish crown with a broad orange-buff median strip, a broad supercilium, a chestnut or rust-colored nape, and a streaky rump (Shriver et al. 2020).

Saltmarsh Sparrow by Peter Paton, USFWS, Public Domain

The Saltmarsh Sparrow is slightly larger than the Nelson's Sparrow averaging 12 to 13 cm (4.7 to 5.1 in) long and weighing 17 to 24 g (0.6 to 0.8 oz.). Males and females appear similar. Saltmarsh Sparrows appear similar to Nelson's Sparrows; however, Saltmarsh Sparrows have a longer bill and more defined streaking on the chest. Nelson's Sparrow and Saltmarsh Sparrow will hybridize (Greenlaw et al. 2020).

Worthington's Marsh Wren by Roxan Chicalo, FWC, CC BY-ND 2.0

The Worthington's Marsh Wren is a small wren reaching up to 12 cm (4.7 in) in length. Male Marsh Wrens are larger than the female but otherwise appear similar. The upperparts of the Worthington's Marsh Wren are grayish-brown and its belly is light gray. It has a white eyebrow and a dark triangular patch with pale streaking on the back (FWC 2013).

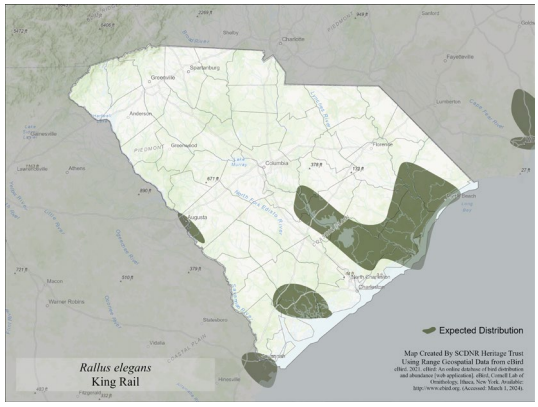
Status

Except for the Black Rail and the Whooping Crane which are detailed in separate accounts, none of the marsh bird species in South Carolina are officially recognized as threatened or endangered. However, all are experiencing documented or suspected declines. All species are being negatively affected by the loss and degradation of wetland habitat through drainage, dredging, filling, impounding, and pollutant discharge. The most serious limiting factor to these species is the availability of wetland habitat (NatureServe 2024). Wetlands in the Southeastern United States represented 89% of the total wetland lost in the United States in the mid-1980s

(Hefner et al. 1994).

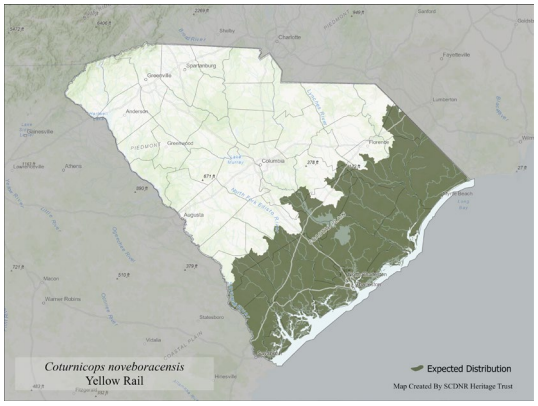
The rail species present challenges in determining statuses due to a difficulty in detection as a result of their secretive nature and a general lack of information. The International Union for the Conservation of Nature (IUCN) lists King Rails as Near Threatened and Yellow Rails as Least Concern (2024). Partners in Flight (PIF) considers the King Rail and Yellow Rail to be Tipping Point species and are placed on their Orange and Yellow Watch Lists, respectively, due to their level of population threats (2024). The King Rail is also a Species of Regional Concern for the Southeastern Coastal Plain (PIF 2024). The King Rail and Yellow Rail are ranked globally as Apparently Secure (G4) and, in South Carolina, the King Rail is ranked as Imperiled (S2) and the Yellow Rail is ranked as Vulnerable (S3) (NatureServe 2024). According to the North American Breeding Bird Survey (BBS) results from 1966-2019, King Rail populations are declining by 3.69% each year in the United States and 2.28% specifically in the Southeastern Coastal Plain (Sauer et al. 2019). BBS data is insufficient to estimate Yellow Rail population trends.

Many of the rail species are categorized as game birds and are hunted in South Carolina. The following species and daily bag limits (in parentheses) are listed in the 2023-2024 Migratory Bird Regulations: King and Clapper Rails (15), Sora and Virginia Rail (25), Common and Purple Gallinules (15), and Wilson's Snipe (8) (SCDNR 2024). The hunting seasons for marsh birds are during the winter, when both resident and migrant birds are likely to be present in South Carolina.



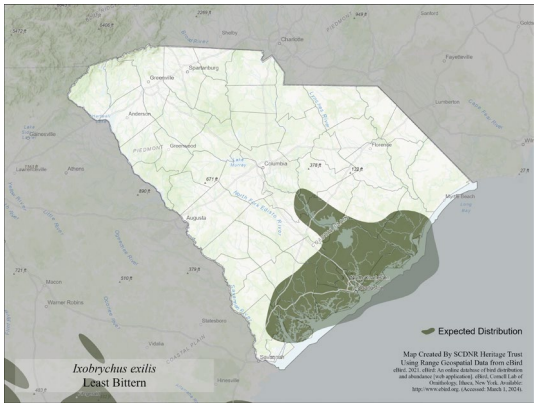
The Least Bittern is considered a species of Least Concern by the IUCN (2024). Globally, the Least Bittern is ranked as Apparently Secure (G4) and in South Carolina, it is ranked as Vulnerable (S3) (NatureServe 2024). PIF considers the Least Bittern to be a Yellow Watch List species range-wide and a Species of Regional Concern and Regional Stewardship species for the Southeastern Coastal Plain (2024). According to BBS results from 1966-2019, Least Bittern populations are declining by 0.14% each year in the United States and 1.30% specifically in the Southeastern Coastal Plain (Sauer et al. 2019).

The Nelson's Sparrow is considered a species of Least Concern by the IUCN and the Saltmarsh Sparrow is considered Endangered (2024). Globally, the Nelson's Sparrow is ranked as Apparently Secure (G5) and in South Carolina, the it is ranked as Vulnerable (S3) (NatureServe 2024). Globally, the Saltmarsh Sparrow is ranked as Imperiled (G2) and in South Carolina, it is ranked as Vulnerable (S3) (NatureServe 2024). PIF considers both sparrow species to be Watch List Species (Red: Saltmarsh Sparrow, Yellow: Nelson's Sparrow) range-wide and a Species of Regional Concern and Regional Stewardship species for the Southeastern Coastal Plain (2024). Saltmarsh Sparrows are also listed as a Tipping Point Species (PIF 2024). BBS results from 1966-2019 show that Nelson's Sparrow populations are increasing by 0.68% each year in the United States. BBS data is currently insufficient to estimate Saltmarsh Sparrow population trends.



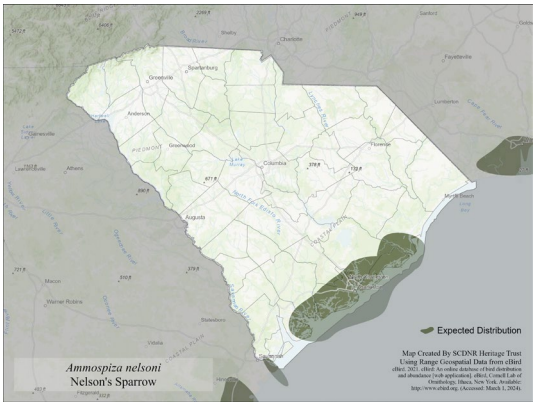
Very little is known about Worthington's Marsh Wren in South Carolina. Research will be needed to understand the population status of the subspecies in the state. The Worthington's Marsh Wren is state listed as threatened in Florida where the species has seen a 80% range contraction (Kale 1996). Globally, the Marsh Wren (nominate race) is ranked as Secure (G5) and

in South Carolina, it is ranked as Apparently Secure (S4) (NatureServe 2024). The Worthington's subspecies is ranked as Vulnerable (T3) throughout its range; however, there is no status rank for South Carolina. Although not specific to the Worthington's subspecies, BBS results from 1966-2019 indicate that Marsh Wren populations are increasing by 2.03% each year in the United States; however, populations in the Southeastern Coastal Plain are declining by 1.85% (Sauer et al. 2019).

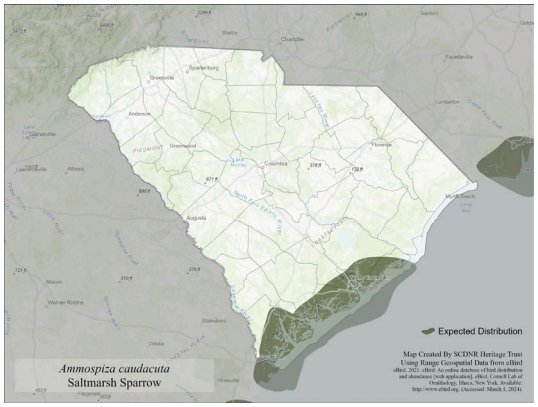


POPULATION SIZE AND DISTRIBUTION

King Rails are found year-round in freshwater to brackish marshes along the Gulf Coast, Florida, the Altantic Coast from Florida to Maryland, and the Greater Antilles. The breeding range also extends up the East Coast to Massachusetts. King Rails breed in inland Texas, Louisiana, and Mississippi. They are rare and localized throughout the eastern United States (Pickens and Meanly 2020). In South Carolina, the King Rail is primarily found in the Coastal Zone, but can be found in the Coastal Plain and Sandhills Ecoregions. It was formerly found statewide, but few, if any, Piedmont locations are currently known (Cely et al. 1993). PIF estimates the global population size of King Rails to be 69,000 individuals with 63,000 in the United States and Canada (2024).

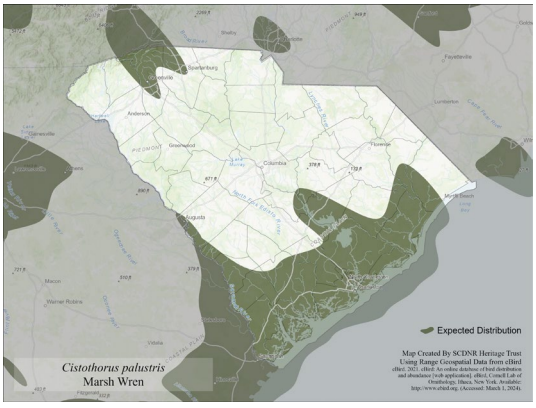


Yellow Rails primarily breed in south-central and southeast Canada. The breeding range extends into the United States near the Canadian border in Montana, North Dakota, Minnesota, Michigan, and Maine (Leston and Bookhout 2020). Breeding is very localized. Yellow Rails primarily winter along the Gulf Coast and Southeastern Coast from North Carolina to Texas. Little is known about the Yellow Rail's distribution and habitat requirements in South Carolina. They are expected to use brackish and fresh marshes, managed impoundments, and wet fields with very shallow standing water. PIF estimates the global population size of Yellow Rails to be less than 12,000 individuals with all populations existing within the United States and Canada (2024), although accurate abundance estimation is difficult due to low detection rates.



Least Bitterns breed in low-lying wetlands across much of the eastern United States, isolated areas in the western United States and southern Canada, the Greater Antilles, Mexico, Costa Rica, and South America. They winter where there is no frost through south Florida, Central America, the Greater Antilles,

and South America (Poole et al. 2020). In South Carolina, the Least Bittern is most abundant in the Coastal Zone. PIF estimates the global population size of Least Bitterns to be 310,000 individuals with 130,000 in the United States and Canada (2024).



The Nelson's Sparrow has three breeding populations. The first breeds in marshes in central Canada and into the Dakotas and Minnesota. The second breeds around James and Hudson Bay in Canada. The third breeds along the St. Lawrence estuaries and the marshes of the Canadian Maritimes and northern New England. Nelson's Sparrows primarily winter on the Atlantic and Gulf Coasts from North Carolina to Texas, although they also occur in California (Shriver et al. 2020). In South Carolina, Nelson's Sparrows generally are detected in marshes in coastal counties from Charleston County to Jasper County. PIF estimates the global population size of Nelson's Sparrows to be 1,000,000 individuals with all residing in the United States and Canada (2024).

The Saltmarsh Sparrow only occupies tidal saltmarsh. The species breeds from Maine to Virginia and winters primarily from Maryland and Virginia to Florida, although in mild years they will winter in North Carolina and Virginia (Greenlaw et al. 2020). In South Carolina, Saltmarsh Sparrows generally are detected in tidal marshes in coastal counties from Charleston County to Jasper County. PIF estimates the global population size of Saltmarsh Sparrows to be 60,000 individuals with all residing in the United States (2024).

The Worthington's Marsh Wren is nonmigratory and can be found in coastal marshes from northeast South Carolina to the northeast coast of Florida year-round (Kroodsma and Verner 2020). Research is needed to better understand the distribution and population size of Worthington's Marsh Wren in South Carolina. The range map for the nominate race is included.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The King Rail habitat includes freshwater to brackish marshes (both tidal and non-tidal), impoundments, early successional marsh-shrub swamp, and rice fields (Pickens and Meanly

2020). King Rails use habitat with dense vegetation and shallow open water interspersed within their home range that provide foraging opportunities (Pickens and King 2013, Pickens and Meanly 2020). Selection for specific vegetation types likely varies with water level and may be more indicative of the water level conditions due to precipitation and flooding at the time of use (Pickens and King 2013). King Rails feed primarily on crustaceans (crayfish, fiddler crabs) and forage under vegetation cover or close to the vegetation edge (Pickens and Meanly 2020).

The Yellow Rail uses the drier areas of coastal marsh, freshwater marsh, "wet" or low-lying fields and pastures, grassy Carolina bays, damp grassy power line right-of-ways, and ditch banks. Due to the bird's small size, it does not use marshes and impoundments with deep water. It is sometimes found in recent clearcuts with scattered puddles of standing water and bunched grasses. Tall or moderate-height grasses seem important for cover. Some woody trees and shrubs are acceptable features in the habitat, but based on personal observations (Cely) at a Yellow Rail site in lower Richland County, SC over an 8 to 9 year period, succession to woody shrubs and trees seemed detrimental. Fire, mowing, and other successional retardants are probably needed to maintain suitable habitat conditions. Yellow Rails forage in shallow water covered by dense vegetation and feed primarily on invertebrates (small snails, insects, spiders, crustaceans) and some seeds (Leston and Bookhout 2020).

The Least Bittern uses freshwater and brackish marsh with tall vegetation, such as cattails, and open water. In addition, pond and lake margins with emergent vegetation and managed impoundments are frequented. As with most members of the Ardeidae family, the Least Bittern may need deeper water for nesting security purposes. Least Bitterns primarily forage from dense stands of emergent vegetation on the edge of open water and feed on small fish and other small vertebrates, insects, and crustaceans (Poole et al. 2020).

Overwintering Nelson's Sparrows use tidal marshes and occasionally cattail marsh. Nelson's Sparrows forage for small invertebrates and seeds beneath the grass and along the edges of pools (Shriver et al. 2020). The Saltmarsh Sparrow similarly uses tidal marsh, usually those dominated by *Spartina* grasses. Saltmarsh Sparrows often forage along muddy edges and can be seen during high tides when they move upslope to the marsh periphery (Greenlaw et al. 2020).

The Worthington's Marsh Wren occupies tidal marshes dominated by *Spartina alterniflora*. They usually nest within colonies in the tall grass along tidal creeks (FWC 2011). Further study is needed to understand Worthington's Marsh Wren habitat use specifically in South Carolina.

CHALLENGES

Loss of wetland habitat is the most obvious problem, but for some species, adequate habitat seems available in South Carolina. Declines may be related to other reasons as yet undefined such as pollutants and/or predators. A marsh bird survey conducted by the SCDNR (Cely et al. 1993) noted that the majority of recorded marsh birds were associated with coastal waterfowl impoundments and managed wetlands. The future of these species in South Carolina could, therefore, be tied to active waterfowl management programs in the State and any threats to those habitats managed for waterfowl. As most marsh bird management is incidental to waterfowl management, more information is needed on how to effectively integrate marsh bird management with waterfowl management. In addition, little is known about the basic nesting

biology of the species in this guild that breed in South Carolina. Black Rails face many of the challenges identified for other species in the Marsh Birds guild, but also face unique challenges due to their specific habitat requirements.

Fire suppression causes habitat loss because plant succession reduces the suitability of wetland habitats. Shrub growth will reduce grass cover preferred by most marsh birds. Prescribed burning is an important tool for managing marsh bird habitat. As development increases along the coasts, managers are more reluctant to use fire as a management tool, and regulations restricting burning have increased. Slow-burning (backing and flanking) fires that leave a mosaic of burned and unburned areas maintain refugia and suitable habitat. Most wetlands should not be burned every year because it takes a couple of years for suitable vegetation to re-grow. Fast-moving and multipoint fires can result in marsh bird mortality (USFWS 2019). Burning during the nesting season can result in the loss of adults and young. The use of aerial ignition to burn huge areas quickly and "clean burns" in which no patches of vegetation are left are probably particularly dangerous practices for rails and other wetland species.

Effects of climate change and sea level rise are currently being studied, with some models being produced to demonstrate loss of marshes and the inundation of managed wetlands, where these species are generally found. The ability of these marshes to accrete soil and migrate inland will be important to the long-term survival of the species that utilize marshes and the estuarine systems. Some long-term projections show that some of the more inland managed wetlands will retain their infrastructure, while those closer to the ocean will likely be inundated. The ability to restore some of these degraded managed wetlands in more inland areas could be very important to the sustainability of these marsh bird populations.

CONSERVATION ACCOMPLISHMENTS

The continued preservation of wetland habitats, including freshwater and saltwater marshes, is beneficial to these species. The Atlantic Coast Joint Venture has published a Salt Marsh Bird Conservation Plan which highlights strategies and actions for supporting salt marsh bird populations experiencing declines, highlighting Black Rails and Saltmarsh Sparrows and flagship species (ACJV 2019). Preservation of areas such as the ACE Basin with extensive protected wetland complexes has provided excellent resources for these species. Some of the best habitats for these species include existing managed impoundments along the coast. Additionally, Conway (2004) has initiated standardized monitoring protocols for these species.

SCDNR is researching ways to maximize useable habitat for marsh birds, especially for rails, through prescriptive impoundment management. Often, traditional impoundment management does not allow for fine-scale water level control. By frequently monitoring water levels and adjusting water level control structures as needed, target water levels are maintained in high-priority breeding and foraging areas. Additionally, SCDNR is researching how experimental irrigation can be used to maximize usable habitat for marsh birds within impoundments as well as create novel habitat that is mindful of future climate scenarios. Some rail species, such as Black Rails and Yellow Rails, will use wet meadow habitat. As impoundment infrastructure becomes increasingly vulnerable to sea level rise and increased storm intensity, wet meadows may provide habitat that is less susceptible to climate stressors.

CONSERVATION RECOMMENDATIONS

- Protect and manage wetlands. This includes retarding plant succession through burning, disking, mowing, herbicide, seasonal flooding and other measures that restore natural disturbance regimes. This can be accomplished, in part, by increasing the utilization of federal incentive programs that compensate private landowners for wetland restoration activities and practices that reduce erosion and increase water quality.
- Control the spread of invasive species such as *Phragmites australis* and *Triadica sebifera* which outcompete native species and have negative wildlife value.
- Research basic life history and management needs for the species in this guild in South Carolina's wetland habitats.
- Survey appropriate habitat to gather distributional data for these species.
- Establish a monitoring initiative to determine current species distributions and evaluate population trends.
- Investigate the role of microtopography on habitat use by marsh birds, especially those that require extremely shallow water levels such as Black Rails and Yellow Rails.
- Acquire lands that are suitable for facilitated marsh migration.
- Create novel wet meadow habitat using irrigation or other land management practices to benefit marsh species, especially Black Rails and Yellow Rails, that rely on very shallow water levels.
- Create and distribute best management practices for guild species, especially rails, and disseminate to local landowners and land managers.

MEASURES OF SUCCESS

The first measure of success would be to implement long-term population monitoring studies which would yield information about distribution, population status, and trends for this group. The next step is to increase quantity and quality of habitat by implementing the above-mentioned conservation recommendations. The ultimate measure of success is to document stable population trends for declining species and to increase populations for species in which research suggests it is warranted.

DESCRIPTION

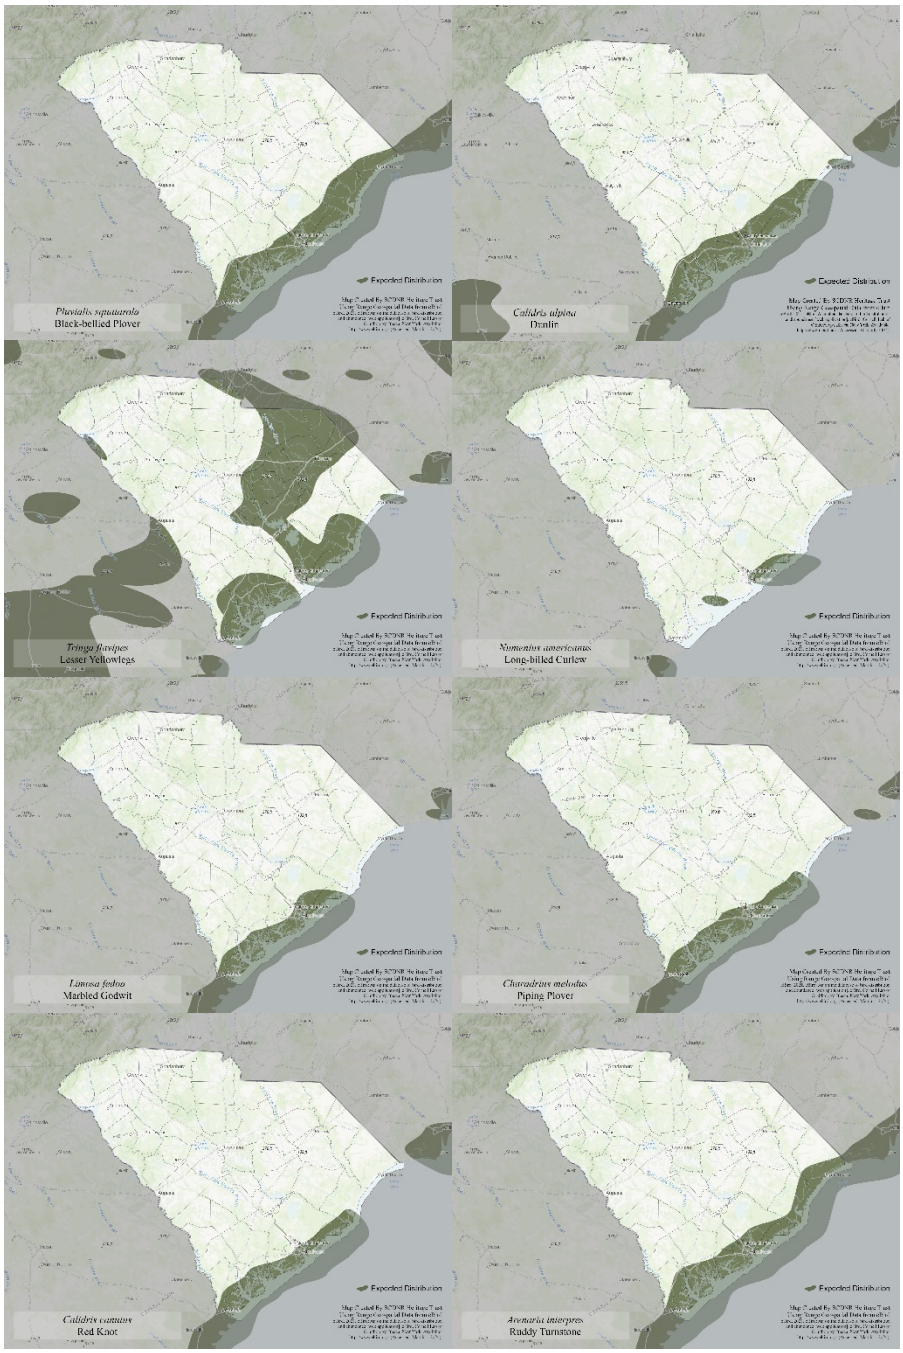
Taxonomy and Basic Description

Mixed shorebird flock by Felicia Sanders

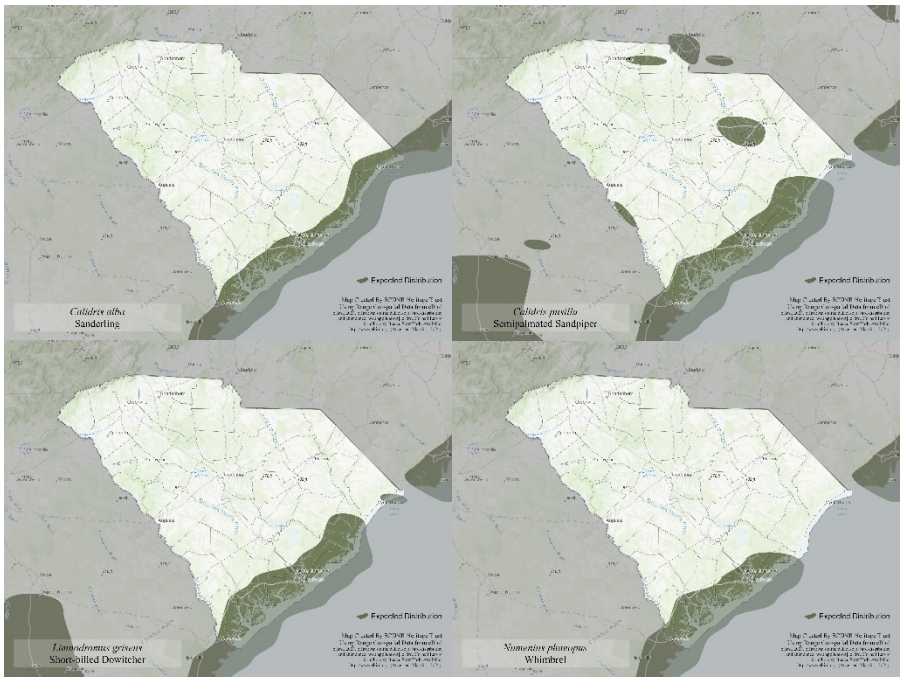
The shorebird guild is composed of birds in the Charadrii suborder. Migratory shorebirds in the SWAP list in South Carolina are in the 2 families: Scolopacidae (sandpipers) and Charadriidae (plovers). Sandpipers are the most diverse family of shorebirds. Their tactile foraging strategy encompasses probing in soft mud or sand for invertebrates. Plovers are medium-size birds, with relatively short, thick bills and employ a distinctive foraging strategy. They stand, looking for prey, and then run to feed on detected invertebrates.

Shorebirds are characterized by long legs for wading and wings designed for quick flight and transcontinental migrations. Migrations can span continents; for example, some Red Knots migrate from the Canadian arctic to the southern tip of South America. Less frequently, shorebirds may migrate from the Northeastern to Southeastern US, as is the case for the Piping Plover. Migratory shorebirds in South Carolina may be transient birds on a northbound flight in the spring, a southbound flight in the fall, or wintering birds.

Plumage can be strikingly different between summer and winter. Although nesting habitat includes inland tundra and prairies, during the non-breeding season, they forage and roost in mixed species flocks primarily on the coast. Thus, they are aptly named shorebirds.



Status



Whimbrel by USFWS

Despite challenges with low precision associated with migration count data, population trends between 1980 and 2019 for 28 shorebird species found in North America were analyzed by a team of experts from the Canadian Wildlife Service, USFWS and Manomet, a scientific research organization. This published study found that 26 of the 28 (93%) shorebird species were found to be declining with more than half of the species losing more than half of their abundance. The greatest declines were along the Atlantic coast from Nova Scotia to North Carolina and the declines are worsening in recent years (Smith et al. 2023). Many shorebird species are in need of protection afforded by federal listing, but Piping Plovers and Red Knots are the only listed shorebird in South Carolina; these species are federally threatened.

POPULATION SIZE AND DISTRIBUTION

Population sizes of most species are not known because shorebird migration can span continents and breeding grounds are mostly inaccessible arctic and sub-arctic habitats. Censuses at stopover areas are useful for estimating minimum population size. Most migrant species are present year-round but are less abundant during short arctic summers. Spring migration along the Atlantic Coast is from March to May while fall migration is from July to October (Helmers 1992). Peak shorebird counts occurred in late March in the Cape Romain Region, the area from Cape Romain National Wildlife Refuge south to Dewees Inlet, while minimum counts were in late June (Dodd and Spinks 2001). Dunlins consist of over half of all shorebirds present with a peak abundance in February (Wallover et al. 2015).

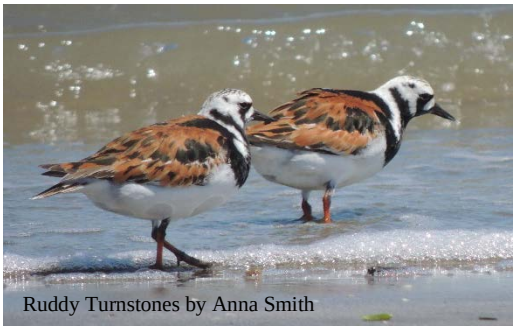
In 1974 Manomet Center for Conservation Sciences (http://www.manomet.org) began coordinating International Shorebird Surveys (ISS) to monitor shorebird numbers at important stopover sites. Surveys can be conducted all year, but most counts are conducted during fall and spring migrations. ISS are conducted by government biologists, staff from partner organizations and volunteers and data are used to identify important areas to individual species, valuable habitat types, and population trends. The most consistently surveyed sites in South Carolina from 2020 to 2023 are: Huntington Beach State Park, Yawkey Wildlife Center, North Inlet, Cape Romain NWR, Capers Island, Dewees Island, Headquarters Plantation Drive on Johns Island, Folly Beach, Bird Key Seabird Sanctuary, Kiawah Island, Seabrook Island, Hunting Island State Park, Harbor Island, Pinckney Retreat and Battery Creek West Basin in Beaufort, Hilton Head Island, and Turtle Island Wildlife Management Area (https://www.manomet.org/iss)

Black-bellied Plover by USFWS

The Western Hemisphere Shorebird Reserve Network (http://www.whsrn.org/) identified essential migratory sites for the western hemisphere using ISS data. The Network in 2024 has 120 sites in 20 countries, from Alaska to Tierra del Fuego in southern South America. In 2018, the Cape Romain NWR Western Hemispheric Shorebird Reserve Network Site (Site) was expanded. The Cape Romain-Santee Delta Region Site of International Importance now stretches for 50 miles of coastline, covering 119,440 acres (48,336 hectares) from the Yawkey Wildlife Center south to Dewees Island. ISS data confirm that the Cape Romain – Santee Delta Region site is a rest stop for 100,000 migratory shorebirds every year. The Site hosts 15% of the U.S. East and Gulf Coast population of American Oystercatchers, and 11% of Short-billed Dowitchers and likely supports more than 10% of the Semipalmated Plover and Red Knot populations. The expansion unites

seven sub-sites managed by three different partners – the federally run Cape Romain National Wildlife Refuge, the South Carolina Department of Natural Resources, and the privately run Dewees Island Property Owners Association. The Yawkey Wildlife Center, Santee Coastal Reserve Wildlife Management Area, and Cape Romain National Wildlife Refuge are additionally recognized by BirdLife International and National Audubon Society as Important Bird Areas (https://whsrn.org/whsrn_sites/cape-romain-santee-delta-region).

Piping Plovers nest in more southern latitudes compared to most migratory shorebirds. Piping Plovers nesting in the Great Lakes region are federally endangered with approximately 70 pairs. During the last range wide census, the 2016 International Piping Plover Census, the number of wintering piping plovers in South Carolina was 126 individuals. The largest proportion of Piping Plovers nesting in the Great Lakes appears to winter in South Carolina and Georgia, thus making South Carolina important for Piping Plovers. Research conducted on Piping Plovers in South Carolina found that plovers wintering on disturbed sites were 7% lighter than those in less disturbed sites and annual survival was lower in more disturbed areas. Movements away from specific areas were uncommon (Gibson et al. 2018). This research emphasizes the need for management of human disturbance for recovery of the species.



Piping Plover by USFWS

The *rufa* subspecies of the Red Knot, breeds in the Canadian Arctic and winters in four distinct areas: the Southeast United States/Caribbean, the north coast of South America, the western Gulf of Mexico/Central America, and in southern South America (Niles et al. 2008, U.S. Fish and Wildlife Service 2020). The Southeast United States/Caribbean hosts one quarter of the total estimated wintering knot population (U.S. Fish and Wildlife Service 2020) and is a critical region for knots as a stopover during north and southbound migration (Schwarzer et al. 2012, Lyons et al. 2017, Pelton et al. 2022). The most recent U.S. Fish and Wildlife Service estimate for the Red Knot population is 63,600 (U.S. Fish and Wildlife Service 2020). The southbound passage population utilizing the Georgia coast was estimated to be approximately 23,400 knots, (Andres et al. 2012, Lyons et al. 2017) while the Kiawah Island, Seabrook Island and Deveaux Bank area of South Carolina, supports a minimum spring passage population of more than 17,000 individuals (Pelton et al. 2022). This suggests the Southeast United States supports upwards of a third of the knot population during migration each year. Most Red Knots that are migrating north from South Carolina in the spring skip Delaware Bay (73%) while 27% of the knots stop in Delaware Bay for at least 1 day. Some knots use an Atlantic Coast strategy that does not include Delaware Bay, relying instead on the areas around Chesapeake Bay or New York Bay for stopovers. Most knots travel north from South Carolina through the eastern Great Lake Basin, without stopping, thus making the Southeast United States the last terminal stopover for some knots before reaching boreal or Arctic stopover sites.

Nocturnal roosts are an essential, yet often overlooked component of shorebird habitat due to their inaccessibility and use at night. South Carolina is an important staging area for Atlantic coast Whimbrel during spring migration, with the largest known Whimbrel nocturnal roost in the Western Hemisphere at Deveaux Bank Seabird Sanctuary. The peak count during spring surveys in 2019 and 2020 at Deveaux Bank was 19,485 roosting Whimbrel, which represents approximately 49% of the estimated eastern population of Whimbrel and 24% of the entire North American population (Sanders et al. 2021).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Ruddy Turnstones by Anna Smith

Shorebirds roost and forage in coastal wetland habitats as well as inland. They feed on invertebrates found in mudflats, sparsely vegetated shallow water, and on beaches and oyster reefs. They also regularly feed on horseshoe crab eggs in the spring. Additionally, the Ruddy Turnstones use rocky, intertidal habitats such as jetties. Different bill lengths and feeding strategies allow mixed species flocks to forage in the same area while exploiting different food resources. Along the coast, tides influence both diurnal and nocturnal foraging. Foraging activity occurs primarily during falling and rising tides and at low tide. At high tide, when foraging grounds are covered, birds roost in flocks on high shell rakes, beaches, estuarine islands, and occasionally on docks. Shorebirds may require different habitats for daytime and nighttime roosting. Roosting sites may contain thousands of shorebirds. Dunlin, Sanderlings, Red Knots, small sandpipers, and plovers primarily use beaches. Short-billed Dowitchers and Marbled Godwits are also found on oyster reefs and docks. Ruddy Turnstones use a variety of habitats (Dodd and Spinks 2001).

Red Knot by USFWS

South Carolina contains many managed coastal wetlands (30,000 hectares) that were historically used for rice production. These managed tidal impoundments are currently used for waterfowl habitat (Miglarese and Sandifer 1982). Managing for spring shorebird migrations requires specific manipulation of water levels. Additionally, shallow water can be periodically maintained in wetlands during August to October for fall shorebird migration (Williams et al. 2002). Management of wetlands for shorebirds and waterfowl provides supplemental habitat that may be preferred to natural mudflats (Weber and Haig 1996).

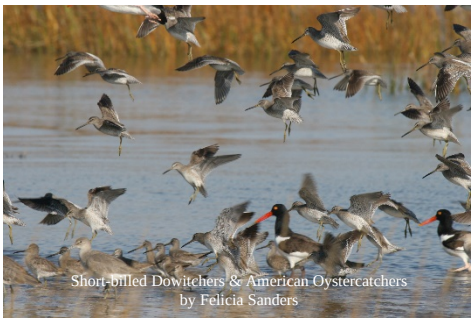
CHALLENGES

Members of this guild share both roosting and foraging sites and are usually impacted by the same factors. Shorebirds are especially vulnerable to habitat degradation because they congregate in large flocks at key stopover sites to replenish fat during long migrations (Myers et al. 1987).

Semipalmated Sandpiper by USFWS

Due to the complicated life history associated with birds of this guild, there are many challenges in conserving these species. Disturbance by humans and boat traffic at foraging areas reduces feeding efficiency, thereby reducing the fat available for migration or winter survival. Disturbance at roosting sites results in an expenditure of energy each time the birds are flushed and may have a cumulative effect of depleting fat reserves, particularly at key stopover areas. There has also been a decline in invertebrates available (for foraging) due to beach renourishment. Overharvests of horseshoe crabs for pharmaceutical use may also impact available forage. Finally, oil spills that degrade marine environments can have potentially major impacts on migrating shorebirds, both by disrupting feeding patterns and by leading to the direct mortality of food sources.

CONSERVATION ACCOMPLISHMENTS



Long-billed Curlew by USFWS

SCDNR organized multiple workshops including a 3-day workshop for managers of impoundments. Topics covered during workshops included: brackish and moist-soil management for multiple species (waterfowl, wading birds and shorebirds), timing of shorebird migration, invertebrate identification, technical and cost-share assistance available to private landowners, and field identification of shorebirds.

SCDNR staff completed important research on shorebirds which was reported in scientific publications. Publications included topics such as: spring migration patterns of Red Knots and Ruddy Turnstones using the Motus Wildlife Tracking System; abundance and distribution of shorebirds in cape Romain National Wildlife Refuge; a population estimate of Red Knots using Kiawah and Seabrook islands; Red Knot migration tracking across the hemisphere using geolocators; spatial and temporal overlap between foraging shorebirds and spawning horseshoe crabs (*Limulus polyphemus*) in the Cape Romain National Wildlife Refuge; the world's largest nocturnal roost of Whimbrel at Deveaux Bank; and migratory shorebird movements to guide wind energy placements.

The SCDNR coordinated or conducted several surveys, including a coast-wide survey of large shorebird roosts. SCDNR conducted 2 statewide shorebird surveys that were not reported in the 2015 SC's SWAP. 38,235 shorebirds (28 species) were counted Jan 31, 2013 - Feb 7, 2014, at 54 sites. The Cape Romain Region had 16,031 (42% of the total) shorebirds. Only one shell rake boating route was covered. The shell rakes along the Intracoastal Waterway in the Cape Romain Region had 7,759 (20% of the total). South Carolina has miles of shell rakes that were not covered so this survey is a minimum count of shorebirds that use South Carolina coastal areas. 47,287 shorebirds (28 species) were counted Jan 22 to Jan 31, 2015. Dunlin (27,087) were over half the total shorebirds. The survey included 122 participant days, 57 sites, 149 miles of habitat and 175 hours. Like the previous year, the highest count was on the Intracoastal Waterway shell rakes in The Cape Romain Region which had 8,895 (19% of total) shorebirds. Kiawah (the east end) had the highest count for a beach with 5,177 shorebirds.

SCDNR partnered with multiple agencies and organizations, especially US Fish and Wildlife Service and the South Carolina Audubon to expand the South Carolina Shorebird Project, a partnership created to promote shorebird conservation in South Carolina. A component of the Shorebird Project is an annual meeting, hosted by SCDNR, to promote collaborative management of shorebirds.

Short-billed Dowitchers & American Oystercatchers by Felicia Sanders

The first shorebird festival in South Carolina was held in 2023. SCDNR and many organizations coordinated the 2-day Sea Islands Shorebird Festival, that consisted of speaking events, bird walks, and family friendly activities to celebrate shorebirds and the islands they depend on. The goal was to educate community members and visitors and raise awareness to protect these magnificent birds and places. After the success of the festival in 2023, in 2024, the Southeast Shorebird Festival will be held. The festival expanded in length and range to include the entirety of the South Carolina-Georgia coast for a full week of festivities. This decentralized model is inspired by the interconnectedness and importance of the entire region's coastal habitats for our shared shorebirds that depend on it for survival.

CONSERVATION RECOMMENDATIONS

- Conduct statewide surveys of large shorebird concentrations to document important areas or habitats and document annual variability and trends.
- Participate in Piping Plover and Red Knot surveys and color band resighting.
- Continue to research shorebird, especially Red Knot and Piping Plovers, migration patterns and prey items.
- Participate in International Shorebird Surveys organized by Manomet.
- Expand the number of sites in South Carolina that are included in the WHSRN.

- Reduce disturbance at foraging and roosting areas, including nocturnal roosts, by educating the public as to the effects of disturbance and the status of shorebirds. Place educational signage where applicable.
- Work with government and private land managers to manage important shorebird roosts and foraging sites.
- Disseminate information on and encourage use of integrated management of wetlands typically managed solely for waterfowl. Host workshops for land managers that encourage management for shorebirds.
- Expand the SC Shorebird Project to include additional partners, a network of volunteers and build a web site with resources for land managers, volunteers and partners.
- Work with the U.S. Army Corps of Engineers to enhance and create shorebird habitat with dredged sediments though the Corps' beneficial use of dredge material programs.
- Work with partners to understand the reasons for the decline in the Southeast wintering Long-billed Curlew.

MEASURES OF SUCCESS

This guild of birds is subject to rapid shifts in distribution and abundance and will require adaptive management to respond to these changes. Management priorities may shift if the severity of species' declines is further documented.

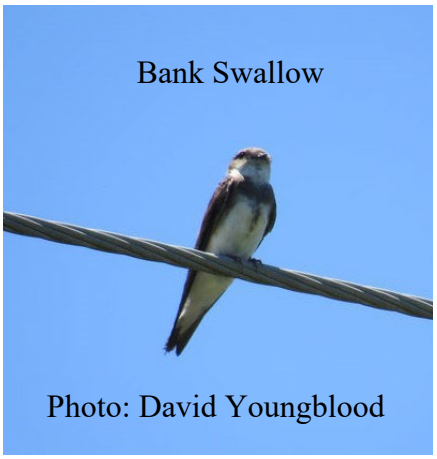
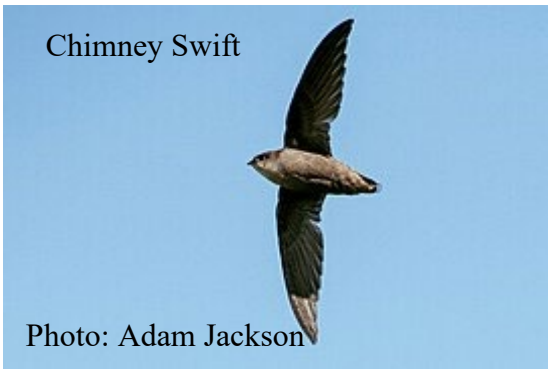
Miscellaneous Bird Guild



Bank Swallow (*Riparia riparia*)
Chimney Swift (*Chaetura pelagica*)
Evening Grosbeak (*Coccothraustes vespertinus*)

Contributor (2013): Paige Koon (SCDNR)
Reviewed and Edited (2024): Amy Tegeler (SCDNR) and Sarah Stewart (SCDNR)



DESCRIPTION

Taxonomy and Basic Description

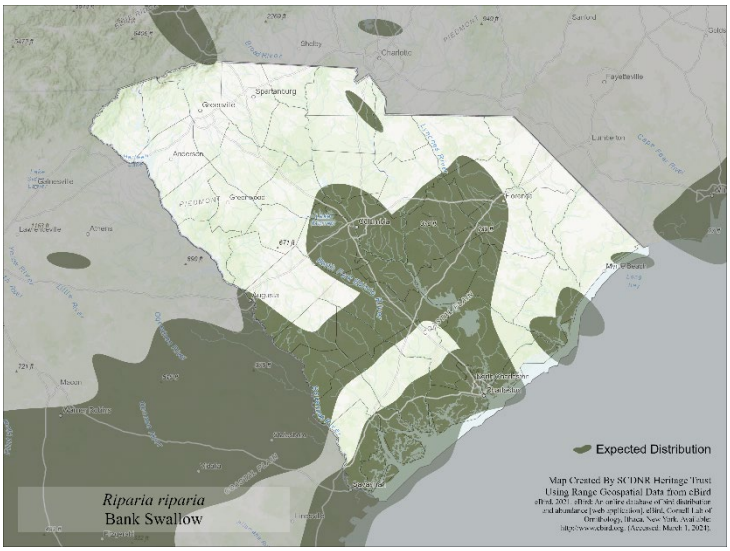
The Bank Swallow is a small swallow (length 12 cm and mass 10.2 to 18.8 g; Garrison and Turner 2020). Adults have a brown back, and white chest with a brown breast band. The tail is slightly notched (Garrison and Turner 2020). Both sexes are similar in appearance. One subspecies occures in North America, although another is a vagrant (Garrison and Turner 2020). The North American subspecies was first described in 1758 by Linnaeus (Garrison and Turner 2020).

The Chimney Swift is dark sooty olive or brown above and plain gray-brown below, with a paler chin and throat. The plumage is slightly glossy. The tail is short and rounded, sometimes with noticable spiny tips. Their flight is agile and fast, with rapid wing beats (Steeves et al. 2020). This species is 13.9 cm long with a 17.0 to 29.8 g mass (Steeves et al. 2020). Both sexes are similar. The Chimney Swift was first described by Linnaeus in 1758 (NatureServe 2014).

The Evening Grosbeak is a large finch species with an average length of 17 cm (6.7 in) and a weight between 53 – 74 g (1.9-2.6 oz). This species has a robust bill used for crushing small berries and seeds (Gillihan and Byers 2020). Males are identified by their distinctive coloring, with a brown-black crown and nape, bright yellow forehead, yellow scapulars and breast, and black wings with white wing bars.

Females are drabber in coloring and lack the yellow forehead of males. Three subspecies are recognized and are distinguished by their breeding ranges, following Howell (1968).

Status

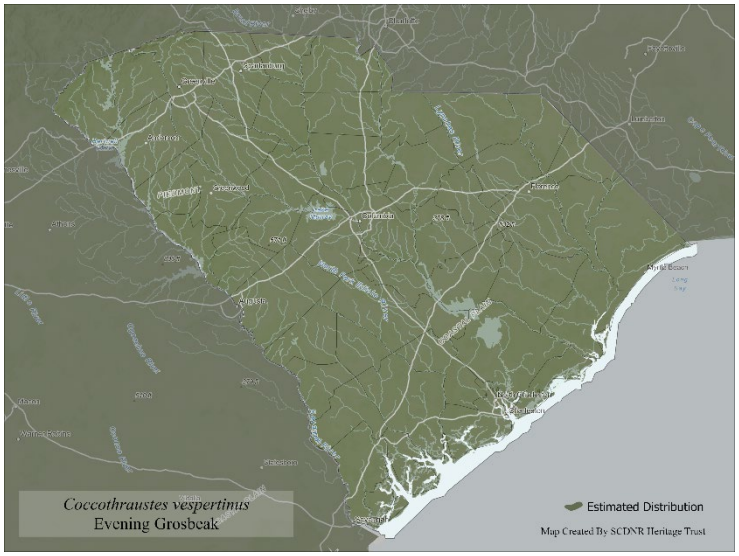


The Bank Swallow is considered a common bird in steep according to Partners in Flight (2016). The species has experienced a 89% population loss between 1970 to 2014 (Partners in Flight 2016).

The Chimney Swift is considered a common bird in steep decline and has experienced a 67% population loss between 1970 to 2014 (Partners in Flight 2016). The IUCN has the species listed as Vulnerable (2023).

The Evening Grosbeak is listed as Vulnerable by IUCN (2023) and included on PIF's Yellow Watch List, which identifies priority species for reversing population decline. The species is also listed as having regional importance for the Atlantic Coast Joint Venture (PIF 2023).

POPULATION SIZE AND DISTRIBUTION



The Bank Swallow is a passage migrant through South Carolina. The species typically migrates in mixed-species flocks during the day (Barrett and Turner 2020). They are more common during spring migration than fall (Seriff and Beirregaard 2018). Most Bank Swallows migrate in spring from early April to the end of May (Seriff and Beirregaard 2018). The species breeds in portions of Canada and the northern U.S. and winters mainly in South America (Barrett and Turner 2020). The U.S. and Canada population estimate is 7,900,000 individuals (Partners in Flight 2020).

The Chimney Swift is found in the spring and summer months throughout the Eastern US and into the southern extremes of Eastern Canada; it winters in the upper Amazon River Basin in northern South America (Cink and Collins 2002). Chimney Swifts are common throughout South Carolina in spring and summer months. They generally arrive in early April and leave in mid-October (Seriff and Beirregaard 2018). Before

migrating south, Chimney Swifts form large roosting flocks, of sometimes thousands of birds (Seriff and Beirregaard 2018). Historically they were considered common, but are currently in steep decline (Seriff and Beirregaard 2018). The current South Carolina population estimate is 290,000 individuals (Partners in Flight 2020). South Carolina has experienced an annual rate of decline of 2.6 from 1966-2022 (Sauer et al. 2021).

The Evening Grosbeak is associated with northern coniferous forests, with resident populations across southern, central Canada and in mountainous regions of the western US. This species migrates irruptively, with large numbers of individuals wintering in southern or low-elevation regions in response to low food availability (Gillihan and Byers 2020). The first Evening Grosbeak observation in South Carolina was at Paris Mountain State Park in Greenville County in 1951 (Seriff and Beirregaard 2018). Irruptive winter populations have been recorded throughout the state and were fairly common in the second half of the 20th century, with a decline in observations since the turn of the millennia (Bonter and Harvey 2008; Seriff and Beirregaard 2018; eBird 2024). Because occurrence records are sparse, and their habitat use during migration and winter can be generalized, the species' distribution in South Carolina is not known. Rangewide, the species' current population estimate is 3.8 million individuals (PIF 2023). However, the Evening Grosbeak has experienced steep declines, with an approximately 94% decline since 1970 (Rosenburg et al. 2016), and an annual rate of decline of 1.5% between 1966 and 2021 (Ziolkowski et al. 2022).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

During migration they utilize a variety of open and water-associated habitats including wetlands, agricultural areas, marshes and prairies that provide sources of food (Garrison and Turner 2020). Bank Swallow haven't been confirmed to nest in South Carolina (Seriff and Beirregaard 2018), but the species nest in vertical banks, cliffs and bluffs in alluvial, friable soils (Garrison and Turner 2020). Breeding sites are typically in lowland areas along ocean coasts, rivers, streams, lakes, wetlands and man-made sites such as quarries and road cuts (Garrison and Turner 2020). Suitability of sites depends on erosion, which both creates and reduces nesting sites. Rivers and streams with nesting habitat are typically low-gradient, meandering waterways with eroding banks. Waves, tidal action, and wind create vertical faces in coastal areas and along lakeshores (Garrison and Turner 2020).

Chimney Swifts use a variety of habitats. They forage over forested, open and urban areas. It appears that access to suitable nest and roosting sites tend to be more important (Steeves et al. 2020). Chimney Swifts are cavity nesters. Historically they nested in hollow trees, but currently almost exclusively nest on man-made structures, most often chimneys (Seriff and Beirregaard 2018) but can also utilize air vents, open wells, man-made Chimney Swift nesting towers and similar structures.

The Evening Grosbeak uses a range of habitats in its overwintering range, including suburban neighborhoods and woodlots, mid-elevation coniferous forests, and mixed hardwood-pine forests (Gillihan and Byers 2020). When observed in South Carolina, the species is most often seen at backyard feeders, though there have been historical winter sightings at Congaree Swamp in Congaree National Park, in mixed forest at Croft and Chester State Parks, and high elevation forest at Caesars Head State Park (Seriff and Beirregaard 2018; eBird 2024). They also appear to use mixed hardwood-pine forests and pine flatwoods in Florida (Gillihan and Byers 2020). While there have not been quantitative winter diet analyses for the species, Evening Grosbeaks appear to have varied diets of invertebrates, fruits, and seeds in the breeding season, and will exploit supplemented food at backyard feeders outside the breeding season (Gillihan and Byers 2020).

CHALLENGES

Loss of suitable nesting locations for Bank Swallow have likely contributed to population declines. Nest sites are eliminated due to flood and erosion control projects, declines in mining sand and gravel pit operations, and other activities that exacerbate erosion (Garrison and Turner 2020). There have also been reports of Bank Swallows colliding with vehicles and windows. Shooting on the wintering grounds has also been documented (Garrison and Turner 2020).

With the arrival of European settlers, Chimney Swifts likely went from being a somewhat uncommon bird to an abundant bird as chimneys and other human-made structures became available for nesting sites. In recent years however, the destruction of old chimneys and the subsequent construction of new chimneys less suitable as nest sites have contributed to the species' decline (Steeves et al. 2020). The species can also succumb to gas or suffocate in soot while in chimneys (Steeves et al. 2020). Collisions with communication towers and vehicles has also been noted (Steeves et al. 2020). It is also possible that declines in insect populations have led to declines in Chimney Swift populations (Steeves et al. 2020).

Despite the Evening Grosbeak's conspicuous flocking behavior during the winter, the species is generally understudied, and the primary drivers of their decline are poorly understood. With concurrent declines of other boreal forest breeders (Ralston et al. 2015), loss or degradation of mature, spruce-pine forests appears to play notable a role in Evening Grosbeak declines (Bonter and Harvey 2008; Gillihan and Byers 2020). Collisions with windows and vehicles, as well as outbreaks of diseases like Salmonellosis, may also negatively influence population dynamics (Bonter and Harvey 2008).

CONSERVATION ACCOMPLISHMENTS

No specific conservation accomplishments have been noted for these species.

CONSERVATION RECOMMENDATIONS

- Develop and implement monitoring programs to better assess breeding and nonnbreeding bird population sizes. Assess habitat management and surveillance monitoring techniques to quantify short- and long-term population responses. Develop measures to integrate state monitoring results into regional and national level databases.
- Reduce communication tower collisions through design modifications.
- Promote construction of Chimney Swift nesting towers at suitable locations.
- Locate and monitor Chimney Swift roosting sites.
- Continue monitoring potential irruptions of Evening Grosbeaks during Christmas Bird Counts and the Great Backyard Bird Count. Encourage greater participation by volunteers and provide information and ID guidance on irruptive species.
- Elucidate factors leading to the Evening Grosbeak's range expansion into South Carolina in the 1950's and eventual contraction at the end of the century. Determine historical timber or land use practices that may have contributed to changes in distribution.

MEASURES OF SUCCESS

As results from current research or surveys on these species are completed, projects will be initiated to address specific needs in South Carolina that arise from these results. Stable or increasing observations of the species will be a measure of success.

DESCRIPTION

Taxonomy and Basic Description

The species in this guild belong to the taxonomic order Passeriformes (perching birds) and are in the family Parulidae (the wood warblers). Wood warblers are small and colorful with sharp, pointed beaks for gleaning insects.

Cerulean Warbler
photo from Wikimedia Commons

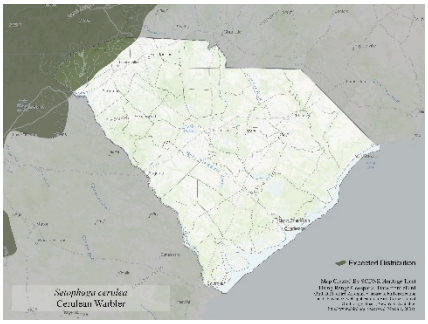
The Cerulean Warbler male is a deep cerulean blue with white underparts and a narrow dark band across the throat. The female Cerulean is bluish green with yellowish underparts and a pale line above the eye. Both male and female have white wing bars. The average length is 11.5 cm (4.5 in.), and the weight is 8 - 10 g (0.3 - 0.4 oz.) (Buehler et al. 2020).

The Golden-winged Warbler is a small, striking songbird averaging 12.1 cm (4.75 in.) in length and 8.8 g (0.31 oz.) in weight. Adult males have a yellow crown, a black mask, and a black throat. This bird has a white belly, gray back, and a yellow wing patch. Adult females and juveniles appear similar to the males but have a duller overall appearance and a greenish-yellow crown (Sibley 2003).

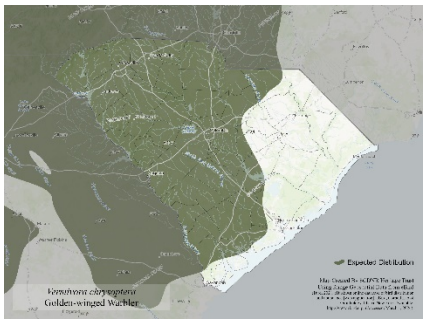
Status

The Cerulean Warbler is one of the most vulnerable Neotropical migrants (Hunter 2001). It is considered critically imperiled in South Carolina (NatureServe 2013). Between 1966-1993, the BBS indicated a 49.5% decline in the species in Eastern North America (Sauer et. al. 2012). This warbler is listed as Vulnerable by IUCN Red List (2011), and a National Species of Conservation Concern by U.S. Fish and Wildlife Service (USFWS 2007).

Golden-winged Warblers are currently facing declines from habitat loss, hybridization, and competition. Golden-winged Warblers are disturbance-dependent birds. Birds in this type of habitat are experiencing precipitous population declines (Askins 2000 and 2001; Hunter et al. 2001). These warblers nest in disturbed sites such as abandoned farmland, clearcuts, and burned



forest stands that are currently in decline in the face of urban sprawl, reforestation, and the succession of grassland and shrubby habitats (Confer et al. 2020, NatureServe 2013).



Golden-winged Warblers frequently become extirpated in areas with Blue-winged Warblers. Blue-winged Warblers are expanding their range northward and out-compete Golden-Winged Warblers for resources such as territories, nesting material, and food. Blue-winged Warblers also hybridize with golden-winged warblers, producing viable offspring. This causes a genetic decline for Golden-winged Warblers (Confer et al. 2020). While the Golden-winged Warbler is not currently ranked in South Carolina, it is ranked at the federal level as a Species of Concern (NatureServe 2013).

POPULATION SIZE AND DISTRIBUTION

The population status of the Cerulean warbler in South Carolina is unknown. Cerulean Warblers have experienced a long-term population decline. Cerulean Warbler numbers have declined at the steepest rate of any North American warbler species monitored by the North American Breeding Bird Survey (Sauer et al. 2005). Analysis of North American Breeding Bird Survey (BBS) data indicate that over the last 40 years, the decline has been steep and steady at a rate of about -3.0% per year (USFWS 2007). It winters in low to medium elevation broadleaf and evergreen forests of northern South America in Venezuela, Colombia and Peru. The Cerulean Warbler is sensitive to habitat changes and modifications. Habitat degradation in its breeding, migrating and wintering ranges over the last decades are suspected of having caused a decline of 72% since the 1970s. Its half-life is estimated at 26 years for a population of approximately 570,000 individuals (PIF 2024).

The Golden-winged Warbler is a northern breeding bird found in Southern Canada, the Northeastern United States and extending south into the Appalachians. South Carolina composes the southern-most extent of the range where these birds occur in small numbers in the extreme northwestern part of the State. The Golden-winged Warbler overwinters in Central America and northern South America (NatureServe 2013). According to BBS trend data (1966-2010), Golden-winged Warblers are declining at a rate of 2.6% per year in the Eastern BBS region. Population trends for the

Southern region cannot be accurately calculated since populations are so small (Sauer et al. 2012).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Mountains of South Carolina refers to the Blue Ridge Mountains, part of the larger Appalachian Mountains, that stretches from Maine to Alabama. It is the smallest geographical region in the whole state. The highest point in the South Carolina mountains is Sassafras Mountain, at an elevation of around 3,533 ft (1,078 m), which is located on the border with North Carolina. The Blue Ridge Region is mountainous and has many hardwood forests, streams, and waterfalls. Many rivers flow out of the Blue Ridge.

The Golden-winged Warbler is an early-successional specialist species. They require shrubby habitat in upland or wetland areas, with sporadic tree cover and an understory of grass and forbs. Early successional habitats are short-lived and turn into mature forests, forcing these warblers out of the habitat (Confer et al. 2020). Golden-winged warblers nest in habitat with dense herbaceous cover and patches of shrubs, often adjacent to a forest edge, usually at moderate elevations. Natural disturbance habitats include beaver glades and openings from natural fires. It also occurs in a variety of anthropogenic disturbance sites such as clearcuts, abandoned farmlands, and power line rights-of-ways. Golden-winged Warblers most commonly occur in clearcuts < 20 yr old (Confer et al. 2020).

The Cerulean Warbler prefers a mature forest with an open understory in large unfragmented tracts of forest (Buehler et al. 2020). Its distribution is not uniform throughout its range, and it can be widespread in some areas and localized in others. It prefers white oaks (*Quercus alba*) and bitternut hickories (*Carya cordiformis*) for nesting, foraging and as singing perches. Forests where red maples (*Acer rubrum*) and red oaks (*Quercus rubrum*) are dominant are avoided (PIF 2024).

CHALLENGES

Loss of mature deciduous forest, especially along stream valleys, has negatively affected Cerulean Warblers. This is the most serious long-term problem facing the species on its breeding grounds. Large areas of potential breeding terrain are uninhabitable by this warbler because they lie in urban areas or because they have been converted to agricultural land uses. Perhaps more than most North American birds, the Cerulean Warbler is sensitive to landscape-level changes in habitat (Buehler et al. 2020). Forest fragmentation is the biggest problem for all deciduous forest interior birds, including Cerulean Warblers. Roads into forests bring native and non-native predators such as rodents and feral cats. Nest parasites, such as the brown-headed cowbird (*Molothrus ater*) can also move into the forest interior (Kilgo and Moorman 2003). As forest habitat shrinks, bird species that are area-sensitive may abandon smaller woodlots altogether.

Local declines of Golden-winged Warblers correlate with both loss of habitat and with expansion of the Blue-winged Warbler into the range of the Golden-wing. Disturbed sites, such as abandoned farmland and aspen clearcuts and fire managed forest stands provide regionally important nesting habitat. Declines of these habitat types owing to reforestation, fire suppression,

reduced timber harvest, urban sprawl, and reduced acreage of recently abandoned farmland are associated with population declines throughout most of the Golden-wing range (Confer et al. 2020). Early successional habitats are short-lived and turn into mature forests, forcing these warblers out of the habitat (Buehler et al. 2006).

Disturbance-dependent birds have suffered steep population declines throughout the Eastern US (Hunter et al. 2001). Historically fire, floods, windstorms, and herbivores maintained habitat conditions conducive to disturbance-dependent species (Askins 2001). Fire suppression, the loss of large canopy tress such as the American chestnut (*Castanaea dentata*), and the extirpation of beaver (*Castor canadensis*) and mega herbivores such as elk (*Cervus elaphus*) and bison (*Bison bison*) following European settlement, reduced the availability of early-successional habitat throughout the Eastern US (Askins 2000).

Communication towers are a significant source of mortality for migratory birds. Nocturnal migrants often become confused by the red lights of communication towers and hit the guy wires or the towers themselves. (Shire et al. 2000),

Additionally, an over-population of white-tailed deer (*Odocoileus virginianus*) can be detrimental to bird habitat. In areas of high densities (greater than 7.9 deer/km2), herbivores browse the understory such that nesting and foraging substrates are greatly reduced (NatureServe 2004).

Although not a problem specific to South Carolina, habitat destruction on the birds' wintering grounds (Central and South America and the Caribbean) is causing a decline in populations.

CONSERVATION ACCOMPLISHMENTS

The purchase by the State and subsequent management of the Jocassee Gorges in 1997 resulted in habitat protection for these and other bird species. The Jocassee Gorges includes at least 1,200 acres of forest 60 years and older; some patches are older than 80 years (M. Hall, SCDNR, pers. comm.). Most stands, however, are still maturing. Completion of PIF plans for Physiographic Area #03: South Atlantic Coastal Plain and Physiographic Area #23: Southern Blue Ridge serve as good sources of continued management interaction. Finally, preliminary (Huckabee 2001) and continued (Boyle et al. 2003) research on forest interior species in the Jocassee Gorges and surrounds have provided—and will continue to provide—important information for these species.

In addition, a new guidance document has been prepared by the ACJV and its partners: The Piedmont Bird Conservation Region (BCR 29) Implementation Plan, Version 1.0, 2013. This Plan will be utilized when reviewing priority bird species in this ecoregion.

No conservation initiatives have been set specifically for members of this guild. South Carolina has many properties under ownership by state and federal agencies which protect habitat that could potentially host the species. These include State Heritage Preserves, Wildlife Management Areas, and National Forests.

Long-term monitoring programs, such as the Breeding Bird Survey (Sauer et al. 2005), have provided population trend data that enables biologists and land managers to prioritize management decisions based on the knowledge of population trends.

National initiatives such as the Partners in Flight (PIF) Landbird Conservation Plan (Rich et al. 2004) and the North American Bird Conservation Initiative (NABCI 2005) have provided a method by which interested parties can coordinate conservation activities. These initiatives have provided guidelines for priority species, population and habitat objectives, and recommendations for conservation actions. State and federal agencies have implemented habitat improvement projects based on guidelines outlined in PIF and NABCI.

CONSERVATION RECOMMENDATIONS

- Utilize GIS and land type associations to determine total area and distribution of available habitat. Modeling will enable SCDNR to prioritize land acquisition and habitat improvement projects.
- Partner with other land management agencies and make recommendations about habitat improvement projects that benefit these species.
- Expand the use of Farm Bill and other cost-share programs to implement activities that integrate habitat objectives for early-succession birds.
- Expand participation in the Landowner Incentive Program (LIP) to create or enhance habitat on private lands.
- Promote the use of Best Management Practices that support providing buffer zones and that increase structural diversity (such as providing small clearcuts).
- Partner with appropriate agencies to encourage prescribed burning activities on public and private lands.
- Work with international partners to identify problems on wintering grounds. Where feasible, provide financial incentives to conserve habitat.
- Breeding Bird Survey routes should continue annually; increase the number of routes in under-sampled areas of South Carolina.
- Initiate agency supported monitoring programs, such as Partners In Flight (PIF) point counts.
- Expand monitoring programs to areas not adequately sampled.
- Monitor bird response to management activities both pre- and post-treatment.
- Continue to strengthen partnerships with regional and national initiatives such as the Atlantic Coast Joint Venture, Appalachian Mountains Bird Conservation Region (BCR), PIF and NABCI.
- Pursue opportunities for funding for land acquisition or management activities through partnerships with regional agencies and NGOs.
- Develop partnerships with recreational bird watching organizations in the State.
- Research effects of bird strikes on migratory bird populations and partner with the communications industry to work toward solutions in SC.
- Identify and protect forest interior and unbroken large tracts of deciduous forest habitat. Determine the best sites for conservation and/or restoration projects by conducting a landscape-level spatial analysis. Utilize GIS-based models as a basis for land acquisition

and delivery of private lands programs to locate areas where opportunities for conservation are the greatest.

- Develop corridors to link forested tracts.
- Continue to promote partnerships to implement forest health measures to prevent, detect, and suppress outbreaks of sudden oak death (SOD) and hemlock woolly adelgid (*Adelges tsugae*) on public and private lands.
- Reduce communication tower collisions. The following recommendations set forth by Shire (2000) may assist in that effort:
    - No aviation lights should be placed on towers that are less than 199 ft. tall.
    - Remove old towers that are no longer in operation. Recycle old communication towers for additional purposes instead of building new ones.
    - Environmental Assessments should be conducted to determine the impact a new tower's construction will have on birds if built in a migratory route.
- If found to be causing an impact in certain areas, the removal of feral cats (*Felis catus*) from public lands through live trapping should be implemented.
- Conduct studies to determine the minimum area requirements for forest birds.
- Investigate the effects of deer on breeding bird habitat.
- Develop and implement monitoring programs to better assess breeding, migrating, and wintering bird population sizes. Management and surveillance monitoring techniques will need to be assessed to quantify short and long-term population responses in order to answer specific monitoring questions. Measures will need to be developed to integrate state monitoring results into regional- and national-level databases.
- Radar ornithology should be continued in order to monitor bird-habitat associations at migration stopover sites.
- Partner with other states and countries to gather data on migratory stop-over sites, wintering ground usage, and the threats faced at each.
- Promote existing and develop new partnerships to facilitate increased land acquisition.
- Promote the participation of volunteers and agency personnel to collect survey and monitoring data.

MEASURES OF SUCCESS

The first measure of success will be to implement monitoring programs that will allow SCDNR to document population trends and avian response to management in the State. Habitat improvement and restoration projects should result in higher breeding populations and nesting success rates. One measure of success is to halt population declines and support population sizes similar to the goals outlined by Rosenberg (2004).

Nesting Shorebird Guild

Willet (*Catoptrophorus semipalmatus*)
Wilson's Plover (*Anarhynchus wilsonia*)

Contributors (2024): Janet Thibault and Felicia Sanders (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The nesting shorebird guild is composed of birds in the Families *Haematopodidae, Scolopacidae* and *Charadridae.* American Oystercatchers (*Haematopodidae*) are covered in a separate SWAP species profile. Species in the nesting shorebird group breed in coastal ecosystems commonly on barrier beaches, islands, and inlets and migrate south to winter in the Caribbean or South America.

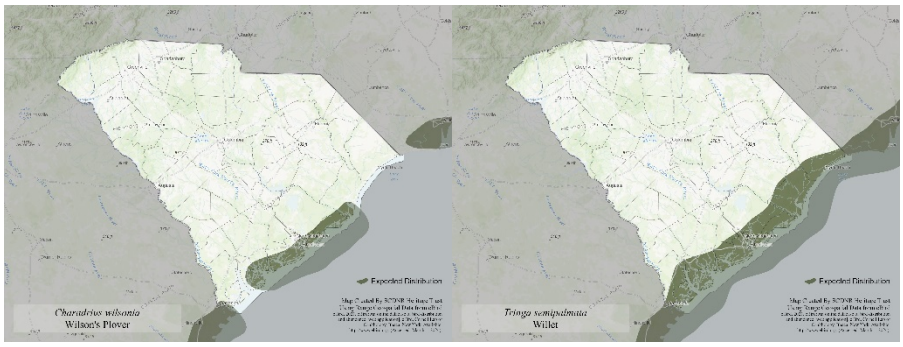
Willet Photograph by USFWS

The Willet has two distinct subgroups of breeding populations: *Tringa semipalmata semipalmata* and *Tringa semipalmata inornata* or Eastern and Western Willet, respectively (Lowther et al. 2020). Eastern Willets nest in South Carolina, whereas Western Willets winter in and migrate through South Carolina. Many aspects of the habitat requirements, challenges and conservation recommendations covered in the Migratory Shorebird Guild SWAP account are also applicable to the Nesting Shorebird Guild, especially for the Western Willet that nests in freshwater habitats of western states and provinces. Hereafter "Willet" will mostly refer to the Eastern subspecies, although the Eastern and Western Willets are often indistinguishable in the field, thus data such as survey results may include both subspecies.

Willet Photograph by USFWS

The Willet is a long-legged shorebird with a striking black and white pattern on its wings revealed in flight, a long bill, and gray to brown plumage.

The Wilson's Plover (*Anarhynchus wilsonia*) is a medium sized, belted plover with a heavy bill. Females have a brown breast band and males have a black band which is more pronounced during the breeding season. Both sexes have white underparts, a white forecrown, and pinkish-gray legs. Males and females are similarly structured with a mean wing length of 118 mm for females and 119 mm for males. Mean mass for males (69 grams) and females (68 grams) is similar (Zdravkovic et al. 2023).



Male Wilson's Plover Photograph by Bess Kellett

Status

Willets have a large geographical range nesting along the Atlantic Coast from Canada to Florida and along all Gulf Coast states. Willets are listed as Moderate Concern according to the US Shorebird Conservation Plan Conservation Plan (Brown et al. 2001) but have no specific protections.

Wilson's Plovers once nested as far north as New Jersey but have not been recorded in that state since 1955 (Zdravkovic et al. 2023). Currently, Wilson's Plovers nest from Virginia to Southern Florida and along the Gulf Coast from Florida to Texas. They are listed as state endangered in Virginia and Maryland, a species of special concern in North Carolina, and state threatened in South Carolina. Wilson's Plovers are listed as High Concern in US Shorebird Conservation Plan Conservation Plan (Brown et al. 2001).

POPULATION SIZE AND DISTRIBUTION

The Eastern Willet has an estimated population of 90,000 birds (Lowther et al. 2001) but there are no estimates for South Carolina. While Willets are observed year-round in South Carolina, the Eastern Willet is only observed from March through July (Tomkins 1965) with the Western Willet present through most of the year. Peak counts of Willets (Eastern and Western are not distinguished) during monthly International Shorebird Surveys from 2013 – 2019 at Deveaux Bank, South Carolina occurred in Apil and June most years. The highest numbers recorded during these surveys were in April 2014 (85), April 2015 (94), June 2015 (166), June 2016 (91), April 2017 (94), and April 2018 (184). Monthly shorebird counts in Cape Romain National Wildlife Refuge also reported peak counts of Willets in April and June but the highest counts were in July (Figure 1 from Wallover et. al 2015).

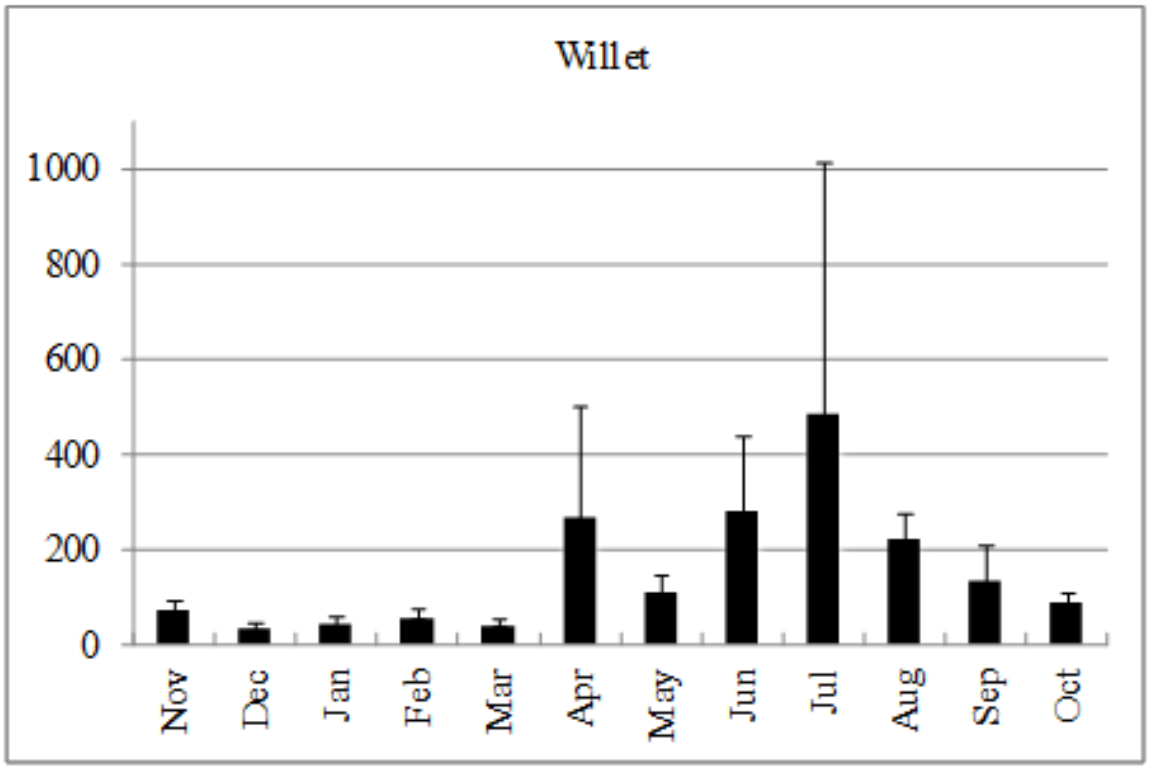


Figure 1. Mean monthly abundance and 95% confidence intervals of Willets censused monthly in Cape Romain National Wildlife Refuge, South Carolina, for three years from November 2007 to October 2010.

In South Carolina, Willets nest in the secondary dune systems of barrier beaches, islands and inlets along the coast often near saltmarsh. Willets make a nest on a raised clump of American beach grass (*Ammophila breviligulata*) or sea ox-eye (*Borrichia fruescens*) and lay 4 speckled eggs in a cup lined with finer grasses. Nests and chicks are at risk of mammalian and avian predation, and even in secondary dune habitat nests can be over washed from tidal inundation due to wind and storms.

Willet on nest Photograph by Janet Thibault

From breeding pair counts from Virginia to Georgia, the Atlantic coast population of Wilson's Plover is estimated to be 1,000-1,100 breeding pairs, although surveys have not been conducted in Florida (Zdravkovic 2013). A state census of Wilson's Plovers was conducted in South Carolina during 2009-2012 and a mean of 376 breeding pairs was recorded (Sanders et al. 2012). Wilson's Plovers nest directly on the ground in open areas of sandy or shell beaches near inlets often in remote areas (Dikun 2008). Harrington (2008) found from analyzing International Shorebird Surveys conducted in the Southeastern US, that

Wilson’s Plovers were found in significantly higher numbers around inlets than in non-inlet coastal locations.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Nesting habitat for Willets and Wilson’s Plovers is primarily on beaches and dune systems. Willets breed near coastal marshes in South Carolina and make their nests behind barrier dunes in vegetation. Wilson's Plovers nest in open areas of sandy islands and inlets, often near dune edges or clumps of vegetation. The nesting season of this group is from March through July. Both parents share incubation duties and chicks are precocial and mobile after hatching. To distract predators from its nest or chicks, Wilson's Plover parents will sometimes exhibit a "broken wing display."

Nesting shorebirds feed on invertebrates found in mudflats, sparsely vegetated shallow water, and on beaches and oyster reefs. Some may feed on horseshoe crab eggs in the spring. Both species feed on fiddler crabs (*Uca pugnax*) in mudflats near nesting sites. Along the coast, tides influence both diurnal and nocturnal foraging. Foraging activity is focused around the time of low tide.

Wilson’s Plover nest Photograph by Janet Thibault

CHALLENGES

Increased development of the South Carolina coast continues to reduce suitable shorebird nesting habitat and may force breeding pairs into less suitable sites. Although actual nesting sites are rarely destroyed, suitability of the sites is greatly reduced when nearby development increases disturbance of nesting birds. Disturbance from sources such as humans, dogs, and boats negatively affects reproductive success by causing threatened adults to leave eggs and/or chicks unattended. Nests are also at risk from native avian and mammalian predators. Flooding and predation were the most common causes of nest failure during a study of Wilson’s Plover nesting at the Yawkey Wildlife Center (Zinsser et al. 2017).

In addition, climate change continues to threaten this guild as sea level rise inundates nesting and foraging sites during the breeding season. Hurricanes and tidal flooding erode beaches and barrier islands and higher tidal amplitudes may flood nests that have been laid during the breeding season. Climate change will also affect coastal habitats where these species over winter in Central and South America where land surface is lost from subsidence (Galbraith et al. 2014). A study of Wilson’s Plovers in South Carolina found that daily survival rates of nests were most strongly related to maximum tide height,

which suggests that flooding and over wash may be common causes of nest loss (Zinsser et a. 2017).

Birds in this guild are also long-distance migrants, therefore, understanding and identifying stopover and wintering locations is crucial to conservation of birds that cross geopolitical and national borders. Shorebirds have historically experienced predation and direct mortality along stopover and wintering areas in Central and South America, where shorebird hunting has recently been identified (Watts and Turrin 2016).

Because of the complicated life history associated with birds of this guild, there are many challenges in conserving these species. Disturbance by humans and boat traffic at nesting areas reduces nest success, thereby reducing chick survival and recruitment. Overharvest of horseshoe crabs for pharmaceutical use may also impact available forage. Finally, oil spills that degrade marine environments can have potentially major impacts on nesting shorebirds, both by disrupting feeding patterns and by leading to the direct mortality of food sources.

Wilson's Plover "Broken Wing" display Photograph by Janet Thibault

CONSERVATION ACCOMPLISHMENTS

To protect nesting habitat, SCDNR maintains seasonal closures of important nesting islands, posts temporary closures of dunes and areas above high tide where these species nest. Approximately 30 properties in South Carolina have nesting shorebirds and are posted during the breeding season.

A geolocator tagging study of nesting Willets was conducted on Deveaux Bank in 2016-2019 to determine when Eastern Willets are present in South Carolina, to determine migration departure and arrival dates, and to identify overwintering and stopover locations (SCDNR unpublished data). Two geolocators were recovered and revealed wintering areas in Sao Luis, Brazil and French Guiana (Figures 2 and 3 respectively). Geolocator tracks were interpreted by Ron Porter of the Delaware Shorebird Project. These Willets departed South Carolina after the nesting season, one bird on 6 July and the other on 17 July. Willet 207 was banded on 8 June 2016 and recaptured on 18 May 2017. The geolocator of this bird failed in February so the return flight to South Carolina was not recorded. Willet 120 was banded on 7 June 2018, returned to South Carolina on 25 March 2019 and was recaptured on 24 May 2019.

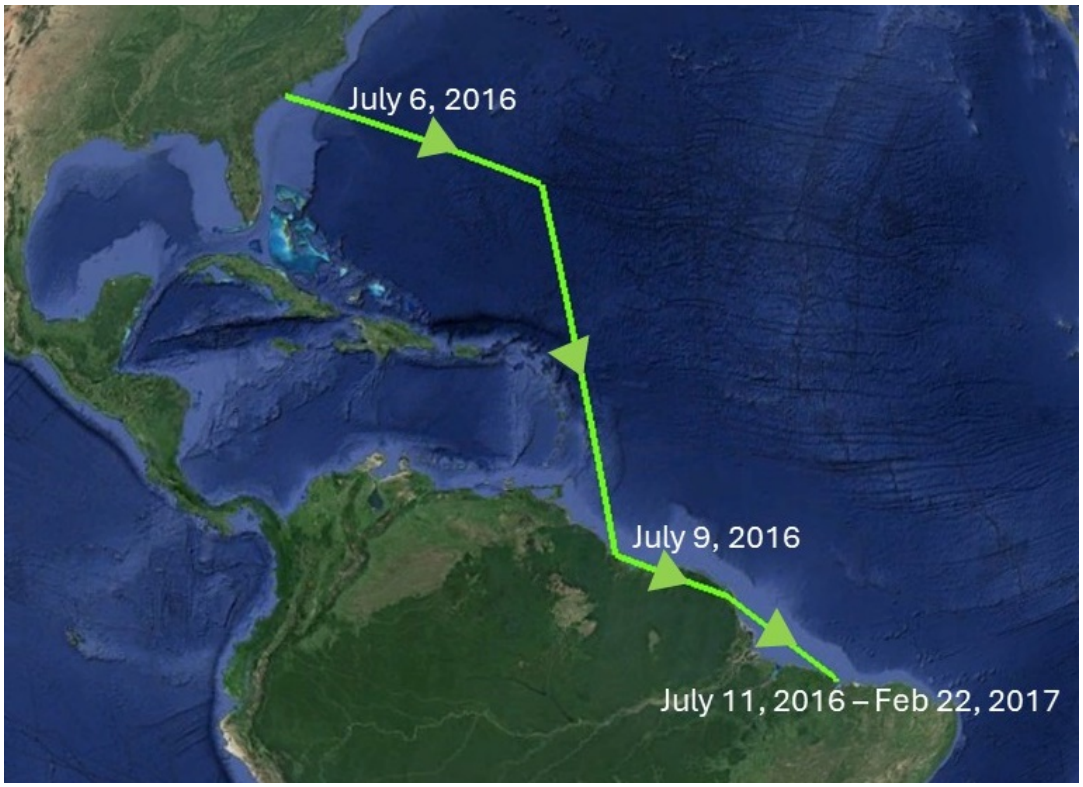

Figure 3. Geolocator track of Willet 207 from South Carolina to South America, July 2016 - February 2017. The geolocator failed in February and did not record the northbound track back to South Carolina.

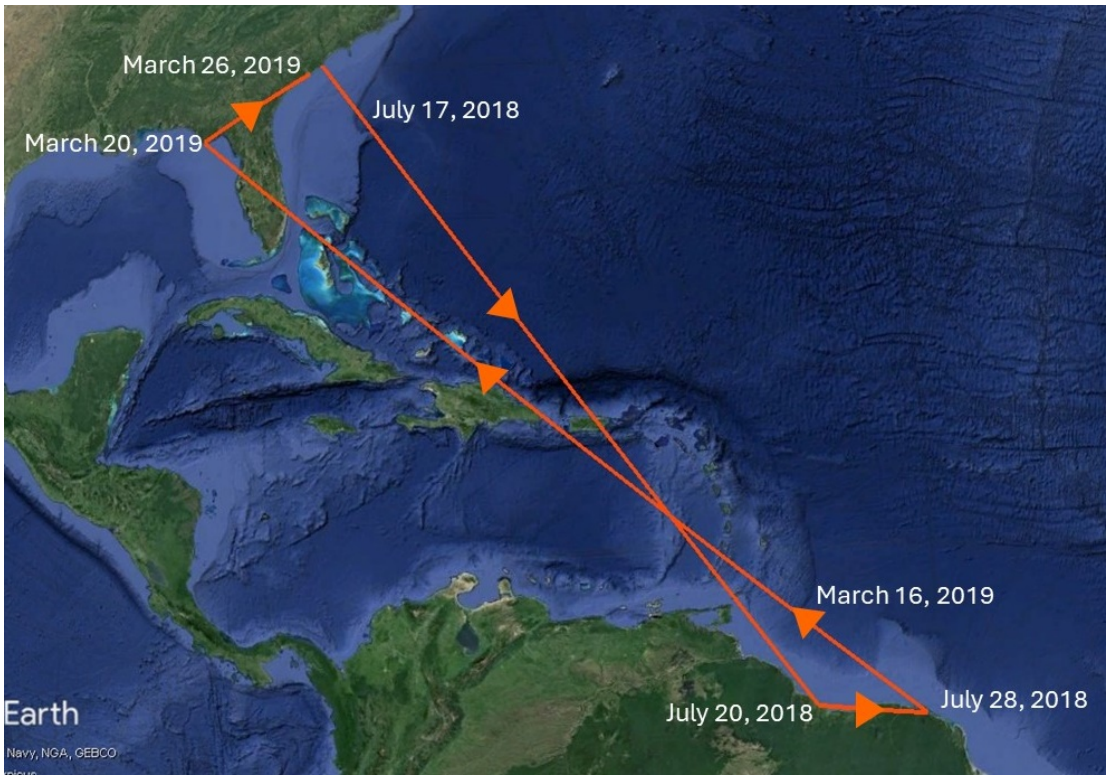

Figure 4. Geolocator tracks of Willet 120 southbound from South Carolina and northbound from French Guiana, 2018-2019.

SCDNR conducted a statewide census of nesting Wilson's Plovers in 2009-2012 to determine abundance and distribution of nesting pairs in the state which prior to 2009 was unknown in South Carolina. All suitable habitats were surveyed, and a mean of 376 pairs were recorded providing a baseline for the state that can be used to analyze population trends. In South Carolina, 29% of the pairs were present on private land and 71% were found on public land (Sanders et al. 2012). This census helped to identify priority areas for seasonal closures and important beaches to engage with public communities to increase awareness of beach nesting species. Graduate students at Coastal Carolina University and Clemson University conducted research projects on nest site selection and nest success of Wilson's Plovers in South Carolina (Dikun 2008; Zissner 2013).

SCDNR partners with multiple agencies and organizations, especially US Fish and Wildlife Service and Audubon South Carolina to develop community engagement, shorebird stewardship and conservation through the South Carolina Shorebird Project. This project organizes workshops and training sessions to promote shorebird conservation as well as educational materials and resources to increase awareness of shorebird conservation. Nesting and roosting site protection has increased due to partnerships and volunteers helping to install and maintain educational signs at important sites.

CONSERVATION RECOMMENDATIONS

- Conduct statewide surveys of nesting shorebirds.
- Reduce disturbance at foraging, roosting, and nesting areas by educating the public about the effects of disturbance and the conservation status of shorebirds.
- Work with government and private land managers to manage important shorebird roost and nest sites.
- Continue cooperative efforts with the US Fish and Wildlife Service to census and manage important shorebird nesting and foraging sites within Cape Romain National Wildlife Refuge.
- Support Shorebird Stewardship programs in beach communities and volunteer engagement activities.
- Expand the SC Shorebird Project to include additional partners, a network of volunteers and build a web site with resources for land managers, volunteers and partners.
- Research shorebird nesting ecology and migration patterns.

MEASURES OF SUCCESS

This guild of birds is subject to rapid shifts in distribution and abundance and will require adaptive management to respond to these changes. Management priorities may shift if the severity of species' declines is further documented.

Northern Bobwhite

Colinus virginianus

Contributor (2005): Billy Dukes (SCDNR)
Reviewed and Edited (2012): Billy Dukes (SCDNR)
Reviewed and Edited (2024): Billy Dukes (SCDNR)

DESCRIPTION

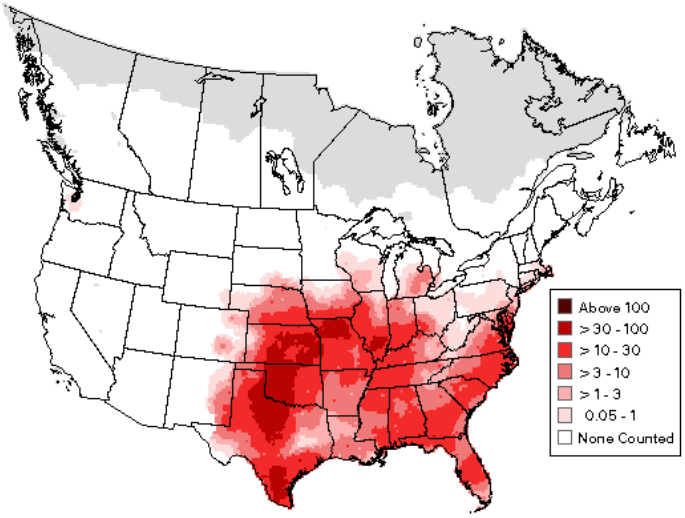
Taxonomy and Basic Description

In 1748, Catesby gave the Bobwhite quail the name *Perdix sylvestris virginiana*. In 1758, Linnaeus dropped the generic name *Perdix* and substituted *Tetrao*. The generic name *Colinus* was first used by Goldfuss in 1820 and, despite several ensuing name changes, became the accepted nomenclature (Rosene 1984). Bobwhite quail are members of the family Odontophoridae, the New World quail.

Bobwhite quail are predominantly reddish-brown, with lesser amounts of white, brown, gray and black throughout. Both sexes have a dark stripe that originates at the beak and runs through the eye to the base of the skull. In males, the stripe above and below the eye is white, as is the throat patch. In females, this stripe and throat patch are light brown or tan. Typical weights for Bobwhites in South Carolina range from 160 to 180 g (5.6 to 6.3 oz.). Overall length throughout the range of the species is between 240 and 275 mm (9.5 and 10.8 in.) (Rosene 1984).

Status

Bobwhite quail are still widely distributed throughout their historic range. However, North American Breeding Bird Survey data indicate a significant range-wide decline of 3.8% annually between the years 1966 and 2009 (Sauer et al. 2004). In South Carolina, quail populations have declined at a rate of 6.1% annually since 1966 (Sauer et al. 2011).



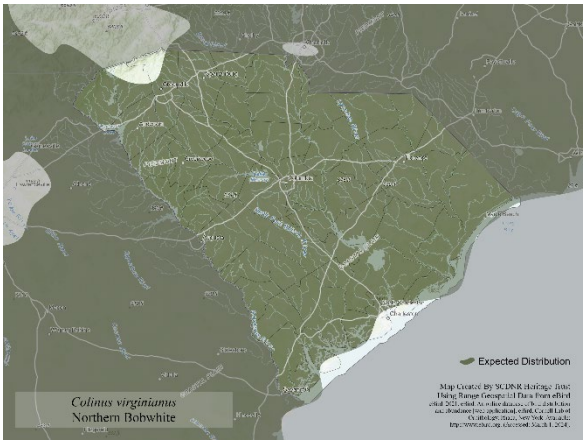


Figure 1: Average summer distribution of northern bobwhite quail 1994-2003. From Sauer et al. (2004).

While not on the Partners in Flight Watch List, the concern for Northern Bobwhite is specifically mentioned due to significant population declines over the past 35 years (Rich et al.

2004). Despite rangewide declines, high densities of quail (6.6 to 7.6 birds/ha) are often maintained on lands where intensive habitat management occurs or conditions are otherwise suitable (Brennan 1999).

POPULATION SIZE AND DISTRIBUTION

Bobwhite quail occur throughout South Carolina, with higher densities found in the Coastal Plain than the Piedmont (SCDNR unpublished data). Within the Coastal Plain of South Carolina, quail population densities are higher in the Inner Coastal Plain than in the Outer Coastal Plain and Coastal Zone. Greater concentrations and more wide-spread distribution of row-crop agriculture in the Inner Coastal Plain creates habitat conditions more favorable for quail than are found in heavily forested landscapes typical of the Outer Coastal Plain and Piedmont.

Quail populations exhibit dramatic seasonal and annual fluctuations, making accurate population estimates difficult. Estimated autumn and breeding populations of Bobwhites in 1999 were 20.1 million and 6.7 million, respectively (Dimmick et al. 2002). Partners in Flight put the estimated global breeding population at 9.2 million, with 82% (7.5 million) occurring in the continental US (Rich et al. 2004).

Quail habitat quality and population levels vary widely across the landscape, resulting in tremendous uncertainty related to extrapolation of population densities to the statewide level. Using assumptions contained in the National Bobwhite Conservation Initiative (NBCI) the estimated quail population for South Carolina in autumn of 2010 was 306,148 individuals (NBTC 2011).

An assumed autumn population of 306,148 individuals translates into a statewide density estimate of 3.9 individuals/km^2 (10.1 individuals/mi.^{2}). Autumn population estimates conducted at select areas in South Carolina where timber density and fire regimes favor quail have documented populations estimated at 98.9 individuals/km^2 (256 individuals/mi.^{2}) (SCDNR unpublished data). Some forested landscapes on which minimal management for quail has occurred have been documented to support autumn densities of 27.2 individuals/km^2 (70.4 individuals/mi.^{2}) (SCDNR unpublished data).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Bobwhite quail use a variety of cover types throughout their broad geographic range. Early successional habitats such as croplands, grasslands, fallow fields, open pinelands and open mixed pine-hardwood forests that have diverse groundcover vegetation are particularly important in the South (Brennan 1999). Perennial warm-season bunchgrasses are the preferred nesting substrate throughout much of the range of the species. Preferred brood-rearing cover consists of

diverse communities of erect annual forbs with abundant insects, bare ground between stems, and a foliage canopy.

Eastern Towhee, Blue Grosbeak, Yellow-breasted Chat, Indigo Bunting, Northern Cardinal, Gray Catbird, Brown Thrasher, and Carolina Wren are among the many species that have habitat requirements similar to Northern Bobwhite such as shrub/scrubland. Many of these species are discussed in more detail in the Early- to Mid-Succession Birds Guild. Those species found in more of an open grassland habitat, which is also frequented by the Northern Bobwhite, include Barn Owl, Loggerhead Shrike, Eastern Meadowlark, Grasshopper Sparrow, Field Sparrow, and Common Ground-dove. All of these species are subject to the same threats as Northern Bobwhite, and will likewise benefit from habitat enhancement practices aimed at restoring populations of Northern Bobwhites. They are discussed in more detail in the Grassland Birds Guild.

CHALLENGES

Habitat loss due to the effects of urbanization, modern agricultural and silvicultural practices, fire suppression, and the introduction of exotic pasture grasses is widely recognized as the primary problem for Bobwhite quail populations (Stoddard 1931; Rosene 1984; Barnes 1995; Brennan 1991; Brennan 1999; Thackston and Whitney 2001).

A lack of nesting and brood-rearing cover is believed to be the major limiting factor over much of the range of the species (Rosene 1984; Dimmick et al. 2002). For a more complete discussion of the effects of habitat changes on Bobwhite populations and habitat suitability, see the Northern Bobwhite Conservation Initiative (Dimmick et al. 2002) and the National Bobwhite Conservation Initiative (NBTC 2011).

Lack of qualified personnel for delivery of technical assistance to private landowners continues to be a limiting factor for state and federal natural resources agencies.

CONSERVATION ACCOMPLISHMENTS

The SCDNR Small Game Program was established in 1978 for the primary purpose of addressing declining populations of traditional small game species, including Bobwhite quail, through technical assistance to private landowners. Since that time, biologists in the Small Game Program have completed over 500 site visits and written management plans for private landowners, potentially affecting over 500,000 acres of habitat. Over the same time period, biologists have developed numerous technical publications and conducted countless seminars, workshops and public presentations on Bobwhite quail life history, habitat requirements, and habitat enhancement techniques. In the past 25 years, over 1,300 landowners, land managers, and natural resources professionals have received instruction on proper quail habitat management techniques through the Small Game Program's annual Quail Management Seminar series. Recently, Program staff have begun to rely more heavily on web-based delivery of technical materials, and have developed a website for dissemination of information on quail habitat management and population status.

Bobwhite population trends in South Carolina are monitored through various surveys which include a summer census of whistling males, a summer brood survey, an annual survey of avid quail hunters, fall covey counts on select Wildlife Management Areas (WMA), and a periodic statewide harvest survey. The Bobwhite Quail Whistling Cock Census, comprised of over 70 routes statewide, was begun in 1979 to provide broad-scale population trend data for Bobwhites. The Summer Bobwhite Quail Brood Survey has been conducted annually since 1994 in order to provide an index to recruitment for Bobwhites. The annual Quail Hunter Survey, conducted since 1987, tracks hunting success as a measure of the quail population at the county, physiographic region, and state levels. Fall covey counts have been utilized since 2001 on discrete WMAs as a measure of fall population and to assess effects of habitat management, and extrinsic factors such as weather, on Bobwhite quail reproduction and survival.

A multi-agency partnership led by SCDNR has established the Indian Creek Wildlife Habitat Restoration Initiative in Newberry County. Bobwhites are a focal species for habitat restoration efforts though the Initiative, and over 3,000 acres of early-successional habitat have been restored and maintained throughout the project area. Habitat restoration efforts through the Initiative are continuing, and relationships established through the formation of the Initiative have resulted in greater cooperation between state and federal agencies for management of early-successional habitat on public and private lands statewide. While not specifically identified as quail focal areas, efforts to restore and maintain early-successional habitat are underway at numerous WMAs across the state including Webb WMA and Hamilton Ridge WMA in Hampton County, Crackerneck WMA in Aiken County, Draper WMA in York County, Canal WMA and Bonneau Ferry WMA in Berkeley County, and Marsh WMA in Marion County.

Over the past decade, relationships have been established between DNR Small Game Program staff and staff of the USDA Farm Service Agency (FSA) and USDA Natural Resources Conservation Service (NRCS), resulting in a higher level of coordination in integrating wildlife objectives into USDA conservation programs. As a result of these relationships, as well as improved relationships between Bobwhite advocates and USDA staff at the regional and national levels, several beneficial programs and practices have been added or implemented to the benefit of Bobwhites and associated early-successional species. Within the Conservation Reserve Program (CRP), South Carolina received an allotment of 10,000 acres under the Habitat Buffers for Upland Birds practice (CP 33) and an additional 2,300-acre allotment under the State Acres for Wildlife Enhancement (CP38E) practice. Both of these practices have been implemented in South Carolina and have the ability to increase quail populations in agricultural landscapes. For years 2006-2008, DNR staff coordinated and participated in a coordinated monitoring effort to determine the effect of CP33 implementation on populations of Bobwhites and select songbird species. This effort indicated that Bobwhites were approximately 2- to 3- times more abundant on agricultural fields with herbaceous field borders than on similar fields with no herbaceous borders (Evans et al. 2009).

Several regional and national developments over the past 20 years have advanced the cause of Bobwhite conservation at the state, regional and national levels. In 1995, the Southeast Quail Study Group (SEQSG) was formed to identify causes of regional Bobwhite population declines and to devise solutions to reverse declining trends at state and regional levels. In 2002, the Northern Bobwhite Conservation Initiative (NBCI) was published (Dimmick et al. 2002). This

range-wide recovery plan for Bobwhites identified specific habitat and population recovery goals at the state and Bird Conservation Region (BCR) levels. In 2009, the SEQSG was expanded to encompass all states in the historic range of Bobwhites nationwide and renamed the National Bobwhite Technical Committee (NBTC). The NBCI was revised and renamed the National Bobwhite Conservation Initiative in 2011 (NBTC 2011). This revision provides a spatially-explicit habitat suitability ranking for all landscapes in South Carolina, which will allow geographic prioritization of future habitat enhancement efforts across the state. The NBCI revision also includes major constraints and opportunities for Bobwhite habitat management and contains estimated and projected densities of Bobwhites under a variety of management scenarios. NBCI was revised and renamed again the National Bobwhite and Grassland Initiative in 2022 (NBGI 2022) to include other associated species and their native habitats.

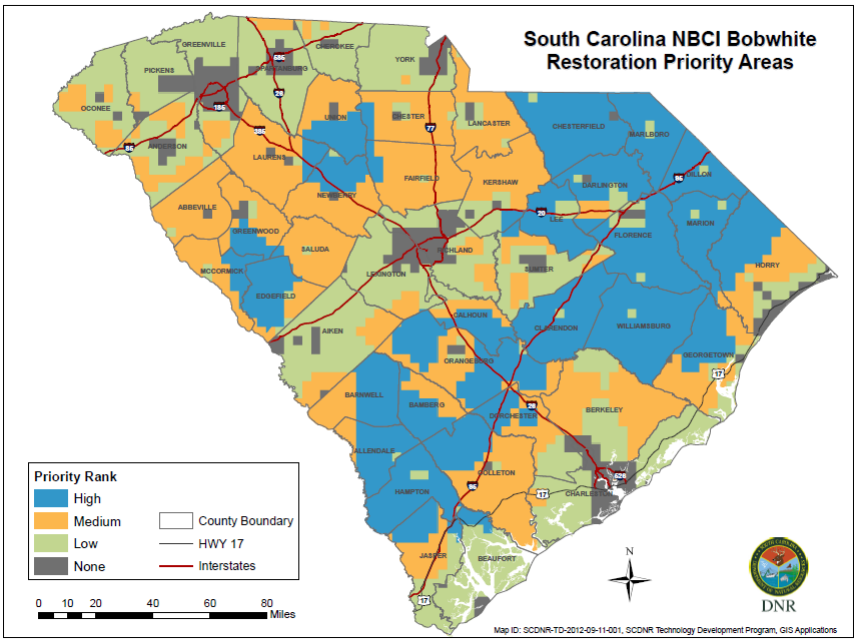

Figure 2: Northern Bobwhite habitat restoration potential as delineated through the NBCI's Biologist Ranking Information process. The BRI ranking process identified 9,150,594 acres as having medium or high potential as Bobwhite habitat in the State (NBCI 2013). (Ranking criteria and the plan in its entirely can be found online.)

CONSERVATION RECOMMENDATIONS

- Increase acreage of volunteer early succession vegetation or native warm season grasses on agricultural landscapes in South Carolina.
- Apply appropriate site preparation techniques, selective thinning regimes, and prescribed fire rotations to forest lands in South Carolina.
- Include protection of farmland and other potential early successional habitat as a priority in land acquisition and habitat protection programs.
- Maximize wildlife benefits in USDA Farm Bill programs through regional and national involvement in planning processes and through direct involvement with local and farm-level conservation planning.

- Identify funding sources for state-level cost-share programs to assist landowners with implementation of beneficial management practices for quail and other early-successional species.
- Identify focal areas for quail habitat enhancement within the state based upon existing land cover and quail populations; strive to focus private lands technical assistance and encourage USDA conservation programs in those areas where habitat enhancement would be most beneficial. Also focus on areas where the potential for positive population response would be greatest utilizing guidance provided by the NBGI.
- Identify public lands with high potential for quail habitat enhancement and assist responsible agencies with planning efforts for habitat enhancement.
- Identify SCDNR lands with high potential for quail habitat enhancement; establish population goals based on "managed density" estimates in the NBGI; and implement management practices necessary to achieve the population goal.
- Develop predictive models of Bobwhite quail occurrence and density based on land cover types from remote imagery.
- Evaluate Bobwhite quail colonization rate and population response to habitat enhancement, particularly in forested landscapes.
- Evaluate effect of geographic isolation on Bobwhite quail population viability and persistence.
- Evaluate effects of patch size and configuration on Bobwhite quail nest success and brood survival.
- Develop improved census techniques for low to moderate densities of quail
- Identify limiting factors for quail populations in agricultural and forested landscapes in South Carolina.
- Increase number of survey routes in spring call count survey for better statewide coverage and to allow regional trend comparisons.
- Increase number of cooperators in statewide quail hunter survey.
- Document habitat enhancement accomplishments that occur as a result of USDA Farm Bill programs, private lands technical assistance, or quail focus area initiatives.
- Establish a statistically-valid, density-based monitoring program for Bobwhites at appropriate scales to evaluate effects of management and monitor annual population fluctuations.
- Train additional observers in the fall covey count technique and expand the technique to additional sites in the State.
- Complete a statewide quail management and recovery plan which incorporates population and habitat objectives of the NBGI.
- Expand existing partnerships and establish new partnerships to advance the cause of Bobwhite habitat restoration.
- Continue annual quail management seminars for private landowners and agency personnel.
- Develop additional technical literature on beneficial quail management practices.
- Utilize agency outlets and cooperative efforts to promote benefits of prescribed burning.
- Provide Bobwhite habitat recommendations and population status updates to private landowners through on-site technical assistance, fact sheets, management bulletins, and websites.

- Establish demonstration areas that illustrate successful quail management practices on public or cooperative private lands within each DNR Wildlife Region.
- Increase capacity for private lands technical assistance and increased coordination and participation in federal Farm Bill program delivery at the state level.
- Support the National Bobwhite Technical Committee through participation of staff in annual meetings, committee involvement, support of the NBGI Director position, and agency participation on the NBGI Management Board.
- Support efforts of non-governmental organizations in South Carolina that promote conservation of Bobwhites through directed management and research.
- Publicize successful quail management efforts on public or private lands through Agency outlets and the popular press.

MEASURES OF SUCCESS

Development, implementation, and refinement of a statistically-valid, density-based monitoring technique will allow an assessment of Bobwhite population response to habitat management at various spatial scales. Managed density estimates, as provided in the NBGI, should be used as population targets in managed landscapes. Effects of landscape-level changes will be monitored using Breeding Bird Survey data and spring call count survey data. Management-oriented research projects will address emerging questions related to Bobwhite population dynamics and habitat enhancement techniques. SCDNR will strive to continue to respond to new data and adapt management actions once assumptions have been further tested.

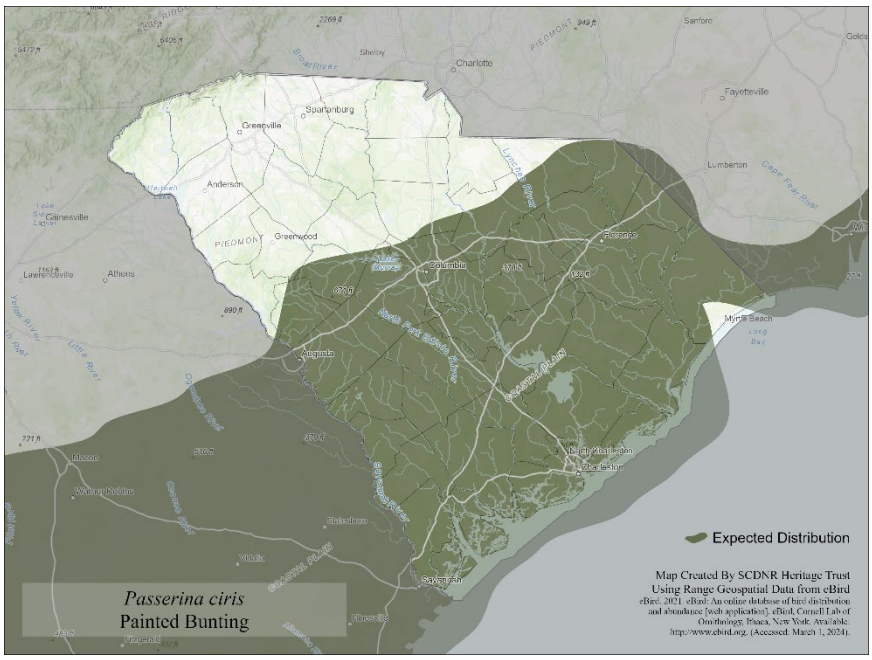
DESCRIPTION

Taxonomy and Basic Description



Buntings are small, New World finches with conical bills. The Painted Bunting is a small finch, typically 12 to 13 cm (4.7 to 5.1 in.) long and 13 to 19 g (0.46 to 0.67 oz.) (Lowther et al. 1999). The male Painted Bunting is among the most colorful birds in North America but is often hard to see as it usually stays close to thickets and dense cover. Males have a blue head and nape with bronze-green back, red rump and underparts, and dark wings and tail (Lowther et al. 1999). Even when in full view, male Painted Buntings may appear dark unless seen close and in good light. Females and immatures of both sexes are almost entirely dull green and are even more rarely seen except when at feeders (Lowther et al. 1999).

Painted Buntings breeding in South Carolina belong to the Eastern subspecies, *Passerina ciris ciris* (Thompson 1991; AOU 1998). During the breeding season, this subspecies is restricted to four states along the Atlantic Coast: North Carolina, South Carolina, Georgia and Florida. They winter exclusively in south Florida and the West Indies (mostly Bahamas and Cuba) (Lowther et al. 1999). Eastern Painted Buntings breed relatively late in the season (Duncan 1999; Springborn 1999).

Status

Formerly, Breeding Bird Survey (BBS) and Christmas Bird Count (CBC) data suggested steep long-term declines in Painted Bunting populations (Cox 1996). Although trend estimation within smaller geographies can be confounded by small sample sizes, more recent BBS analyses suggest the Eastern subspecies may not be declining as steeply as once thought. BBS trends from 1966-2010 for South Carolina are deemed to be moderately precise, and estimate a decline of 0.8% per year (Sauer et al 2011). While not particularly "steep" relative to other declining species, if accurate, this trend still equates to a loss of 55% of present populations in 100 years. The Painted Bunting is identified as a Watch List species by Partners in Flight (Rich et al. 2004), and is also identified by the US Fish and Wildlife Service as a Bird of Conservation Concern throughout the Southeast (USFWS 2008). Considering also that South Carolina supports one-third to one-half of the total breeding population of the Eastern subspecies, and that breeding habitats are disappearing or under increasing threat, it is clear that pro-active efforts will be required to ensure the future conservation of this popular species in the State and throughout its eastern range.

POPULATION SIZE AND DISTRIBUTION

Eastern Painted Buntings occur in highest densities around the sea islands of Georgia and South Carolina, occurring commonly but in lower densities in the adjacent mainland that is roughly parallel to U.S. Highway 17 and eastward. Their range extends north into coastal North Carolina and south into northeastern coastal Florida. These Buntings become uncommon, occurring sporadically farther inland along some river systems, most notably the Savannah River. More recently, Breeding Bird Atlas work in South Carolina and Georgia has documented Eastern Painted Buntings as more numerous than previously thought in fallow fields, woodland edges, and hedgerow habitat of the Upper Coastal Plain when looking north and east to the Santee River and on both sides of the Savannah River (Cely 2003). Although densities are lower in suitable habitats inland, these areas by far support the largest number of birds overall by virtue of their much larger geographic extent.

The vast majority of wintering Eastern Painted Buntings are concentrated in south Florida, Cuba, and the Bahamas (Lowther et al. 1999). Geolocation studies showed that an inland painted bunting from South Carolina wintered in South Florida, while a tracked bird from the Dewees Island, a barrier island North of Charleston, wintered in Cuba (Sharp, 2023). However, there does not seem to be any one reliable place where large numbers of Eastern Painted Buntings can be located during winter, at least in recent years, which may be cause for serious concern. Sykes and Holzman (2005a,b) provide a detailed state-by-state and site-by-site account of the breeding and non-breeding distributions of the Eastern Painted Bunting.

The total population size for Eastern Painted Bunting was estimated previously at well below 500,000 breeding adults (Sauer et al. 1997). Later, Partners in Flight (Rich et al. 2004) provided populations estimates at the continental level using BBS, and estimates at smaller geographic scales could be developed through application of similar methodologies (Rosenberg and Blancher 2005). Hence, South Carolina's population could be estimated at 50,354 (± 18,704) breeding adults using the Rosenberg and Blancher (2005) approach. According to this estimate, South Carolina supported 54% of the total Eastern population of breeding adults. Most recently, a "range-wide" survey effort for the Eastern population, competed in 2009, yielded data for a more robust assessment of the status of the Eastern population at ~1.2 million (C. Watson, pers.

comm.). There are several caveats that need to be considered with this estimate. First, sea and barrier islands, where the largest populations now occur, are not well represented in the BBS data and additional survey work may raise our estimate of total breeding adults. Second, if we decrease the statistical rigor of the estimate, then the maximum population estimate may be as large as 165,112 breeding-aged birds. Third, the ability to detect all individual Buntings (or at least all singing males) and make adjustments for estimating all breeding adults needs to be evaluated. If coastal sea and barrier islands were fully incorporated, then it is presumed that Georgia, with a larger quantity of quality coastal habitat, would have a higher proportion of the total population than South Carolina. However, it is clear by any of these estimates that both South Carolina and Georgia habitats are extremely important for the majority of breeding Eastern Painted Buntings (Meyers 2004). As of 2024, the PIF estimate for the species in South Carolina is 140,000, far more than Georgia (51,000), North Carolina (9,400), and Florida has decreased dramatically from 5,316 in 2013 to 640 (2024 Partners in Flight Database).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Eastern Painted Buntings are associated with maritime shrub-scrub and grassy habitats mixed in a woodland setting. The species is mostly absent from forests with no understory development and from large patches of scrub-shrub habitat separated from large woodland patches. Nearby grassy fields are also important for post-breeding foraging adults and fledglings (Lowther et al. 1999). High quality habitat is defined as largely forested areas with substantial edge and grassy forest openings and stands exhibiting structural diversity and large amounts of fleshy fruit (Lowther et al. 1999). On barrier islands the dominant habitat type utilized by Painted Buntings was maritime forest and scrub / shrub habitat. (Latshaw, 2011)

Research on annual survival and other demographic characteristics will lead to a more definitive understanding of the habitat requirements of the Painted Bunting. Current research indicates the defended territory of Buntings as ranging from 0.81 to 4.0 ha (2 to 10 ac.) with isolated males holding larger territories from one year to the next; there is also about a 95% breeding ground site fidelity for males. Annual survival estimates have yet to be calculated. The longevity record for the species was recorded in June of 2023 at a horse farm in St. Matthews South Carolina with an adult male who reached 14 years old. Adults use grassy areas for seeds and marshes for arthropod foraging near nest sites in scrub habitat.

Additional research has shown that Buntings will use Spanish moss as nest building material, especially in nests found higher in the canopy. Nests found 3 m (10 ft.) or higher in the canopy had higher productivity than nests found lower (Garcia 1994). In general, researches also observed that a greater number of nests were located in medium category trees/shrubs. On barrier islands, the primary substrates Painted Buntings were observed using were Live Oak, Wax Myrtle, Slash Pine, Redbay, Yaupon Holly, and Eastern Red Cedar (Latshaw, 2011). Additionally, successful nests were located in taller plants with greater distances from the trunk of the tree, greater canopy cover, and fewer small limbs. Cely and Glover (unpublished SCDNR data) concluded that early-successional habitat associated with fields and field-edges seem to consistently support Eastern Painted Buntings. However, while this research reported a high abundance of Eastern Painted Buntings in these habitats, the potential for nest predation and

parasites also increases in such environments, and effects on Bunting reproductive output has not been studied.

Finally, additional research by Duncan (1999) and Springborn (1999) was conducted on Sapelo Island Wildlife Management Area in Georgia from 1996 to 2000. These studies further described habitats found past the primary dune line where shrubs appear (maritime shrub habitat) as optimal for Painted Buntings. Pinelands with open canopy had Bunting densities at about 50% of those in optimum shrub-scrub habitat. Buntings preferred open freshwater wetlands to salt marsh. Data on telemetry of Buntings on Sapelo Island indicate home ranges of 2.8 to 7.3 ha (7 to 18 ac.) and ASY males on Kiawah Island had home ranges from 5.9 to 6.2 ha (Latshaw, 2011). Males had larger home ranges compared to females, and Buntings had significantly smaller home ranges in shrub-scrub habitat with high grass cover when compared to open pine forest habitat. With these data, it is estimated that areas between 486 and 1,012 ha (1,200 and 2,500 ac.) are required to support 100 to 200 breeding pairs of Eastern Painted Buntings.

CHALLENGES

Because the Eastern Painted Bunting is a true edge species, populations may be particularly vulnerable to increased nest parasitism by Brown-headed Cowbirds (*Molothrus ater*) and increased nest depredation. Although actual causes for Eastern Painted Bunting declines remain unclear, continued changes in landscape in inland areas are correlated with documented population declines (Hunter et al. 1993). During the BBS of inland sites in Georgia and South Carolina, landscape changes have included a doubling in developed land from 4 to 9%, an increase in pine plantation from 25 to 35%, while agriculture has declined from 18 to 9% (Meyers 2004). During this same time period, no change in emergent wetlands has been documented. Assuming that we have a correct understanding of Eastern Painted Bunting habitat characteristics, 35 to 45% of the variation in Eastern Painted Bunting population change is accounted for through changes in landscapes (Meyers 2004).

There appears to be a delicate balance between a landscape with enough fields to support larger populations of Eastern Painted Buntings, but with enough forest to keep predators and cowbirds at a low enough level to maintain high reproductive success. However, the landscape context of the Inner Coastal Plain of South Carolina is changing to the point where conditions are becoming less suitable overall for supporting Eastern Painted Bunting populations. Converting agriculture areas to hard edges, residential areas or pine plantations results in less suitable habitat for Eastern Painted Buntings. Overall landscape conditions may become less favorable for Eastern Painted Buntings with continued land conversion outside of public lands like Santee National Wildlife Refuge in the Inner Coastal Plain (Hunter pers. obs.). From 2001-2016 South Carolina lost 280,700 acres of agricultural land, and it is one of the top ten states most threatened with agricultural land loss (Martinson, 2023).

Because Eastern Painted Buntings breed late in the season, these birds could be prone to global climate change (Duncan 1999; Springborn 1999). Audubon's Survival by Degrees study suggests that Painted Buntings may expand their breeding range Northward over time. Mature habitat disturbance from hurricanes and tropical systems may provide maritime shrub and scrubland establishment.

Preliminary results from sea islands indicate few problems with nest predators or cowbirds in these protected areas; however, future coastline development may contribute to higher levels of nest parasitism and nest predation on these otherwise secure sites. On sea and barrier islands, development pressure is increasing at many privately owned sites. Development is expected to adversely affect island populations in the same manner as those on the mainland. In 2024 South Carolina has the fastest population growth of any state. Development pressure on the coast is increasing resulting in habitat loss and fragmentation. Sea level rise has increased 1 inch every two years, exceeding previous estimates. This has resulted in the loss of maritime forest and scrub / shrubland habitat, turning them into “ghost forests”. The combination of sea level rise and human development pressure results in a phenomenon called “the coastal squeeze” that threatens the Eastern Coastal population of Painted Buntings.

Also, on sea and barrier islands, feral horses and hogs severely damage and destroy forests by trampling and uprooting understory shrubs, as well as overgrazing grassy habitats. Where feral horses and hogs are established, Eastern Painted Buntings are not expected to thrive.

Management of public lands through the use of prescribed burning may affect Eastern Painted Bunting populations. In many areas, prescribed fire is an essential management tool for providing and maintaining appropriate conditions for Eastern Painted Buntings. However, fire at high frequency return intervals may eliminate the shrub layer, while fire at low frequency return intervals also may eliminate the shrub layer as well as the grassy conditions over time. Present experience suggests an average return interval between 3 to 6 years in maritime habitats is adequate to maintain the mosaic of structure Eastern Painted Buntings prefer, while not allowing succession to proceed too far. Of course, once a burn occurs, there will be a temporary reduction in habitat quality (Hunter, pers. obs.).

Golf courses may provide marginal habitat for Eastern Painted Buntings under certain circumstances, especially when all native vegetation is removed and there is a high reliance on pesticide and herbicide use. However, an increasing number of golf courses are modifying their practices to accommodate native birds in general and Eastern Painted Buntings specifically in coastal South Carolina. The US Fish and Wildlife Service is working with golf course managers in South Carolina with the objective of maintaining Eastern Painted Bunting populations in what is otherwise a rapidly developing landscape (Gordon et al. 2003).

Threats on the wintering grounds include trapping for the pet trade. Males wintering in Cuba had 20% less chance of returning from the wintering grounds (Rushing, 2020). Trapping has been banned in the United States where and has been banned since the early 1900’s, in Mexico the trade was banned from 1982 to 1999, but the ban was lifted and trapping continued. In Cuba there has been variable reports on the commonality of wintering Painted Buntings, but the most important wintering regions appear to be (1) The keys within the Archipiélago de Sabana-Camagüey along the northern coasts in the provinces of Matanzas, Villa Clara, Sancti Spiritus, Ciego de Ávila, and Camagüey (this region is rapidly being developed for the growing tourist trade); (2) From the north- eastern coast of Las Tunas Province, eastward along the northern coast of Holguín Province to Bahía de Naranjo, to include areas in and around the village of

Gibara, City of Holguín, Bahía de Nipe, and from Mayarí and Nipe eastward to Bahía Sagua de Tá-namo (Nils Navarro, pers. comm.); (3) The Península de Guanahacabibes; (4) Mil Cumbres in Pinar Del Río Province; (5) The northern coast of La Habana Province; and (6) The Península de Zapata in Matanzas Province, including the Zapata Swamp, the area from Jagüey Grande southward to Pálpite (Nils Navarro, pers. comm.), and near-by areas in the southern part of the province. (Sykes 2007). In a personal observation documented by Iñigo-Elias, in May 2003 an estimated 700 buntings were trapped for the pet trade near the capital Havana. (Sykes, 2007).

Historically, John James Audubon observed thousands of Painted Buntings exported to Europe through New Orleans ports for the pet trade in 1841.

CONSERVATION ACCOMPLISHMENTS

The Eastern Painted Bunting enjoys relative popularity as a species garnering conservation attention in the Southeast. The future security of the Eastern subspecies is particularly dependent on proactive conservation attention in South Carolina and Georgia, where a large percentage of the Eastern population breeds. Agencies and industrial landowners are incorporating the needs of this species into conservation strategies and management practices. There is increasing interest in linking the needs of Painted Buntings into other conservation efforts and initiatives where compatible objectives exist, such as with the Northern Bobwhite Conservation Initiative. The "Eastern Painted Bunting Working Group" successfully collaborated to complete a 3-year, range-wide population assessment for the Eastern taxon. Analyses have been conducted, and reports and publications are being prepared that will present results and conclusions to all appropriate conservation interests. A listserve exists to increase communication among managers and researchers.

CONSERVATION RECOMMENDATIONS

- Protect and maintain existing high-quality maritime woodland, shrub-scrub, and grassy habitats through easements/purchase.
- Determine more specific habitat objectives as research reveals a better understanding of present status for breeding populations.
- Target programs for both public land mangers and private landowners to encourage provision of adequate cover, food and habitat that presents minimal nest parasitism and depredation.
- Continue to conduct and support research on habitat selection, reproductive success and taxonomy of Eastern Painted Buntings.
- Conduct and support public outreach programs to solicit observations of Buntings and cowbirds from feeder watchers throughout the range of the species.
- Establish a network of sites for monitoring the population trends of Eastern Painted Buntings and address responses to local management and landscape conditions. Among generalized habitats used by Eastern Painted Bunting, there are 4 that merit treatment at the macro-scale, as follows:

  - Sea Islands/Barrier Islands – evaluate habitat management practices and suitability over the long term.
  - Coastal Mainland – evaluate development pressures on Buntings.
  - Agricultural Interior – evaluate farming and forestry practices on Buntings and determine how to implement conservation practices.
  - River Corridor – evaluate forestry practices and flood plain dynamics.
- Provide news releases when appropriate to announce key events or findings involving Eastern Painted Buntings that would allow opportunities to highlight general conservation goals and needs for the public.

MEASURES OF SUCCESS

Of particular importance in measuring success of conservation actions for this species is the demonstrated stability for Eastern Painted Bunting populations on sea islands. Measures of reproductive success should be used to gauge population health and habitat quality.

American Kestrel / Steve Kilpatrick

DESCRIPTION

Taxonomy and Basic Description

The American Kestrel is the smallest falcon in North America with an average length of 27 cm (10.6 in.), wingspan of 58 cm (22.8 in.), and weight of 117 g (4.13 oz.). Adults are identified by a russet back and tail, two black stripes on a white face, and blue-gray wings. Howe and King first described the Southeastern subspecies in 1902; this subspecies is nonmigratory and resides primarily in the Piedmont and Coastal Plain of South Carolina (Smallwood and Bird 2020). The male of the Southeastern subspecies is smaller and less spotted on the breast than males of northern subspecies. However, the northern subspecies are migratory and may coexist with the Southeastern subspecies outside of the breeding season.

Bachman's Sparrow / Steve Kilpatrick

The Bachman's Sparrow is a large songbird, averaging 15 cm (5.91 in) in length and 21 g (0.74 oz.) in weight. Known for their inconspicuous nature, these sparrows are often identified in the field by their two note-trill song (Dunning et al. 2020). This species has a large bill, fairly flat forehead and a long, rounded dark tail. Adults are gray above and heavily streaked with chestnut or dark brown. Their breast and sides are buff or gray with an off-white belly and a thin, dark eye line. Three subspecies are recognized, but the taxonomic record is complex, and more research is needed to parse out their geophysical distributions (Dunning et al. 2020).

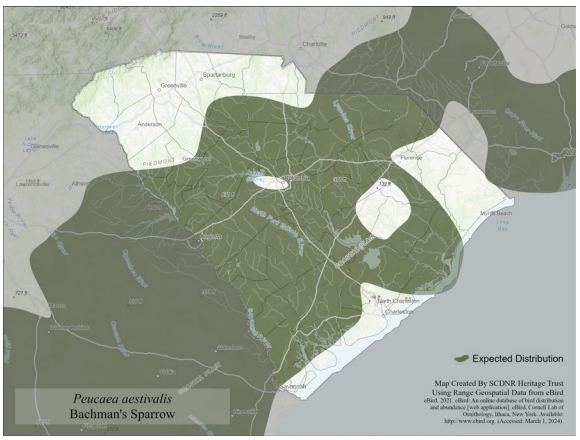
Henslow's Sparrow / Andy Reago & Chrissy McClarren

The Henslow's Sparrow is a mid-sized,

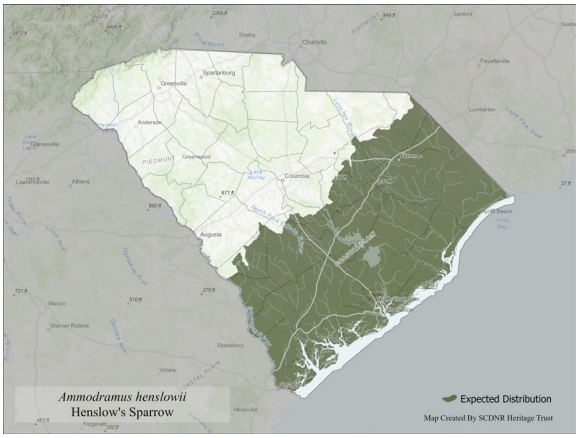
Pine Siskin / Cephas

insectivore-granivore songbird averaging 13 cm (5.11 in) in length and 13 g (0.46 oz) in weight. This species has a large flat head, gray bill, and short tail. Adults are greenish on the head, nape, and central crown strip with dark chestnut wings (Herkert et al. 2020). Although they tend to be very quiet outside the breeding season, they may be identified by their sharp "*tsip*" call. Two subspecies of Henslow's Sparrows are recognized and both winter (or wintered) in South Carolina, though the eastern subspecies (*C. henslowii susurrans*) may be extinct. The Pine Siskin is a small finch species averaging 12 – 13 cm (4.7 – 5.1 in) in length and 12 – 18 g (0.42 – 0.63 oz) in weight (Dawson 2020). There is little sexual dimorphism in plumage; both sexes and juveniles have heavy brown streaking over a gray or light brown background with a brown-black wing and tail. A yellow wash on the remiges and base of rectrices is visible in flight. Three subspecies are recognized and distinguished by morphological characteristics such as body size, degree of yellow plumage, and presence-absence of an eyeline (Dawson 2020).

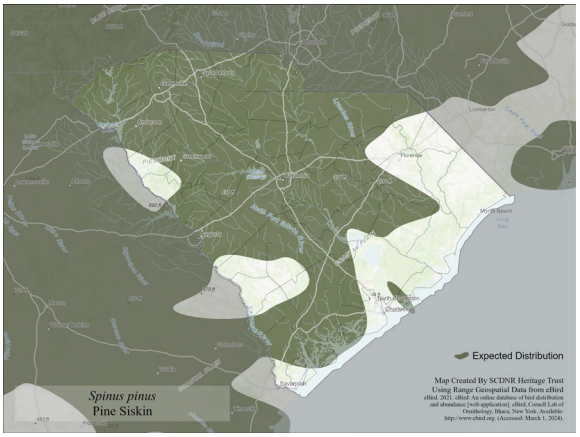
Red-headed Woodpecker / David Youngblood



The Red-headed Woodpecker is a mid-sized woodpecker averaging 19 – 24 cm (7.5 – 9.4 in) in length and 56 – 91 g (2 – 3.2 oz) in weight. It is one of the most recognizable North American woodpeckers, with a bright red head and collar, light gray bill, white breast and underparts, and black wings with a white outer rectrices. Adult males and females have identical plumage, while juveniles are primarily gray until their definitive molt (Frei et al. 2020). No subspecies have been described, but Red-headed Woodpeckers in western and northern regions tend to average larger than those in the Southeast.



Status



Of the species included in this guild, the Bachman's Sparrow has the highest levels of conservation status. The Bachman's Sparrow is listed as Near Threatened on the IUCN Red List (2023) and is included on Partners in Flight's (PIF) Red Watch List, indicating that the species' recovery should be prioritized due to the species' sharp population decline and small population size and distribution (PIF 2023). The species is also listed as having regional importance for the Atlantic Coast Joint Venture, with the region accounting for approximately 63% of the Bachman's Sparrow's breeding population (Rosenberg et al. 2016).

The American Kestrel, Henslow's Sparrow, Pine Siskin, and Red-headed Woodpecker are listed as species of Least Concern by the IUCN (2023). The Southeastern subspecies of American Kestrel does not have any state protections in South Carolina but is listed as state threatened in Florida. The Henslow's Sparrow is included on PIF's Yellow Watch List, while the Pine Siskin and the Red-headed Woodpecker are considered Common Birds in Steep Decline by PIF (PIF 2023).

POPULATION SIZE AND DISTRIBUTION

The Southeastern American Kestrel, Bachman's Sparrow, and Red-headed Woodpecker are resident species in South Carolina. Historically, the core distribution of each of their ranges coincided closely with the distribution of the Red-cockaded Woodpecker (*Dryobates borealis*), longleaf pine (*Pinus palustris*), and short leaf pine (*Pinus echinata*) (Hunter et al. 2001). Breeding Bird Atlas records for Bachman's Sparrows exist for the Piedmont and Coastal Plain while records for American Kestrels and Red-headed Woodpeckers are scattered throughout the State (Cely 2003). The American Kestrel is ubiquitous across North America, while the range of the Southeastern subspecies extends from the Atlantic coast to Louisiana, and north into South Carolina. Multiple subspecies can be found during the winter due to regional migration, but the Southeastern subspecies is a year-round resident (Hamel 1992). The species' rangewide population estimate is 2.8 million individuals (PIF 2023), which has declined approximately 48% since 1970 (Rosenberg et al. 2016). In South Carolina, the current population estimate in 1,100 individuals (PIF 2023). Based on Breeding Bird Survey (BBS) data, the species has experienced a 1.2% annual decline in South Carolina between 1966 and 2021, with higher rates of annual decline in the Piedmont conservation region (2.5%) compared to the Southeastern Coastal Plain conservation region (1.6%) (Ziolkowski et al. 2022). Caution should be exercised when extrapolating these data to the state or conservation region level due to consideration of various subspecies. The Florida Fish and Wildlife Conservation Commission estimates that Southeastern American Kestrels have declined by 82% over the last 70 years in Florida (FFWCC 2024), but it is not known whether declines have been as severe in South Carolina.

The Bachman's Sparrow can be found in localized populations throughout the Southeastern Coastal Plain and Piedmont, with isolated groups in central states like Tennessee, Kentucky, and Missouri. The

current rangewide population estimate for the species is 170,000 individuals, which is an estimated 73% decline since 1970 (Rosenberg et al. 2016). In South Carolina, the Bachman's Sparrow has an estimated population size of 6,000 individuals (PIF 2023) and has experienced a 0.6% annual decline between 1966 and 2021, with higher rates of annual decline in the Piedmont conservation region (3.6%) compared to the Southeastern Coastal Plain conservation region (1.1%) (Ziolkowski et al. 2022). This may reflect a noted range contraction along the northern and western peripheries of their range (Dunning et al. 2020). Bachman's Sparrows are often reported in low abundance by traditional survey methods (e.g. BBS), so estimates of population size and the degree of decline should be interpreted with caution.

The Red-headed Woodpecker is present locally throughout the eastern US. They can be found year-round in the Southeast, with breeding and wintering populations in the upper Midwest and Texas, respectively. However, Red-headed Woodpeckers are best described as facultative migrants, as their winter movements appear to be partially driven by availability of hard mast. Depending on the year, populations may only partially migrate or not migrate at all (Vukovich and Kilgo 2013; Frei et al. 2020). The current rangewide population estimate is 1,800,000 individuals (PIF 2023), reflecting an approximately 67% decline since 1970 (Rosenberg et al. 2016). However, the species appears to be stable in South Carolina, with a population size of 39,000 individuals (PIF 2023) and an 0.6% annual rate of increase between 1966 and 2021, with much higher rates in the Piedmont conservation region (2.1%) compared to the Southeastern Coastal Plain conservation region (0.1%) (Ziolkowski et al. 2022).

The Henslow's Sparrow and Pine Siskin are overwintering species in South Carolina that occur in and rely on resources found in pine savannas. Due to the lack of BBS data for these species in the state, only rangewide population trends are reported. The Henslow's Sparrow is found locally in the eastern US, breeding from eastern Kansas to central Pennsylvania, and north into Wisconsin and Minnesota. Its winter range is similarly localized but the species has been observed in the Southeastern coastal plain from east Texas to North Carolina (Herkert et al. 2020). In South Carolina, Henslow's Sparrows winter throughout the Coastal Plain, extending inland from the coast and throughout the Sandhills (Cely 2003; Seriff and Beirregaard 2018). Although the species is inconspicuous and not often reported on BBS routes, long-term declines are evident for this species both within South Carolina (McNair and Post 2000) and across its range. The rangewide population estimate is 410,000 individuals (PIF 2023) with a 10% estimated decline between 1970 and 2014 (Rosenberg et al. 2016).

The Pine Siskin can be found across North America, with resident populations in the western US and Canada. This species is an irruptive migrant and winters in large flocks throughout the Midwest and eastern US in response to poor food availability in their breeding range (Dawson 2020). In South Carolina, Pine Siskins are a common winter visitor in irruption years throughout the state and are often observed at backyard feeders; Root (1988) also indicated the species uses xeric pine forests throughout the Southeast. Although the rangewide population estimate for the

species is still quite high (46 million individuals; PIF 2023), BBS data report a concerning 2.2% annual rate of decline between 1966 and 2021 (Ziolkowski et al. 2022).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Each of these species is dependent upon southern pine-dominated landscapes for all or part of their life cycles. The American Kestrel is a secondary cavity nesting species and habitat generalist, though they prefer semi-open habitats. The Southeastern subspecies' historical range was closely associated with longleaf pine savannas (Hunter et al. 2001; FFWCC 2024), which provide the open structure preferred for foraging as well as an abundance of pine snags for nesting or perching (Smallwood and Bird 2020). Kestrels are "sit-and-wait" predators and will locate insects and small mammals in natural or artificial habitat openings, such as agricultural fields, roadsides, savannas, and woodland margins (Hamel 1992). As with other obligate cavity nesters, the species is often limited by the availability of suitable cavities; currently, few birds nest in natural cavities due to a lack of standing snags in open pinewoods and agricultural areas (Hunter et al. 2001). Nest box installation programs have allowed Kestrels to breed in previously unoccupied habitats (Smallwood and Bird 2020) and led to an increase in occupancy in the midlands of South Carolina (Cely and Sorrow 1988) and north-central Florida (Smallwood and Collopy 2009). Given that suitable cavities are available, preferred nest sites are located in open sites with minimal woody cover.

Bachman's Sparrows are found in open pine forests and grassland habitats and appear to occur at higher densities in areas also managed for Red-cockaded Woodpeckers (Dunning et al. 2020). They are ground nesters, constructing domed cup nests in patches of grasses and forbs. In addition to nesting on the ground, Bachman's Sparrows also forage primarily on the ground for grass seeds and invertebrates. The species is associated with habitat that possesses a relatively dense grass and forb layer and few tall shrubs or understory trees, with young (1- to 5-year-old clearcuts or powerline rights-of-way) and mature pine stands (≥80 years old) most frequently occupied (Dunning and Watts 1990a; 1990b). Generally, one of the strongest predictors of Bachman's Sparrow occupancy is the frequency of fire in a landscape; the species has been shown to abandon areas that go longer than 3 years without burning (Engstrom et al. 1984; Tucker et al. 2004; Dunning, personal observations). Landscape connectivity is also an important aspect of habitat suitability for Bachman's Sparrows, as they appear to be intolerant of habitat fragmentation and isolation (Taillie et al. 2015; Jones et al. 2017).

Red-headed woodpeckers are strongly associated with open forest, savanna habitats that have snags and decaying trees available for cavity excavation. The species has a varied diet of flying insects, seeds, nuts, and berries, and often captures insect prey by flycatching (Frei et al. 2020). In the Southeast, Red-headed Woodpeckers are found in the variety of habitat types, including pine flatwoods and savannas, mixed-pine hardwood forests, or urban areas, though disturbances that create snags or reduce midstory presence (e.g. prescribed fire, weather events) appear to have a positive effect on species density (Steen et al. 2013; Rose and Simons 2016; Frei et al. 2020).

The winter habitat requirements of Henslow's Sparrows are generally understudied, though open areas with dense, moist ground cover are likely important (Hunter et al. 2001; Herkert et al. 2020). In the Gulf Coastal Plain, wintering individuals have been observed in moist grassy areas or pitcher plant bogs under open pinewoods (Plentovitch et al. 1999). In the Coastal Plain of South Carolina, Henslow's Sparrows winter in grassy, non-inundated Carolina bays and in utility rights-of-way maintained in grasses (Champlin 2007). Soil moisture may not be as important further inland, where xeric upland rights-of-way supported more sparrows than Carolina bays (Champlin and Kilgo, unpublished data). Overall, the species appears to benefit on wintering grounds from pine savanna habitat that is frequently burned and has dense groundcover with high seed and insect availability for foraging (Thatcher et al. 2006; Johnson et al. 2011; Herkert et al. 2020).

The Pine Siskin primarily moves and forages in groups during the winter. They are seed eaters and feed in the canopies of conifer and hardwood trees but are also common visitors at artificial bird feeders in South Carolina (Dawson 2020). As their name suggests, Pine Siskins select for open, coniferous habitats on their breeding and wintering ranges. However, their winter habitat use tends to be more generalized to areas with high food availability (Dawson 2020), with sightings of Pine Siskins in South Carolina ranging from mature pine savanna, river bottoms, maritime forests, and suburban to urban habitats (Seriff and Beirregaard 2018; eBird 2024).

CHALLENGES

The greatest challenge to viability of these species is directly related to the availability and condition of their optimal habitat: the pine savanna. Prior to European settlement, the greater longleaf savanna ecosystem spanned over 92 million acres of the southeastern US and was maintained through frequent wildfires and indigenous land management. However, by the 1930s, the majority of these pines had been harvested; approximately 3% of the original longleaf forests remain standing today (Frost 1993). The loss of longleaf pine stands, especially those with intact understory, is particularly devastating to plant and animal species that depend upon a fire-maintained ecosystem. Although longleaf pine is ecologically the most important species of pine found in South Carolina, other species, such as loblolly (P. taeda) and slash pine (P. elliottii) have become more important economically and can also be managed to create savanna habitat in the absence of longleaf. Direct loss of habitat occurs when mature pine stands are converted for urban development, agricultural purposes, or timber production, while fire suppression leads to indirect habitat loss. For existing pine savanna habitat, intensive management is required to restore and maintain its historic condition. Prescribed fire on a 2-3-year rotation is the most effective tool for managing pine savannas, as this prevents midstory encroachment and maintains groundcover conditions, but Outcalt (2000) estimated that only half of available longleaf stands were burned within the previous 5 years. Additionally, former agricultural areas restored to longleaf may no longer provide the appropriate herbaceous groundcover due to deficiencies in the seed bank (Imm and McLeod 2005).

Species-specific challenges for the three resident species in this guild include low availability of suitable natural nest cavities for the Southeastern American Kestrel (Smallwood and Bird 2020) and Red-headed Woodpecker, as well as the negative effects of pine habitat fragmentation and

isolation on Bachman's Sparrow populations (Dunning et al. 2020). Dead and dying trees in suitable habitat are often removed because they are believed to be safety hazards, a refuge for pests, or are undesirable from a timber revenue or aesthetic standpoint, resulting in decreased nesting opportunities for obligate cavity nesters. Additionally, the current lack of state survey or monitoring programs outside of the BBS poses a barrier to understanding the ecology of wintering species. Standardized winter monitoring efforts may improve data on the distribution and habitat associations of Henslow's Sparrows and Pine Siskins in South Carolina.

CONSERVATION ACCOMPLISHMENTS

Continued restoration of the longleaf pine ecosystem in South Carolina is the most notable accomplishment to date for conservation of the pine savanna guild. Multiple public and private partners lead initiatives to reintroduce and restore longleaf pine habitat, as well as educate the public on the importance of the longleaf ecosystem. The federal Natural Resources Conservation Service (NRCS) introduced the Longleaf Pine Initiative in 2010 to encourage longleaf restoration on private forest and agricultural lands via financial and technical assistance. Since its formation, approximately 870,000 private acres have been restored to longleaf forest (NRCS 2024). Private organizations, such as Longleaf Alliance and the American Forest Foundation have also contributed to the effort of restoring longleaf ecosystems. For example, the American Forest Foundation has supported the publication of the *Forest Ecosystem Conservation Handbook for Birds in Georgia: A Guide for Family Forest Owners* (DeBerry 2005). Longleaf Alliance is a frequent partner with public and private stakeholders and provides cost share and grant opportunities for projects aimed at restoring the longleaf pine ecosystem in the Southeast. Additionally, state and federal agencies in South Carolina prioritize the acquisition and protection of land with remnant longleaf or pine savanna habitat and manage it to maintain its historic condition and benefit wildlife resources.

Red-cockaded Woodpecker (RCW) conservation has a symbiotic relationship with longleaf and pine savanna conservation, where both directly advance the other. A landmark benefit to the longleaf ecosystem was the completion and implementation of the updated RCW Recovery Plan in 2003 (USFWS 2003). Management requirements for RCW outlined in the Recovery Plan promote an open stand structure, reduced hardwood midstory, and improved groundcover condition, thus benefitting ecosystem health and conservation goals for other species which benefit from pine savannas. The RCW Safe Harbor Program has played a notable role in promoting management of pine savanna habitat on private lands. The program was developed by USFWS in 1998 to address land-use restrictions incurred under the Endangered Species Act. Those enrolled in the program do not incur additional regulatory restrictions for RCWs nesting on their land, thus removing the disincentives for managing pine forests in a manner that benefits pine savanna species.

Finally, measuring accomplishments for these species depends on the continued participation by state employees and volunteers in the Breeding Bird Survey and other avian surveys established in South Carolina, such as the Christmas Bird Count, International Migratory Bird Day, and the Great Backyard Bird Count. In the last decade, eBird has also become an important means of

crowdsourcing data on avian abundance, range limits, and habitat use, and will likely play a large role in assessing population status for species of concern (eBird 2024).

CONSERVATION RECOMMENDATIONS

Landscape-Level

- Continue the restoration and reintroduction of the longleaf pine ecosystem across South Carolina.
- In areas devoid of site-appropriate savanna species or with depauperate seed banks, establish wiregrass (*Aristida stricta, A. beyrichiana*) and other herbaceous species through propagation from local seed sources.
- Conduct landscape level spatial analyses on the geographic distribution and patch sizes of pine forest types in South Carolina to identify priority reintroduction or management areas and assess potential for land acquisition.
- Increase state and federally owned acreage through strategic acquisition to reduce forest fragmentation and create dispersal corridors, while protecting and managing existing areas that support pine savannas.
- Continue involvement in and delivery of private, state, and federal conservation programs aiding pine savanna restoration and management in South Carolina (NRCS Longleaf Pine Initiative, SCDNR Safe Harbor Program, USFWS Partners for Fish and Wildlife, Longleaf Alliance plantings and cost share program, etc.)
- Promote the use of best management practices (BMPs) for all pine species in Forest Stewardship Plans, including increased rotation length, decreased stocking densities, promotion of site prep burning, decreased use of chemicals, increased use of growing and dormant season prescribed fire, increased width of Streamside Management Zones, and selection of site-appropriate species.
- Derive quantitative habitat objectives for priority pine savanna species and test assumptions (identify habitat-specific densities, limiting factors) in order to model habitat requirements necessary to meet population objectives.
- Develop and implement monitoring programs to better assess breeding and wintering bird abundance and to quantify short- and long-term population trends in pine savannas (e.g. species response to fire reintroduction, etc.). Monitoring will need to be more frequent and tailored to better detect cryptic species such as Bachman's and Henslow's Sparrows. Develop training workshops or establish a bird counting team for volunteers, or utilize publicly-available eBird data.
- Continue to use the Breeding Bird Survey as a surveillance monitoring technique for pine savanna residents.
- Continue participation in the Atlantic Coast Joint Venture at the management board and science committee levels.

Species-Level

- Encourage the retention of standing pine snags on public and private land to provide nesting structures for Southeastern American Kestrels and Red-headed Woodpeckers.

- Provide artificial nest boxes for Southeastern American Kestrels in cavity-limited areas.
- Maintain a 1-2 -year fire rotation and intensive midstory management in areas that currently, or have the potential to, support Bachman's Sparrow populations.
- Investigate overwintering habitat preferences of Henslow's Sparrows and Pine Siskins through increased winter survey efforts and eBird data.

MEASURES OF SUCCESS

Reintroduction and restoration of the longleaf pine ecosystem and other pine savanna habitats in significant acreages across South Carolina provides benefits to a wide range of taxa. The continued use of prescribed fire at 1-3 year intervals, mechanical or chemical midstory treatments, and improvement of understory characteristics will improve ecological function of these habitat types. The resulting increase in plant species richness should expand food web complexity and plant-pollinator relationships, thus improving resource availability for priority bird species. Strategic land acquisition and protection of existing pine savanna by public agencies and other conservation programs will improve habitat connectivity, thus reducing impacts of isolation or small patch size on resident source populations.

Priority species occurrence and/or density increases within pine savanna habitats through a combination of habitat and monitoring improvements. Quantifying species-specific habitat objectives will indicate if PIF population goals are attainable for South Carolina and whether changes to these objectives are necessary. In some cases, it may be unrealistic to achieve PIF continental population goals due to irreparable habitat loss. However, South Carolina may provide essential source populations or habitats for some species, so measures will need to be developed to integrate monitoring results into regional- and national-level databases.

Other bird species that are likely to be positively affected by pine savanna management and restoration include: Brown-headed Nuthatch (*Sitta pusilla*), Carolina Wren (*Thryothorus ludovicianus*), Eastern Towhee (*Pipilo erythrophthalmus*), Northern Bobwhite (*Colinus virginianus*), Prairie Warbler (*Setophaga discolor*), Red-bellied Woodpecker (*Melanerpes carolinus*), Red-shouldered Hawk (*Buteo lineatus*), White-eyed Vireo (*Vireo griseus*), Wood Thrush (*Hylocichla mustelina*), Yellow-throated Vireo (*Vireo flavifrons*), and Yellow-throated Warbler (*Setophaga dominica*) (Rich et al. 2004). Management efforts for bird species in this guild should also positively impact other state priority species including the fox squirrel (*Sciurus niger*), gopher frog (*Lithobates capito*), flatwoods salamander (*Ambystoma cingulatum*), gopher tortoise (*Gopherus polyphemus*), and indigo snake (*Drymarchon couperi*).

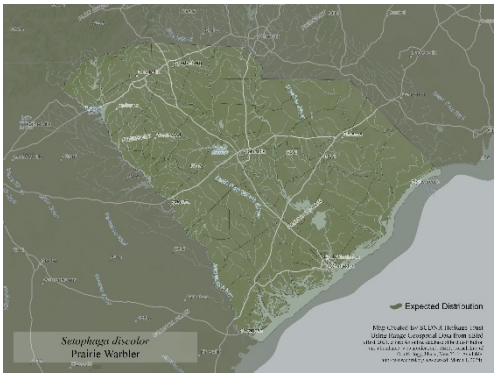
DESCRIPTION

Taxonomy and Basic Description

The Prairie Warbler is a small songbird averaging 12.1 cm (4.75 in.) in length and 7.7 g (0.27 oz.) in weight (Sibley 2003). Male and female Prairie Warblers look similar. This bird has yellow underparts, black stripes on the sides of the body, a brownish green back, and two black face marks. Males can be distinguished from females by darker coloration and the presence of chestnut-colored streaks on the back. This species can also be identified by its propensity to bob its tail. Juvenile birds appear quite differently, but also bob their tails (Peterson and Peterson 2002).

Prairie Warbler by USFWS



Two subspecies occur distinguished by rectrix pattern, plumage color, and body size. *S. d. discolor* is the smaller of the subspecies and is found in South Carolina. It breeds across the southeastern United States to northern Florida. *S. d. discolor* winters primarily in the Caribbean Basin, particularly on the Greater Antilles, with some occurring south along the eastern edge of the Yucatan Peninsula (Nolan et al. 2020).

Status

Prairie Warblers nest in shrubby habitat without a closed canopy. This habitat occurs in disturbed sites such as abandoned farmland and burned forest stands. These habitats are currently in decline in the face of urban sprawl and reforestation thus Prairie Warblers are experiencing population declines (Askins and Zickefoose 2000 and 2001, Hunter et al. 2001). Prairie Warblers are not state or federally listed but were listed as “Birds of Conservation Concern” by the U.S. Fish and Wildlife Service in 2021 (USFWS 2021). The 2021 Birds of Conservation Concern was an effort to identify those bird taxa (beyond those already designated as federally threatened or endangered) that represent the highest conservation priorities of the USFWS. Partners in Flight rate the species a 14 out of 20 on the Continental Concern Score, placing it on the Yellow Watch List for species with declining populations.

POPULATION SIZE AND DISTRIBUTION

Prairie Warblers nest in South Carolina and winter in Florida and islands south of Florida. Although rare, they regularly winter in coastal South Carolina. Partners in Flight estimates a global breeding population of 3.6 million individuals (Partners in Flight 2024). The North American Breeding Bird Survey estimates a loss of almost 2% per year between 1966 and 2015, resulting in a cumulative decline of 63% during that time. The Prairie Warbler has experienced long-term (1966 through 2010) population declines of 0.8% in South Carolina with the steepest declines (6.3%) occurring from 1966 through 1979 (Sauer et al. 2012). Recently (2011 through 2021), population trends in South Carolina have continued downward (USGS 2024).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Prairie Warbler's name is a bit of a misnomer because open prairie is not the preferred habitat. This bird requires a shrubby component to its habitat. The Prairie Warbler can be found breeding in southern pine forests with a well-developed shrub layer, dunes along the Atlantic Coast, scrub oak forests, pine and scrub oak forests, and abandoned pastureland or fields (Nolan et al. 2020). Historically fire, floods, windstorms, and herbivores maintained habitat conditions conducive to disturbance-dependent species, such as Prairie Warblers (Askins 2001). Fire suppression, the loss of large canopy tress such as the American chestnut (*Castanaea dentata*), and the extirpation of beaver (*Castor canadensis*) and mega herbivores such as elk (*Cervus elaphus*) and bison (*Bison bison*) following European settlement, reduced the availability of early-successional habitat throughout the Eastern US (Askins and Zickefoose 2000). In Eastern North Carolina, minimum patch size of suitable shrubland habitat for Prairie Warblers is estimated to be 1.1 ha (Shake et al. 2012). Prairie Warblers place their nests in trees and shrubs, 1-2 meters from the ground.

CHALLENGES

Habitat loss and suppression of disturbance regimes are the main challenges to Prairie Warblers. The loss of the American chestnut (*Castanea dentata*) resulted in reduced availability of larger tree-fall gaps that create early-successional habitat within a forested landscape. The extirpation of elk and bison, large animals that drive successional processes through herbivory, has also reduced the ecological forces that maintain early-succession habitat. Additionally, fire suppression and a less abundant population of beavers have reduced available habitat for disturbance-dependent birds.

Even-aged timber management reduces the structural complexity of forested landscapes upon which the Prairie Warbler depends. Urban development and the conversion of agricultural land

to monoculture plantations has reduced the available habitat for the Prairie Warbler. Other causes of population decline in members of this guild may be attributed to bird strikes at communication towers and wind turbines, brood parasitism by the Brown-headed Cowbird (*Molothrus ater*) (another disturbance-dependent species), and habitat loss on wintering grounds. Although brood parasitism of Prairie Warbler nests in South Carolina is low (14%), Prairie Warblers are among the 4 most frequently parasitized species in the region (Kilgo and Moorman 2003).

CONSERVATION ACCOMPLISHMENTS

No conservation initiatives have been set specifically for Prairie Warblers.

Long-term monitoring programs, such as the Breeding Bird Survey have provided population trend data that enables biologists and land managers to prioritize management decisions based on the knowledge of population trends.

National initiatives such as the Partners in Flight (PIF) Landbird Conservation Plan (Rich et al. 2004) and the North American Bird Conservation Initiative (NABCI 2005) have provided a method by which interested parties can coordinate conservation activities. These initiatives have provided guidelines for priority species, population and habitat objectives, and recommendations for conservation actions. State and federal agencies have implemented habitat improvement projects based on guidelines outlined in PIF and NABCI.

CONSERVATION RECOMMENDATIONS

- Utilize GIS and land type associations to determine total area and distribution of available habitat. Modeling will enable SCDNR to prioritize land acquisition and habitat improvement projects.
- Partner with other land management agencies and make recommendations about habitat improvement projects that benefit early-succession species.
- Expand the use of Farm Bill and other cost-share programs to implement activities that integrate habitat objectives for early-succession birds.
- Expand participation in the Landowner Incentive Program (LIP) to create or enhance habitat on private lands.
- Promote the use of Best Management Practices that support providing buffer zones and that increase structural diversity (such as providing small clearcuts).
- Partner with appropriate agencies to encourage prescribed burning activities on public and private lands.
- Work with international partners to identify problems on wintering grounds. Where feasible, provide financial incentives to conserve habitat.
- Continue to monitor populations of early-succession birds through participation in the Breeding Bird Survey (BBS).
- Initiate agency supported monitoring programs, such as Partners In Flight (PIF) point counts.
- Expand monitoring programs to areas not adequately sampled.
- Monitor bird response to management activities both pre- and post-treatment.

- Continue to strengthen partnerships with regional and national initiatives such as the Atlantic Coast Joint Venture, PIF and NABCI.
- Pursue opportunities for funding for land acquisition or management activities through partnerships with regional agencies and NGOs.
- Develop partnerships with recreational bird watching organizations in the State.
- Research effects of bird strikes on migratory bird populations and partner with the communications industry to work toward solutions in SC.

MEASURES OF SUCCESS

The first measure of success will be to implement monitoring programs that will allow SCDNR to document population trends and avian response to management in South Carolina. The next goal will be to determine population and habitat objectives for this species. Finally, implementing the above-mentioned recommendations to provide the appropriate quantity of habitat to support target populations will be important.

TAXONOMY & BASIC DESCRIPTION

Red-cockaded Woodpeckers were first described by the amateur naturalist Vieillot (1807) and named *Picus borealis*. In 1810, Alexander Wilson, unaware of Vieillot's previous description, described the species as *Picus querulus* because of its distinctive vocalizations (Wilson 1810). The species had been known as *Picoides borealis* until 2018 when the name was changed to *Dryobates borealis* after overwhelming scientific consensus found the genus *Picoides* to be polyphyletic; they share common characteristics with the *Picoides* woodpeckers, but do not share an immediate common ancestor (American Ornithological Society, 2018). The common name used today, Red-cockaded Woodpecker, was given to the species by AlexanderWilson. During Wilson's time, cockade was a commonly used term for a ribbon or other ornament worn on a hat to indicate rank or membership, and refers to the small patch of red feathers on the head of adult males, located between the black crown and white cheek patch.

Red-cockaded Woodpeckers are relatively small; adults measure 20 to 23 cm (7.8 to 9 in.) and weigh 40 to 55 g (1.4 to 1.9 oz.) (Jackson 1994; Conner et al. 2001). They are smaller than other southern woodpeckers except the Downy Woodpecker (*Picoides pubescens*) and are similar in size to Yellow-bellied Sapsuckers (*Sphyrapicus varius*). Red-cockaded Woodpecker size varies geographically, with larger birds to the north (Mengel and Jackson 1977).

Red-cockaded Woodpeckers are relatively slender, long-tailed and small-billed woodpeckers. They are black and white with a coarsely barred back, white cheek patch and black crown. Their breasts and bellies are white to grayish-white with spots on the sides changing to bars on the flanks. Outer tail feathers are white with black barring and central tail feathers are black. Adult plumage is nearly identical between sexes and generally indistinguishable in the field without optics. The only difference between adult males and females is the presence of the red cockade at the upper edge of the white auriculars, which is virtually invisible in field situations (Jackson 1994). Juveniles appear similar to adults but may be distinguished in the field by duller plumage, white flecks often present just above the bill on the forehead, and diffuse black shading in the white cheek patch. Juvenile males have a distinctive red patch on the crown and may be distinguished from juvenile females in this way (Jackson 1994). A juvenile's head plumage is generally molted and replaced with adult plumage by early Fall of their birth year.

STATUS

The Red-cockaded Woodpecker was among the first species to be listed as endangered in 1970 and received federal protection under the Endangered Species Act of 1973. Once a common bird, historical population estimates range from 1-1.6 million family groups (Conner et al. 2001). However, by 1970, the species had declined to no more than 4,000 family groups in widely scattered, isolated and declining populations (Jackson 1978). Due to advances in knowledge of Red-cockaded Woodpecker population dynamics and the use of highly effective management tools, such as artificial cavities and translocations, most public land populations of Red-cockaded The Partners in Flight Watch List has classified Red-cockaded Woodpecker as "tipping point yellow;" species that are range restricted and occur in small populations in need of constant care (Panjabi et al, 2020). The South Carolina Department of Natural Resources Heritage Trust program describes the species as imperiled state-wide because of rarity or factor(s) making it vulnerable (S2) while globally the species is ranked as vulnerable (G3). In November 2024, USFWS made a final ruling downlisting the species from Endangered to Threatened. Although this determination was made based on a number of important recovery milestones and stable to increasing population numbers across the species' range, Red-cockaded Woodpecker population viability is still threatened by the small, scattered, and isolated nature of most populations. Thus, the species continues to receive similar levels of protection, with some exceptions concerning incidental take from beneficial management practices, under Section 4(d) of the Endangered Species Act.

POPULATION SIZE AND DISTRIBUTION

Red-cockaded Woodpeckers are monitored based on the number of groups (a breeding pair with 0 to 7 helpers or a solitary male) and the clusters on which they depend (the actual physical cavity trees and acreage surrounding those trees). In 2020, there were an estimated 7,794 known active clusters across 11 states and distributed among 124 demographic populations; this number represents a small fraction of the estimated Red-cockaded Woodpecker abundance at the time of European settlement (USFWS 2020). In 2024 South Carolina, there were 278 groups on state-owned lands and another 921 groups on federal properties. Private properties enrolled in the SCDNR Safe Harbor program held another 479 groups. Based on these numbers, there were 1,678 known red-cockaded woodpecker groups in South Carolina in 2024, representing approximately 21.5% of all known Red-cockaded Woodpecker groups range-wide.

Populations of Red-cockaded Woodpeckers are distributed across the Southeastern United States and managed by distinct recovery units, across which recovery criteria must be met for the species to be removed from the Endangered Species List. In South Carolina, there are recovery populations in 4 of the 13 recovery units. These recovery units are the South Atlantic Coastal Plain, Mid-Atlantic Coastal Plain, Sandhills and Piedmont. No public lands RCW populations existed within the South Carolina Piedmont when the 2003 RCW Recovery Plan was published so these populations were not included in the recovery criteria.

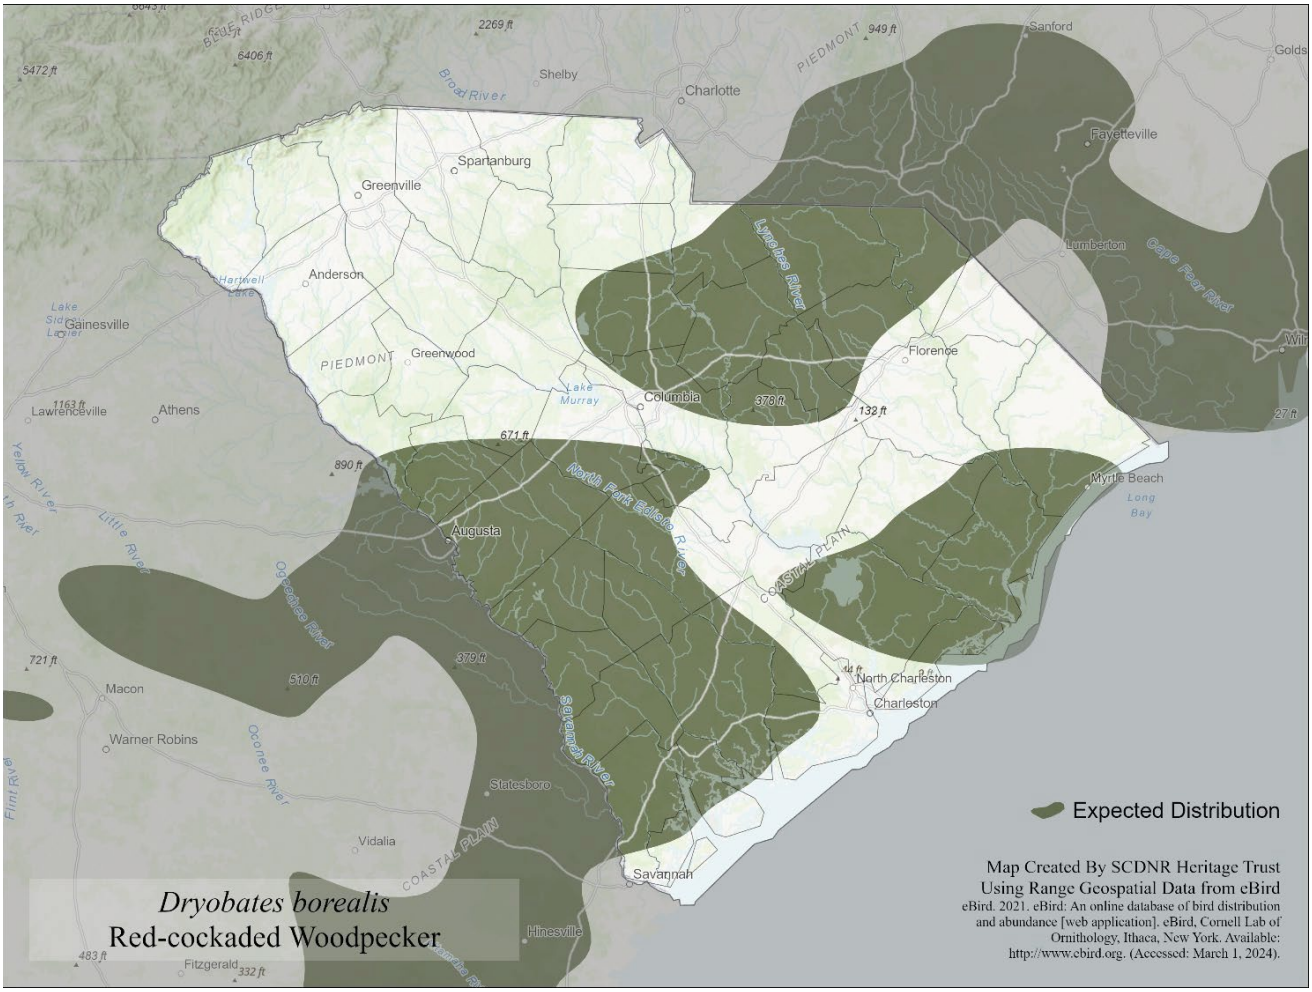

Figure 1. Current range of Red-cockaded Woodpeckers in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Red-cockaded Woodpeckers depend on open, “park-like” mature pine woodlands and savannahs with large, old pines for nesting and foraging habitat. Large old pines are required because these birds excavate roost and nest cavities in living pine trees. The cavities are excavated completely within the heartwood; therefore, the trees must be old and large enough to have room for the cavity chamber. Additionally, old trees are more likely to have heartwood decay, which greatly facilitates cavity excavation. The cavity trees must be in open stands with little or no hardwood midstory and little or no hardwood in the canopy. Once the midstory reaches cavity height, Red-cockaded Woodpeckers typically abandon the cluster. Red-cockaded Woodpeckers will use nearly all of the southern yellow pines for cavity trees, including loblolly pine (*Pinus taeda*), shortleaf pine (*Pinus echinata*), pond pine (*Pinus serotina*), slash pine (*Pinus elliottii*) and longleaf pine (*Pinus palustris*), but prefer longleaf pine (Jackson 1994).

Red-cockaded Woodpeckers have very large foraging territories requiring vast areas of open pine habitat. Suitable foraging habitat consists of large mature pines, little or no midstory, and abundant herbaceous ground cover including native bunchgrasses and forbs. Red-cockaded Woodpeckers require 30 to 81 contiguous hectares (75 to 200 acres) of this foraging habitat, depending on the habitat quality. Red-cockaded Woodpeckers prefer to forage on mature longleaf pine trees, but will forage on younger trees and other pine species and the occasional hardwood tree. High-quality foraging habitat that results in the highest Red-cockaded Woodpecker productivity is contiguous open stands of mature longleaf pine with an herbaceous ground cover (Jackson 1994).

Red-cockaded Woodpeckers evolved in a fire-dominated ecosystem. The history of fire in the Southeast has both natural and human components. Fires were ignited naturally due to frequent lightning strikes. Both Native Americans and European settlers used fire to clear land and improve hunting grounds. Frequent fires resulted in an open forest with large pines, little to no midstory, and diverse herbaceous ground cover; this represents the ideal habitat for Red-cockaded Woodpeckers and other species of the longleaf pine ecosystem. However, much of the currently available habitat has been subjected to fire suppression and has become unsuitable for Red-cockaded Woodpecker use due to the presence of a dense hardwood midstory and/or canopy. Fire is essential to maintaining and restoring southern pine ecosystems, particularly the longleaf pine ecosystem, and is essential to Red-cockaded Woodpecker habitat maintenance and restoration (USFWS 2003).

CHALLENGES

Lack of suitable habitat is the underlying cause for all the primary threats to Red-cockaded Woodpecker species viability. First, there is very little of the open mature pine habitat remaining. The majority of the longleaf pine habitat that once covered the southeast has been destroyed. Of the remaining habitat, only a small amount is thought to be in pristine condition.

The serious threats from this lack of habitat fall into 4 basic categories (USFWS 2003):

(1) insufficient number of existing suitable cavities and the continued net loss of cavity trees in the environment (Costa and Escano 1989; James 1995; Hardesty et al. 1995);
(2) habitat fragmentation and the resulting impacts on genetic variation, dispersal, and demography (Conner and Rudolph 1991);
(3) lack of sufficient amounts of quality foraging habitat (Walters et al. 2000, 2002; James et al. 2001); and
(4) risks of extinction inherent to critically small populations (Shaffer 1981, 1987).

Red-cockaded Woodpeckers depend on mature pine trees for both cavity excavation and foraging substrate. Lack of mature pine trees in suitable habitat because of past and present fire suppression and silvicultural practices resulted in a severe shortage of these trees in the landscape. Red-cockaded Woodpecker groups that lack sufficient cavities for the group have been shown to decrease reproductive output. Decreased reproductive output has also been linked to an insufficient amount of quality foraging habitat. Habitat fragmentation reduces the ability for Red-cockaded Woodpeckers to disperse between clusters. This reduces the ability of individuals to find breeding vacancies, which influences both the genetic variation of populations

and overall demographic stability. Most critically, small populations face an inherent set of risks related to the size of the population. These risks include extirpation due to random environmental, demographic, genetic, and catastrophic events (Shaffer 1981, 1987).

In South Carolina, there are two primary threats that affect the availability of habitat, and, ultimately, Red-cockaded Woodpecker recovery now and in the future. The first is a lack of prescribed fire in existing and potential habitat. It has become increasingly difficult for private landowners and government agencies to burn their properties for wildlife management because of liability issues. Until this problem is solved, more and more landowners will opt not to conduct prescribed burning activities. The ultimate result will be less suitable habitat for Red-cockaded Woodpeckers and other wildlife.

The second major threat to Red-cockaded Woodpeckers in South Carolina is the risk of natural catastrophes, specifically hurricanes. The majority of Red-cockaded Woodpeckers in South Carolina are present in the Coastal Plain and face significant risks from hurricanes. Cavity trees are particularly susceptible from winds associated with tropical weather systems while foraging habitat can be devastated from hurricane force winds (Conner et al. 2001).

Red-cockaded Woodpecker surveys on SCDNR lands are ongoing; complete surveys should be conducted at least once every 10 years. Further, the last update to Red-cockaded Woodpecker status on private lands in South Carolina was conducted in the late 1980s to early 1990s. Private lands status should be updated periodically by field surveys and questionnaires to determine the current trend and management needs on private lands. This goal can largely be achieved by annual reports completed by Safe Harbor enrollees.

Avian Keratin Disorder

Avian keratin disorder (AKD), also called hyperkeratosis, is a disorder seen in several avian species often resulting in a dramatic elongation of the beak. Research with Black-capped Chickadees points toward Poecivirus, a rapidly mutating RNA-virus that is able to move between species, as the culprit, though this has yet to be confirmed with RCW (Zylberberg et al. 2018). Infected individuals can have significantly elongated bills that impair their ability to forage effectively. Birds suffering from AKD often experience beak elongation, increase in brittleness of beak, elongation/curvature of claws, deterioration of feather and body condition and skin ulcers or tumors (Handel et al. 2010). RCW's with AKD have been observed in multiple populations throughout the state of South Carolina. Recommendations to prevent spread include standard disinfection measures on any equipment used while capturing or handling RCW. Research regarding AKD in RCW is ongoing.

CONSERVATION ACCOMPLISHMENTS

Conservation accomplishments can be divided into 3 major categories. The first relates to advances in understanding population dynamics and advances in management techniques related to stabilizing and increasing populations of Red-cockaded Woodpeckers. The second category results directly from the recovery plan for Red-cockaded Woodpeckers (USFWS 2003). The

third category of accomplishments relates to the successful development and implementation of the Safe Harbor program in South Carolina.

Population Dynamics/Management

- Increased knowledge of population dynamics due to extensive research in South Carolina and across the Southeast has led to better translocation procedures which facilitates Red-cockaded Woodpecker population growth range-wide.
- Advancements in artificial cavity installation technique have allowed for unprecedented growth of existing populations and the creation of new populations through a combination of cavity creation and translocations.
- Due to these practices, most populations of Red-cockaded Woodpeckers on public lands were stabilized to increasing by the mid-1990s. Prior to these advances, nearly all populations were declining.

Red-cockaded Woodpecker Recovery Plan

- Drafts of the USFWS Red-cockaded Woodpecker Recovery Plan established required population goals for all federal properties and for one state property, Sandhills State Forest, and suggested goals for all other public properties in South Carolina (Figure 2). These established goals have resulted in population growth across all federal properties and most state properties. The most recent draft of the Recovery Plan was published in 2003. Many new populations have been established since that time that are not included in the plan (Figure 3).
- Recovery Plan guidelines established standard practices for management and reporting, resulting in a consistent recovery effort range-wide, including South Carolina.
- Recovery Plan guidelines call for annual average growth rates of 5% on all recovery populations. These goals have been met on most properties, resulting in overall growth on public lands in South Carolina.
- Translocation, intensive habitat management, and creation of recruitment clusters have yielded marked increases in many populations and creation of new populations in recent years.
- Efforts to establish RCW populations on suitable SCDNR properties have resulted in the creation 17 new colonies on 4 different properties since 2015. Donnelley WMA has a population of 10 active clusters, Aiken Gopher Tortoise HP has 3 active clusters, Lynchburg Savanna HP has 1 active cluster and Tillman Sandridge HP has 3 active clusters.

Safe Harbor Program

Since its introduction in 1998, the South Carolina Red-cockaded Woodpecker (RCW) Safe Harbor Program has grown to include 198 enrollees and 479 RCW groups, with enrolled properties stretching from Jasper County north to Horry County on the coast and inland from Aiken County north to Chesterfield County. These properties total over 360,000 acres. The Program's success stems from the flexibility the Endangered Species Act (ESA) offers: in exchange for voluntary habitat maintenance and enhancement, landowners are exempted from

ESA restrictions for any RCW groups that move onto their property in the future as a result of those habitat improvements. Though the November 2024 USFWS ruling to down-list RCW from Endangered to Threatened under the Endangered Species Act will affect neither the Safe Harbor program nor benefits to enrollees, agreements signed after that date will be referred to as Conservation Benefit Agreements.

Key conservation accomplishments related to this program include the following:

- The program has ensured habitat maintenance and enhancement for nearly 500 groups of Red-cockaded Woodpeckers on private lands across 24 South Carolina counties.
- As of 2024, 332 baseline groups and 147 above-baseline groups were known to exist on Safe Harbor properties. These 147 above-baseline groups represent a 44.2% growth in private lands RCW populations after enrollment in the program.
- The use of prescribed fire is a requirement for Safe Harbor enrollment; the program has helped facilitate widespread reintroduction and maintenance of fire on the landscape, thus maintaining and restoring critically imperiled longleaf pine habitat.
- Longleaf restoration is often included as part of a landowner's agreed-upon management activities in a Safe Harbor Agreement, resulting in the creation of higher quality habitat.
- The program continues to create and foster positive working relationships between the private sector, government organizations and private landowners, producing a cooperative effort toward conservation. These relationships provide open communication between RCW biologists, consultants, and landowners who have RCW colonies or habitat, resulting in more favorable management for RCW and other species.

CONSERVATION RECOMMENDATIONS

- According to the 2020 USFWS Species Status Assessment Report for the Red-cockaded Woodpecker, all RCW populatons under 30 breeding groups are considered to have "very low" resiliency and are grouped with those populations most vulnerable to extirpation (USFWS 2020). All SCDNR RCW populations fall within this grouping. Continued growth of the smallest, least resilient public lands populations through provisioning of recruitment clusters and targeted property acquisition will be essential to their long-term persistence.
- Continued annual monitoring of all public lands RCW populations including:
    - Number of active cavities
    - Number of potential breeding groups
    - Number of actual nests including clutch size, number of chicks, number successfully fledged, and sex of all individuals.
- Catastrophic weather events present the greatest immediate threat to RCW populations throughout South Carolina. Rapid post-storm assessment and insert provisioning are essential to reducing population losses. Public lands agencies should make efforts to maintain small teams of individuals who are properly trained to complete this work. In the case of a catastrophic weather event, these teams could work quickly to provision RCW clusters with needed cavities to avoid population declines. As the threat of catastrophic weather is perennial, a continued effort to maintain trained staff should be sustained indefinitely.
- As artificial cavities have allowed for rapid growth and expansion of RCW populations, many RCW groups throughout South Carolina are currently reliant on these cavities. The

goal for all RCW groups that are reliant on artificial cavities should be to provide assistance through maintenance and replacement of these artificial cavities until the group has completed and is roosting and nesting in natural cavities. Kleptoparasite removal will be necessary in the smallest populations (10 groups or less) until cavities are abundant enough within a cluster to reduce cavity competition.

- With the apparent high prevalence of color-band-related injuries in RCW, it is recommended that color banding should only be used if the following conditions are met:
    - Bird health is prioritized and banding/monitoring protocols are closely followed.
    - Banded birds are being closely monitored via resighting for potential band-related injuries, preferably multiple times throughout the year.
    - Any noted injuries are immediately addressed.
    - Banding data is being actively used to further our scientific understanding of RCW.
    - Beginning in 2020, with concurrence from USFWS, SCDNR ceased all color banding activities on SCDNR properties. Banding may be used in the future, as needed, to meet project objectives or requirements.
- Manage Red-cockaded Woodpecker habitat by adhering to the management objectives of the Recovery Plan for this species prepared by the USFWS (2003) including:
    - Application of frequent fire to foraging and cluster habitat.
    - Protection and development of large mature pines throughout the landscape.
    - Protection of existing cavities and provisioning of artificial cavities as necessary to facilitate population growth or to stabilize existing populations.
    - Creation of recruitment clusters to promote population growth.
    - Restoration of sufficient habitat quality and quantity to support species recovery.
- Monitor any birds translocated to or from state-owned properties to determine translocation success.
- Monitor any populations on state-owned properties donating birds for translocation to determine the effect on the donor population.
- Continue administration of the Safe Harbor Program by enrolling properties with Red-cockaded Woodpecker populations and/or longleaf pine habitat and offering technical/management support to landowners.
- Regularly discuss with Safe Harbor enrollees the potential for establishing recruitment or translocation clusters. Public opinion regarding RCW's has shifted dramatically since the 1990's and many of those enrolled in Safe Harbor would like to have birds. Maintain a list of potential recipient properties.
- Provide technical support to private landowners and other public land managers on issues of Red-cockaded Woodpecker management and recovery in cooperation with representatives of the USFWS.
- Continue a focused effort to disseminate RCW and Safe Harbor information to the public. Increased public knowledge of RCW is beneficial to the birds and their recovery.
- Produce annual informational RCW Safe Harbor updates for distribution to Safe Harbor participants, foresters and environmental consultants. Working to celebrate program successes and provide this information to enrollees will make them feel more involved and connected to the goals of the program.

MEASURES OF SUCCESS

If management and conservation recommendations are followed, we should expect to see the following:

- Continued work in expanding public land RCW populations through recruitment, translocation and land acquisition should result in increased population resiliency over time. It is expected that some of SCDNR's larger populations, such as Webb Wildlife Center and Bonneau Ferry WMA, will move from "very low" to "low" resiliency as defined in the USFWS RCW Species Status Assessment.
- Continued enrollment into the Safe Harbor program with no net loss in number of baseline clusters. Though the program is only intended to prevent population decline on private land, we expect to see a continued increase in the number of above-baseline clusters as groups bud and dispersing birds pioneer new clusters.
- Recovery goals for Red-cockaded Woodpeckers will be met on all state-owned lands by the time of de-listing.
- Adequate monitoring and surveys will result in an accurate measure of Red-cockaded Woodpecker status and trends on public and private lands facilitating management decisions to make recovery goals.
- Outreach efforts will educate the public about issues relating to Red-cockaded Woodpecker management and legal responsibilities.

On November 25th, 2024, the USFWS announced the down-listing of Red-cockaded Woodpecker from Endangered to Threatened status under the Endangered Species Act, marking a significant milestone in the species' recovery. Though RCW populations are likely to require active management indefinitely in order to prevent future declines, we believe that populations will continue to expand and become increasingly resilient as long as recovery efforts continue.

Ruffed Grouse

Bonasa umbellus

Contributors (2005): Judy A. Barnes (SCDNR)

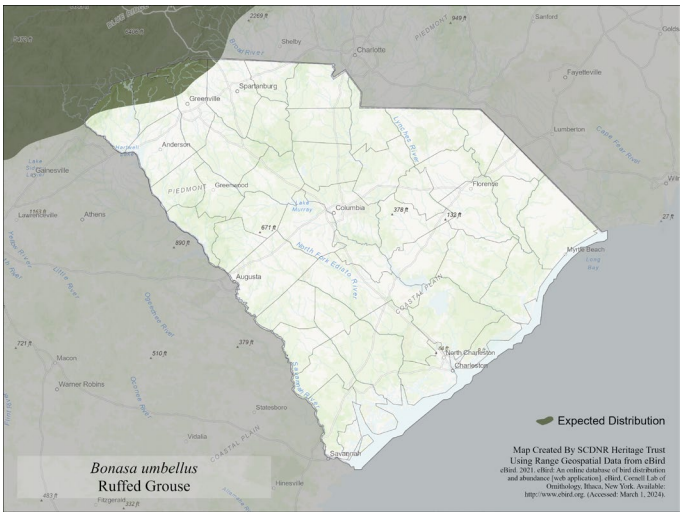
DESCRIPTION

Taxonomy and Basic Description

Linnaeus first described the Ruffed Grouse in 1776, and since then, many subspecies have been named. Johnsgard (1983) distinguishes 11 subspecies; Atwater and Schnell (1989) list 12; and del Hoyo et al. (1994) recognizes 14 subspecies. The Ruffed Grouse is a gallinaceous bird in the Order Galliformes and the Family Phasianidae, which includes grouse, quail, turkey, and pheasants.

The Ruffed Grouse is a chicken-like bird that weighs about 500 g (1.1 lbs.). The genus *Bonasa* is translated as “good when roasted” and the specific epithet *umbellus* means “sunshade” referring to the long, shiny, black or chocolate colored neck feathers most prominent on the male. Males tend to be slightly larger than females and have a large tail that it fans to attract a mate or defend its territory. The female’s tail is similar but smaller and usually is the best external basis for determining sex (Gough 1998). Across most of its range, a fully-grown tail feather of over 14.9 cm (5.87 in.) in length usually belongs to a male; less than 14 cm (5.5 in.), a hen. Ruffed Grouse have two or more color phases ranging from a grayish to a reddish-brown color. Red-phased grouse become more prevalent in milder climates while gray birds are more abundant where winter climates are more severe. Male Ruffed Grouse are aggressively territorial throughout their adult lives and proclaim their area with a “drumming” display. The male usually stands on a log, stone or mound of dirt and beats his wings against the air to create a vacuum, creating a drumming sound. The substrate, often called a “drumming log,” is used strictly for a stage; the bird does not strike the “log” to make the sound (Rusch et al. 2000).

Chicks are precocial and are not much larger than a man’s thumb when they leave the nest. They are very mobile and begin flying when about 5 days old. The hen may lead her brood as far as four miles from the nest to a summer brood range during their first 10 days of life. By 17 weeks of life, the chicks have reached their adult weight and usually disperse to find their own home range at 18 weeks.



Status

According to the North American Breeding Bird Survey (BBS), Ruffed Grouse populations have been in a slow decline throughout the Appalachian region over the past 45 years (Sauer et al. 2011). Except for localized declines, Ruffed Grouse generally appear to be stable and secure in Canada and the Western United States, but numbers appear to be declining in the Eastern United

States (Atwater and Schnell 1989; Rusch et al. 2000). Ruffed Grouse have a state rank of apparently secure (S4) in South Carolina and a global rank of G5, indicating that they are considered secure globally (NatureServe 2011).

Though the Ruffed Grouse is considered peripheral in South Carolina's southern Appalachian ecoregion, eggs and young have been found in the vicinity of the Foothills Trail in Pickens County (Huckabee 2000). The species is included as a species of concern because South Carolina could provide more suitable habitat for Ruffed Grouse if disturbance regimes such as prescribed fire are used and early successional habitats are created within its mountain range.

POPULATION SIZE AND DISTRIBUTION

Ruffed Grouse is the most widely distributed upland game bird in North America (Gullion 1977). Its range spans from northern Georgia north through Labrador in the east, and west throughout northern California into Alaska. In the central portion of the United States, Ruffed Grouse are found in the Great Lakes states north into Canada to the tree line (Gullion 1977). Trippensee (1948) described the range of Ruffed Grouse; according to his range map, Ruffed Grouse did not occur in South Carolina. However, he reported that isolated populations of the species still maintained themselves outside the indicated range. Nesbitt (1966) reported that though the literature did not disclose information regarding population levels and distribution, Ruffed Grouse did occur in the northwest mountain counties of Greenville, Pickens, and Oconee in South Carolina. Population numbers are relatively low in the southern and southwestern parts of its range. The Ruffed Grouse breeding population density was estimated at about 1.9 drumming males per km^2 (5 males per $mi.^2$) in 2005 (Dessecker et al. 2006). Northern populations show approximately 10-year cycles. Other populations can exhibit significant year-to-year variation, largely dependent upon spring weather and its effects on brood production.

Densities vary between forest types. Throughout their range, Ruffed Grouse find most of their habitat needs in mixed age, upland hardwoods. In more northern reaches of their range, Ruffed Grouse are associated with aspen (*Populus tremuloides*) stands that meet all of their food and cover requirements (McDonald et al. 1998). In southern portions where aspen is sparse to absent, Ruffed Grouse are typically associated with upland oak (*Quercus* spp.) stands (Cole and Dimmick 1991).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Ruffed Grouse have 4 main habitat requirements: nesting cover, a "drumming log" for males, brood cover for females and fall/winter cover (Atwater and Schnell 1989). Proctor (2003)

indicated that in the southern portions of their range where long-term snow cover is absent, Ruffed Grouse utilize other methods of winter cover for protection from predation and thermal insulation. During winter in the southern Appalachians, Ruffed Grouse can be found using evergreen thickets in the form of rhododendron (*Rhododendron* spp.) and mountain laurel (*Kalmia latifolia*). Not only do Ruffed Grouse seek refuge in such evergreen habitats, but also in the southern Appalachians, Ruffed Grouse often forage on the leaves and buds of mountain laurel where the largely popular aspen trees of the north are absent (Stafford and Dimmick 1979). Ruffed Grouse in Tennessee were found to utilize evergreen thickets comprised mainly of mountain laurel where desirable higher stem density stands were lacking (White and Dimmick 1978). Young clear-cuts that provide tall and dense stands of sapling age trees, also provide excellent year round cover where Ruffed Grouse can find adequate food and protection from aerial predators. Literature concerning home range sizes of Ruffed Grouse varies widely, with differing tendencies in males and females. Densities of Ruffed Grouse and habitat quality also play a large role in determining average home range size for a particular area.

The Appalachian region is classified as oak-hickory or mixed-mesophytic forest associations; this classification is based on literature review, canopy tree composition, and abundance data collected as part of the Appalachian Cooperative Grouse Research Project (ACGRP) (Tirpak, 2002 unpublished data) and a Relative Phenology Index. Oak-hickory forests are dominated by chestnut (*Quercus prinus*), white (*Q. alba*), northern red (*Q. rubra*), scarlet (*Q. coccinea*), and black (*Q. velutina*) oaks and shagbark (*Carya ovata*), pignut (*C. glabra*), mockernut (*C. tomentosa*) and bitternut (*C. cordiformis*) hickories. Mountain laurel and great rhododendron are important understory species. Dominant species on mixed-mesophytic sites are sugar (*Acer saccharum*) and red (*A. rubrum*) maple, yellow birch (*Betula alleghaniensis*), basswood (*Tilia Americana*), black (*Prunus serotina*) and pin (*P. pensylvanica*) cherry, yellow poplar (*Liriodendron tulipifera*), white pine (*Pinus strobus*), beech (*Fagus grandifolia*), northern red oak (*Q. rubra*), and Eastern hemlock (*Tsuga canadensis*).

The ACGRP (2004) reports the nutritional quality of Ruffed Grouse diet differs markedly between the core range and the Appalachian region. Throughout most of their range, Ruffed Grouse depend on aspen buds, twigs and catkins to meet their nutritional requirements. In contrast, Ruffed Grouse diets in the Appalachian region consist of the leaves and seeds of herbaceous plants, buds of beech, birch and cherry trees, acorns and the fruits of grape, greenbrier, and numerous other soft mast producers. In the Appalachian region, diets of grouse tend to be higher in tannin and phenol levels, which serve as potential toxins. Additionally, Appalachian diets tend to have lower protein levels than the diets of grouse in the Northern United States and Canada. The poor nutritional quality of grouse diets in the Appalachian region may result in increased foraging time and predation risk, as well as decreased body condition, reproductive potential, and chick survival.

CHALLENGES

In the Appalachian region, habitat loss and degradation are the principle causes for Ruffed Grouse population declines. Fire suppression, maturing eastern deciduous forests, and lack of management practices involving timber harvest are major causes of habitat degradation and loss.

The quantity and quality of Ruffed Grouse habitat has declined in recent decades in the Appalachian region (ACGRP 2004).

Although the Ruffed Grouse is still a popular game species, hunting mortality is considered compensatory to some extent and is not thought of as a major factor controlling grouse populations. In a recent study, it was reported that, on average, hunting accounted for only 12% of all mortality and ranged from 0 to 35% across sites and years. This study did not conclude or infer that hunting would be compensatory at higher harvest rates (ACGRP 2004).

CONSERVATION ACCOMPLISHMENTS

Prior to 1996, Ruffed Grouse management in the Appalachian region was based on research conducted in the Northern United States and Canada. ACGRP was established in 1996 by state natural resource agencies to investigate potential factors limiting Ruffed Grouse populations in this region. Data were collected on twelve study sites in eight states over a 6-year period. Partners in this project were varied and provided funding and personnel as well as study sites. Partners consisted of state wildlife agencies, universities and various foundations and conservation organizations.

The objectives of the ACGRP were to:

1. Estimate survival rates and identify limiting factors,
2. Estimate reproductive rates and identify limiting factors,
3. Determine if harvest mortality is compensatory or additive, and
4. Evaluate habitat selection and quality.

This enormous undertaking has provided much needed information for management of Ruffed Grouse habitat in the Appalachian region. State wildlife agencies now have critical information to develop management strategies to slow or stop the decline of Ruffed Grouse in the Appalachian region.

Another accomplishment was the purchase of the Jocassee Gorges and creation of the Franklin Gravely Wildlife Management Area, a core area of South Carolina’s grouse range.

Throughout the Appalachian region, land ownership varies and includes National Forest land, state public land and industrial land. In South Carolina, land ownership is similar and a majority of potential grouse habitat will be protected by virtue of being within National Forests and state public land.

Finally, the *Ruffed Grouse Conservation Plan* (RGCP) which identifies Ruffed Grouse habitat needs and sets population and habitat restoration goals for each Bird Conservation Region (BCR) across the range of the species was completed in 2006 (Dessecker et al. 2006).

CONSERVATION RECOMMENDATIONS

- Implement management practices developed through the ACGRP (2004) on DNR lands and encourage implementation of these practices on National Forests and other public lands within the state. Action items include:
  - Maintain current Ruffed Grouse harvest levels and season; the current level of hunting pressure does not limit populations in South Carolina.
  - In mixed-mesophytic areas, employ "traditional" early-successional habitat management techniques that emphasize timber harvest techniques that provide a diversity of younger aged stands interspersed among mature forests.
  - In oak-hickory dominated sites, forest management should strive to provide both food (acorns) and cover (early successional habitat) needs of grouse in close proximity. Clearcutting, shelterwood, two-age and group selection silviculture offers managers alternatives to create these contrasting needs of acorns from mature oak trees in association with cover from young stands.
  - Manage roads by gating and planting preferred herbaceous foods to supplement existing natural foods.
  - Utilize prescribed fire as appropriate within Ruffed Grouse range in South Carolina to restore, enhance, and maintain habitat.
- Conduct surveys as appropriate to evaluate Ruffed Grouse population response to habitat management.
- Partner with private landowners and interested constituents to publicize and implement the recommendations of the ACGRP and the RGCP.
- Provide Ruffed Grouse habitat management recommendations to private landowners through on-site technical assistance, fact sheets, management bulletins and websites.

MEASURES OF SUCCESS

Existing bird surveys are insufficient to detect changes in the population of Ruffed Grouse in South Carolina. However, increased sightings of Ruffed Grouse by DNR personnel and members of the public would be considered one measure of success. Likewise, increased interest in management of Ruffed Grouse by the general public, as demonstrated by increased phone calls or e-mails related to Ruffed Grouse management and hunting, would be considered a measure of success of outreach and public awareness efforts.

DESCRIPTION

Taxonomy and Basic Description

Photo by Harry D Sell

The Swallow-tailed Kite is unmistakable with its long, pointed wings (wingspan of 1.2 m or 4.0 ft.) and long forked tail (32 cm or 12.6 in.). The dorsal coloration is black while the head and underparts are white. Average weight for adults is 440 to 480 g (1 lb.), with females being slightly heavier than males. Swallow-tailed Kites capture most of their food and eat, drink, and bathe on the wing. This bird spends much of the day in flight and feeds year-round on insects (particularly airborne; Meyer 1995, Baird 2011). However, they provision their young mainly with small vertebrates, including anoles, tree frogs, small arboreal snakes, nestling birds, and (roosting) bats (Meyer et al. 2004), all of which they glean from vegetation while in flight.

Status

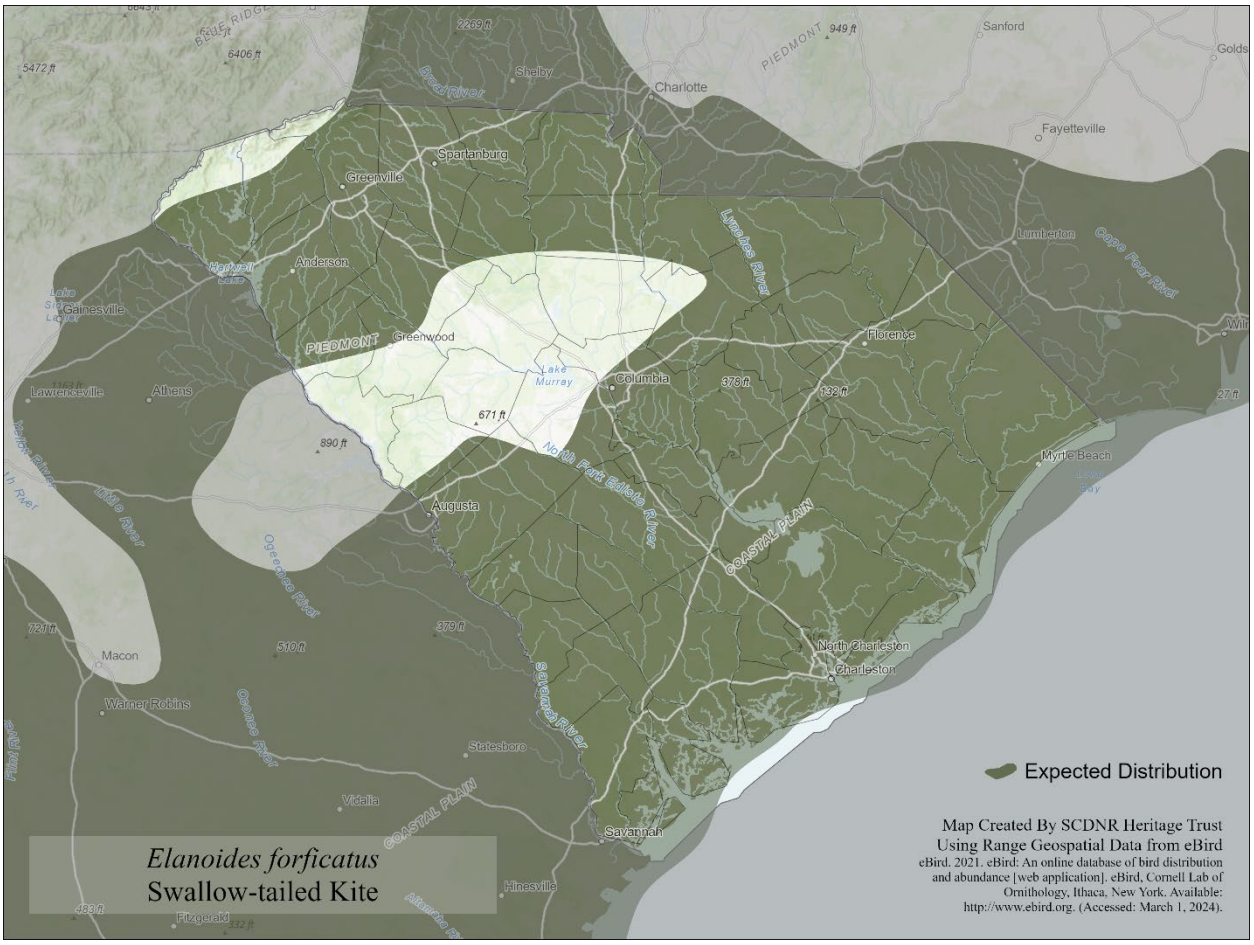
The Swallow-tailed Kite is listed by the South Carolina Department of Natural Resources as a state endangered species, and is considered a high-priority species of concern by the other states in which it occurs, the United States Fish and Wildlife Service, Partners in Flight, and national conservation organizations. There are 3 distinct genetic populations that nest from the Southeastern United States to south-central South America (Washburn 2007). The degree of difference between the United States population and the two in Latin America equals or exceeds differences found between taxonomically-recognized species (Washburn 2007).

POPULATION SIZE AND DISTRIBUTION

Historically, the United States range included at least 21 states as far north as Minnesota (Cely 1979). The Swallow-tailed Kite is presently found in floodplain forests and other large tracts of forested wetlands and mixed pine habitats (Meyer et al., *in prep)* of the Outer Coastal Plain (OCP) from South Carolina to east Texas, with most of this remnant breeding range occurring in 6 Southeastern states: South Carolina, Georgia, Florida, Alabama, Mississippi, and Louisiana. The disappearance of the Swallow-tailed Kite from three-fourths of its US breeding range between 1880 and 1910 was one of the most dramatic range contractions of any bird before the post-World War II decline of the peregrine falcon. Since about 1940, populations have apparently stabilized with some evidence of a possible reoccupation of former habitat, including parts of South Carolina and small areas in eastern Texas; southeastern North Carolina, where

limited nesting may have begun around 2003; and southeastern Arkansas, where a few unsuccessful nesting attempts were documented in the early 2000s in Arkansas's White River bottoms, over 320 km (200 mi.) north of the nearest nesting population (J. Bednarz, pers. comm.).

Because Swallow-tailed Kites are so distinctive, noteworthy, and able to range widely in the United States prior to and following nesting, their unexpected or repeated appearance often leads people to believe that they are increasing in number. There are no clear indications from the limited samples of Breeding Bird Survey data or annual counts at large pre-migration roosts (Meyer and Zimmerman 2006; K. Meyer, unpublished data) that the population is presently changing substantially in number or distribution. Until recently, the estimated population for the entire United States was about 800 to 1,150 pairs (Cely and Sorrow 1990), or about 2,500 to 5,000 individuals allowing for sub-adults and juveniles at the end of the nesting season (Meyer 1995). About two-thirds of these birds are thought to reside in Florida (Meyer 1995). However, systematic, synchronized counts at large, pre-migration communal roosts in peninsular Florida since 2004, which have peaked at about 7,000 individuals each year, indicate that the United States population may include as many as 10,000 individuals, or 2,000 to 2,500 pairs (Meyer and Zimmerman 2006; K. Meyer, unpublished data).



The estimated number of breeding pairs in South Carolina is 120 to 170; these are primarily found in large floodplain forests and swamps of the OCP, with significant populations occurring on the lower Great Pee Dee, Santee, Black, Edisto, and Savannah Rivers (and their tributaries), and in the Francis Marion National Forest.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In South Carolina, the Swallow-tailed Kite is closely associated with large tracts of forested wetlands of the Outer Coastal Plain, such as those found in the Francis Marion National Forest and along the lower Savannah, Edisto, Santee, Black, and Great Pee Dee Rivers. It shows a strong preference for nesting in dominant or co-dominant loblolly pines (*Pinus taeda*) growing within or on the edges of wetland forests. However, kites will regularly use bald cypress (*Taxodium distichum*) when pines are unavailable. Swallow-tailed Kites have also been recorded nesting in water tupelo (*Nyssa aquatica*), sweetgum (*Liquidamber styraciflua*), and willow oak (*Quercus phellos*).

The average dimensions of loblolly pine nest trees in the Francis Marion National Forest were 32 m (104 ft.) tall and 49 cm (19 in.) diameter breast height. Pines were located within stands averaging 13.5 m^2/ha (60 $ft.^2$/ac.) basal area and 61 years of age (Cely and Sorrow 1990). Dimensions for cypress nest trees were similar to the pines; these trees had an average height of 29 m (96 ft.), with a diameter above the swell of 50.5 cm (20 in.) and a basal area of 13.5 m^2/ha (60 $ft.^2$/ac.). Smith, 2023, found a positive correlation between nest success and large DBH of the nest tree. Cypress ages were not determined but all were at least second, if not third, growth and probably no more than 75 years of age (J. Cely, unpublished data). Nest trees were only slightly larger than surrounding trees. The average distance to a waterway for kite nests in South Carolina was 135 m (455 ft.), but this distance ranged from 25 to 544 m (82 to 1,795 ft.) (J. Cely

and A. Day, unpublished data). As Spanish moss (*Tillandsia usenoides*) is a key component of nest construction, this epiphyte may be a necessary ecological requirement (Meyer 1995). In addition to nest tree DBH, nests initiated earlier in the season were three times more likely to be successful compared to nests started mid season, May, in the Corkscrew Regional Ecosystem Watershed Wildlife and Environmental Area (Smith, 2023). Old growth forests with large mature trees in bottomland forests provide superior nesting locations compared to other habitat types.

Based on VHF telemetry research, Swallow-tailed Kites have a large home range that encompasses thousands of acres (Cely and Sorrow 1990; Meyer and Collopy 1995). Foraging birds use a variety of stand types and ages and will often commute long distances, up to 24 km (15 mi.), from the nest site, to feed on various prey (Meyer 2004b). Once nestlings have fledged and are becoming independent, foraging kites gather to prey on beetles, dragonflies and grasshoppers associated with upland fields, pastures and freshwater marshes (Baird 2011). Other Swallow-tailed Kites are attracted to “hot spots” of insect abundance; feeding aggregations sometimes consist of more than 50 birds.

CHALLENGES

Swallow-tail Kites are highly social in all seasons, foraging, roosting, and migrating in flocks and nesting in loose aggregations (neighborhoods) within sight of each other, often only 60 to 100 m (197-328 ft.) apart. Their social behavior, undoubtedly adaptive, makes them conspicuous, relatively easy to count, and fascinating to observe. Predictably, Swallow-tailed Kites show strong site fidelity when joining in large roosts (Meyer 1998; Meyer and Zimmerman 2006) and especially when nesting, most likely because returning to previously used sites helps ensure that they will encounter conspecifics (Meyer 1995). This provides opportunities for resource managers to focus their attention and protection more efficiently.

Unfortunately, it also means that specific locations become very important to Swallow-tailed Kites. Because most of the United States' breeding population nests on unprotected, private lands, particularly commercial timberlands, human activities that alter or destroy natural habitats or create repeated disturbance will displace not just a single pair or roosting individual, but large numbers of kites (Meyer 2004b). Social bonds, and the benefits that accrue, may be lost, especially if the scale of the intrusion and the subsequent displacement are large. This creates one of the biggest challenges for conserving Swallow-tailed Kites, from local to landscape scales.

There appears to be substantial suitable-but-unoccupied habitat range-wide, including in South Carolina. This can be misleading. Because social needs and attractions result in clumped distributions, they intensify the use of some patches of suitable habitat while leaving other patches vacant. The Swallow-tailed Kite’s demography also may contribute to this incomplete use of suitable habitat. Adult survival is relatively low for a bird of this size and general ecology (Meyer 2005). This may stem, at least in part, from the risks of long-distance migration, which also may contribute to the low survival of first-year kites (Meyer 2004a, Meyer and Kent 2012).

Thus, the loss of habitat *is* a serious threat to Swallow-tailed Kites when it is *occupied* habitat. The loss of unoccupied habitat, furthermore, represents a threat when suitable habitat is relatively limited locally, forcing the associated groups of kites to move long distances and, therefore, to risk dissolution. This explains the recommendation that the size of clear-cuts on industrial forests occupied by Swallow-tailed Kites should be limited to allow for relocation of displaced birds within a reasonable distance (Meyer and Kent 2010a, 2011a). It also relates to the recommendation (Meyer and Kent 2011a) that forest managers should maintain a minimum total area of suitable nest trees (mature pines or cypress with open crowns within stands of uneven height and structure) within a specified areas of the landscape at all times. This would allow for flexibility in harvest planning while still accommodating the kites’ needs for attractive nest trees within a sufficiently small area to ensure that the social nesting neighborhood can move cohesively when they return to find the previous year’s nest trees gone.

Non-sustainable timber management (including short rotations), altered wetland hydroperiods, uncontrolled invasive species, budgetary limitations, or landowner restrictions that preclude appropriate land management, etc. are all forms of habitat loss. Additional factors limiting swallow-tailed kite recovery include shooting (which may have played a role in the decline of the early 1900s; Cely 1979); predation (e.g. where anthropogenic habitat alterations, such as

fragmentation, promote unnatural increases in key predators such as Great Horned Owls); and the loss of essential habitats combined with unexpectedly high mortality on the South American winter range, perhaps due to agricultural contaminants.

The Louisiana-Mississippi subpopulation (Coulson 2006; Coulson et al. 2008) appears to be limited by predation. Raptors, particularly great horned owls (*Bubo virginianus*), kill kites of all ages, but especially adult females attending nests, possibly limiting breeding-aged females. During monitoring of 290 nests, recently fledged young, and radio-tagged birds (90 fledglings, 13 adults), such predation accounted for 51 to 57% of mortality. Predation of nestlings and attending adults appears to be increasing in the Eastern portion of the breeding range, particularly in Florida and Georgia on industrial timberlands experiencing increased harvest rates, and high predation rates by Great Horned Owls have recently been observed in coastal kite neighborhoods (Meyer and Kent 2011b, 2011c). Little is known about the regional ecology of great horned owls, particularly abundance, breeding density, habitat associations, and range sizes. This predator, in particular, also is known to have high impacts on water bird colonies in South Carolina (Goyette et al. 2011).

CONSERVATION ACCOMPLISHMENTS

Following the example of South Carolina's initial research in the late 1980s, additional efforts have been directed towards the species during the past 15 to 24 years in Florida, Louisiana, Mississippi, and Georgia. Finding and monitoring active nests has yielded data on breeding biology, vegetation features of nest sites, philopatry, group sizes, prey species and feeding rates, estimates of nesting success and productivity, and causes of nest failures (see various references). In South Carolina, research by Cely and colleagues centered mainly on the Francis Marion National Forest from the mid-1980s into the 1990s (Cely and Sorrow 1990; J. Cely and A. Day, unpublished data). Later studies focused more on the Waccamaw National Wildlife Refuge and adjacent areas of the Winyah Bay watershed (Meyer and Kent 2009, 2010b, 2011d).

Long-term studies in Florida, Georgia, and South Carolina have investigated survivorship for large samples of adults tracked by satellite (Meyer 2005) and individuals tagged as nestlings with VHF transmitters, for which first-breeding age, breeding dispersal, and recruitment also were examined (Meyer 2004a; Meyer and Kent 2009, 2010b, 2011d, 2012).

Quantitative descriptions of selected habitats at the forest-stand and landscape scales have been derived from large sets of accumulated nest locations (Meyer et al. *in prep*). These results, in turn, are now being combined with spatially-explicit demographic and land-ownership data to produce a model that will prioritize land protection and management strategies across the Southeast (K. Meyer, G. Kent, S. Beyeler, and J. Cely, unpublished data).

Post-breeding / pre-migration communal roosts of Swallow-tailed Kites probably facilitate foraging efficiency in preparation for migration (Meyer 1995 and 1998). These aggregations, numbering from a few to 100 or more along rivers of the Atlantic and Gulf Coastal Plains and 2,000 to 3,000 at the largest roosts in peninsular Florida, may be used habitually year after year and are sensitive to human disturbance. Communal roosts offer unusually good opportunities for population monitoring (Meyer 2004a; Zimmerman and Meyer 2006). Systematic, synchronized

aerial counts were conducted in 2009, 2010, and 2011 in South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, and Texas with funding from the United States Fish and Wildlife Service and matching support from cooperating partners (South Carolina Nature Conservancy, Georgia Department of Natural Resources, Avian Research and Conservation Institute, Alabama Department of Conservation and Natural Resources, and The Orleans Audubon Society). The goal of this collaborative project was to refine and recommend population monitoring methods and, combined with concurrent location data from satellite/GPS telemetry (K. Meyer and J. Coulson, unpublished data), to identify previously unknown roost sites and apply occupancy data to systematically estimating national population size. Knowing the locations of pre-migration communal roosts, especially the larger, repeatedly used sites, is the first step toward land protection, habitat management, and prevention of human disturbance (Meyer 1998; Zimmerman and Meyer 2006). Annually the public is encouraged to report roost sightings through a web form to locate and count pre-migratory roost sites from July 15 through August 10.

The long-distance migration pathways (over 17,000 km or 10,563 mi. round trip) and wintering destinations of the United States population of swallow-tailed kites, described from satellite and VHF telemetry from 1996 to 2004 (Meyer 2004a; Meyer 2005; Zimmerman 2004; Zimmerman and Meyer 2004) and recent GPS tagging efforts, present international threats, challenges, and opportunities for year-round management and conservation. Particular portions of the migration route appear to pose greater risks based on associated mortality (Meyer 2004a and 2005). In some cases, the causes are natural and unmanageable (e.g. long over-water flights north- and southbound between the United States and Mexico/Central America; and when crossing the Andes Mountains in northwestern South America). Increased storm frequency and strength from climate change could increase the impacts of migration route mortality associated with water crossings during Fall migration. However, greater-than-expected mortality (inferred from loss of telemetry signals) on the winter range in central South America may be linked to rapid conversion of traditionally used ranchland habitats to intensive, highly-treated industrial agriculture (Meyer 2004a and 2005). A satellite/GPS telemetry study (see previous paragraph; K. Meyer and J. Coulson, unpublished data), including adults tagged in South Carolina, Georgia, Florida, Mississippi, and Louisiana, has produced much finer-scaled location data over several years and may reveal likely causes of death on the winter range. Wintering range of this species is highly concentrated with the majority of tracked individuals wintering in an area of Matto Grasso State of Brazil in a mixed-use landscape of agriculture and grazing near the Paraná River. Altering or use change in this landscape would have large impacts on the population and affect the Spring return rates. It is estimated that from 2001 to 2018 in Mato Grasso, more than 4.5 million ha of natural cerrado vegetation has been removed (Simoes, 2020). Much of this lost vegetation has been converted to agricultural use for corn, soybean, and cotton production, as well as increased cattle grazing (Simoes, 2020).

In 2007, a partnership, the Swallow-tailed Kite Conservation Alliance, was established to determine priorities for research, monitoring, management, and public education; to share information; and to advance conservation for the species (Zimmerman 2009). The Alliance has functioned mainly through the collaborations and cooperative efforts of sub-groups within the organization, depending on the goals and geographic scope of the respective activities.

In some instances in South Carolina, nest site information has increased land acquisition incentives and protection efforts, such as at the Waccamaw National Wildlife Refuge and the lower Santee/FMNF. Because of the species' large home range, it could serve as an umbrella species for the conservation of other area-sensitive wetland wildlife including neotropical migrants, Barred Owls, Red-shouldered Hawks, Pileated Woodpeckers, river otters, and black bears. South Carolina maintains an unusually active, collaborative approach to Swallow-tailed Kite conservation that is based on the combined interests and efforts of agencies and organizations devoted to land management, land acquisition, research, and public education.

One of the most important endeavors for researchers has been to produce management recommendations, particularly for breeding habitats on both public and private lands. Combined results of studies in 5 states point to favorable silvicultural practices at the nest-site, forest, and landscape levels. This is particularly important given the large proportion of Swallow-tailed Kite nesting territories on corporate and private lands. *Appendix 1* in Meyer and Kent (2010a), *Management recommendations for swallow-tailed kite nesting habitat in Florida*, lists actions that include thinning of even-aged pine plantations, establishment of Streamside Management Zones (SMZs), and maintaining mature pine and cypress stands of uneven age and structure within heterogeneous wetland landscapes. A recent study found nestling success correlated with nest tree DBH, suggesting Swallow-tailed Kites benefit from larger mature trees left in forest stands (Smith 2023). The *Synthesis* section, however, describes an encompassing approach:

> *"...our most important recommendation, based on 23 years of direct observation and integration of all available information from over 1,200 nesting attempts, is deceptively simple: Protect nesting swallow-tailed kites where they choose to be. This species, mainly due to its pervasive social nature, is exceptionally persistent in its attachment to place. This affinity, which transcends the short-term behavior of individuals within their relatively brief lifespan, is expressed by a continually shifting succession of pairs (and turnover within the pairs) and their collective return and adherence to locations where they can expect to find other swallow-tailed kites. 'Occupied habitat' is not a static, within-year physical condition exploited by a breeding pair. It is set of natural features, some essential, associated with a location that has taken on cultural and traditional importance. There is no question that many of the swallow-tailed kites in our study populations continue to nest where they do – despite local habitat alteration and loss that is often severe – due to this over-riding attachment to location. We do not know if their nesting success, productivity, and survival are compromised as a result… Protecting occupied swallow-tailed kite habitat where we find it is vitally important. This simple expression, however, masks the challenges this concept poses for implementing swallow-tailed kite conservation. The necessary, over-arching strategy will require communication and coordination among public, corporate, and private conservationists and land managers at all levels. The required effort will not be sustained without the active engagement of attentive conservationists from many disciplines. Critical-species leads in state and federal wildlife agencies will be in the best positions to monitor and guide this concerted effort. Favoring success is the unqualified allure of this spectacular bird and the public's keen interest in its persistence."*

CONSERVATION RECOMMENDATIONS

While most of the following recommendations also apply to management of the continental population of Swallow-tailed Kites, we have focused on the highest priority needs for South Carolina's breeding population.

- Incorporate Swallow-tailed Kite nest locations into management and protection efforts by ensuring that conservation agencies and organizations are aware of this database.

- Continue to participate in the national pre-migration monitoring surveys of Swallow-tailed Kites to protect critical pre-migration communal roost areas and detect population changes.

- Document and mitigate the impacts of avian predators on Swallow-tailed Kite nesting success, particularly for Great Horned Owls, which also are a threat to water bird breeding colonies in coastal South Carolina.

- Document present Swallow-tailed Kite habitat associations and reproduction in the Francis Marion National Forest (FMNF) and compare with 1980s and 1990s data (Cely 1979; Cely and Sorrow 1990) to inform current forest management in and beyond FMNF.

- Document nesting, land ownership, and management potential southwest of Charleston, (particularly the ACE Basin and lower Savannah River drainage), and compare with better-studied areas to the northeast.

- Work with the public, NGOs, volunteers, agencies, timber companies, private landowners, and the Swallow-tailed Kite Conservation Alliance to increase partnerships for the protection of Swallow-tailed Kites.

- Continue to maintain the citizen-science efforts to report Swallow-tailed Kites; increase applications of this information to address priority management needs.

- Instruct timber managers in practices that increase Swallow-tailed Kite reproduction and promote long-term forest stewardship, with a strong emphasis on conserving presently-occupied Swallow-tailed Kite nesting, foraging, and roosting habitat.

MEASURES OF SUCCESS

A recovery goal of roughly doubling the United States population has been established, which would require approximately 100 birds per river drainage range-wide (C. Hunter, personal communication). South Carolina's portion of this goal is approximately 400 nesting pairs, or at least twice the present breeding population.

A realistic, but still challenging, goal is to at least maintain the various subpopulations at their present levels by protecting suitable nesting and surrounding foraging habitats that breeding

Swallow-tailed Kites have already selected and are using repeatedly. This challenge is compounded by the relatively large portion of nests on private and corporate lands.

Identifying the cause(s), and thereby reducing mortality on the winter range along with establishing long-term protection of privately-owned traditional ranch and farm lands selected by wintering kites from the United States, should increase annual survival. This would thus help to offset, rather than add to, some of the natural mortality associated with long-distance migration and relatively low reproductive rates.

DESCRIPTION

Taxonomy and Basic Description

The species described in this report are in the perching bird order, Passeriformes, and represent 3 families: Cuculidae (cuckoos), Parulidae (wood warblers), and Turdidae (thrushes). Alexander Wilson first described the Black-billed Cuckoo in 1811, and the Yellow-billed Cuckoo was described by Linnaeus in 1758 (Hughes 2020). The accepted name for the Wood Thrush is from Gmelin (1789; Evans et al. 2020), while the Blackpoll Warbler was first described by Johann Forster in 1772 (AOU 2011).

Black-billed Cuckoo / Wikimedia Commons

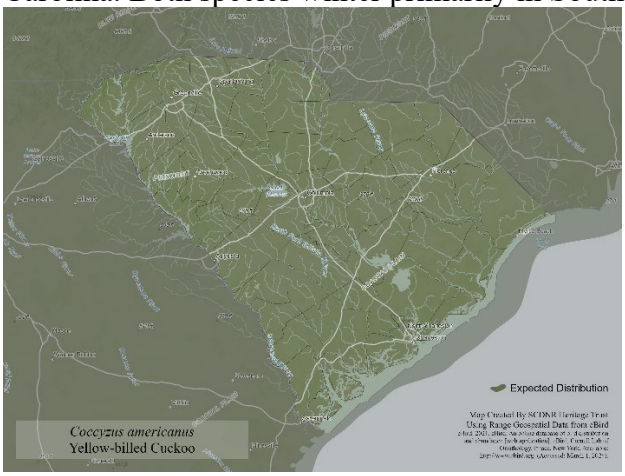
Yellow-billed Cuckoo / Flickr

The Black-billed Cuckoo and the Yellow-billed Cuckoo are members of the Family Cuculidae. Both are similar in appearance and behavior, each slender birds with a long tail, gray-brown plumage and light underparts, a curved bill, and zygodactyl feet. The Black-billed Cuckoo has a black bill and a bright red eye ring during the breeding season. The Yellow-billed Cuckoo is distinguished by a bright yellow lower mandible, a rufous patch on the outer primaries, and distinctive white tips on the outer rectrices. Black-billed and Yellow-billed Cuckoos are similar in size, with the former having an average length of 28-31 cm (11-12 in) and weight of 45-55 g (1.5-1.0 oz), and the latter having an average length is 26-30 cm (12 in.) and weight of 55-65 g (2.3 oz.) (Hughes 2020).

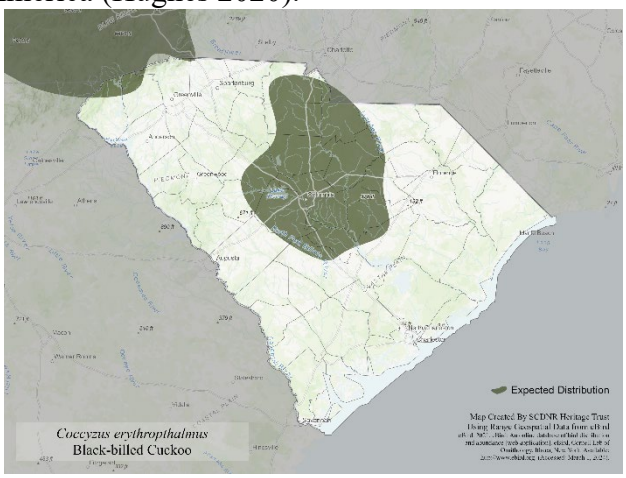
The Family Parulidae includes the Blackpoll Warbler. Birds in this family are small and colorful with sharp, pointed beaks for gleaning insects. The Blackpoll Warbler is a large *Setophaga* warbler, measuring 14 cm (5.5 in) in average length and 12-13 g (0.4-0.45 oz) lean body mass. Some individuals reach nearly double this mass prior to fall migration (DeLuca et al 2020). Breeding male Blackpoll Warblers have a distinctive black cap, or "poll." The rest of the head is white with black malar stripes. The breast and underside are white, with black bars lining the flank and back. Wings are dark brown to yellow-green with two white wing bars. Breeding females have comparable but more subtle coloration; the cap is streaked rather than solid and flank streaking is paler. Females have a broken white eye ring. Basic, juvenile plumage is usually washed with yellow. Orange legs and feet are diagnostic in differentiating from similar warblers (DeLuca et al 2020).

The Wood Thrush is a member of the Family Turdidae, a group of cryptically colored birds known for their beautiful songs. Basic coloration of the Wood Thrush is rusty brown with white underparts punctuated by dark brown spots. A white eye ring is also present. The Wood Thrush is a medium-sized thrush, measuring 19-21 cm (7.5-8.25 in.) in length and weighing 40 to 50 g (1.4 to1.8 oz.) (Evans et al. 2020).

Status



The Black-billed and Yellow-billed Cuckoo are considered species of Least Concern by the IUCN (2023) but are both included on Partners in Flight's (PIF) list of Common Birds in Steep Decline List (PIF 2023). Both species are listed as having regional importance for the Atlantic Coast Joint Venture (Rosenberg et al. 2016). In South Carolina, the Black-billed Cuckoo has a Vulnerable (S3) ranking and the yellow-billed Cuckoo has an Apparently Secure (S4) ranking (NatureServe 2024).



The Blackpoll Warbler is considered Near Threatened by the IUCN (2023) and, having declined by 92% since the 1970's, is included on the Partners in Flight list of Common Birds in Steep Decline (PIF 2023). In South Carolina, NatureServe ranks Blackpoll Warbler as Apparently Secure Migrant (S4M), though dramatic declines have been observed in some of the breeding range (NatureServe 2024). Birds of the World states that, though declines have been observed, the sampling effort only covers a very small part of the breeding range (DeLuca et al 2020).

The Wood Thrush is considered a species of Least Concern by IUCN (2023), but with decreasing populations. It is estimated that Wood Thrush populations have declined 1.92% per year from 1970 to 2017. Breeding Bird Survey (BBS) data has shown a slow in the decline in recent years (Partners in Flight 2019). Partners in Flight considers Wood Thrush a "D" Yellow Watch List species; "species with population declines and moderate to high threats" (2023). NatureServe considers Wood Thrush to be S3/S4, Apparently Secure/Vulnerable in South Carolina (2024).

POPULATION SIZE AND DISTRIBUTION

Black-billed and Yellow-billed Cuckoos breed throughout much of eastern North American, though there are rare and localized populations of Yellow-billed Cuckoos west of the Rocky Mountains (Hughes 2020). The breeding range of Yellow-billed Cuckoos extends southward into the Caribbean and northern Mexico, while Black-billed Cuckoos breed only as far south as South Carolina. Both species winter primarily in South America (Hughes 2020).

The current rangewide population estimate for the Black-billed Cuckoo is 880,000 individuals (PIF 2023), but no estimates exist for South Carolina, as the species is rarely recorded during breeding bird surveys. In the South Carolina Breeding Bird Atlas (1988-1995; Cely 2003), the Black-Billed Cuckoo is not documented. However, more recent sources, including NatureServe (2024) and the Carolina Bird Club (2024), confirm that Black-billed Cuckoos breed statewide. The species is in steep decline, with an estimated annual decline of 1.3% in the US between 1966 and 2021 (Ziolkowski et al. 2022). The Yellow-billed Cuckoo has a rangewide population estimate of 8.4 million individuals (PIF 2023) that is declining at an annual rate of 0.9% in the US (Ziolkowski et al. 2022). In South Carolina, the species appears to breed statewide (Cely 2003) and has an estimated state population of 240,000 individuals (PIF 2023). Between 1966 and 2021, the Yellow-billed Cuckoo has an average annual growth rate of 0.1% in South Carolina, though it appears to be declining in most other states where it breeds (Ziolkowski et al. 2022).

The Blackpoll Warbler breeds throughout Canada, inland Alaska and, in much smaller numbers, high elevation sites in the northeastern USA (PIF 2023). The Partners in Flight range-wide population estimate is 60,000,000 individuals (2023). During southward migration, individuals generally move southeast and congregate along the Atlantic Coast from Nova Scotia to Cape Hatteras, North Carolina before heading further south (DeLuca et al 2020). It has long been hypothesized that Blackpoll Warblers fly non-stop over the Atlantic Ocean during migration. Research by DeLuca et al. in confirmed this hypothesis by tracking five migrating individuals using light-level geolocators; the birds averaged 2540 km (1578 mi) of non-stop flight over three to four days before a short stopover in the Greater Antilles or Northeastern coast of South America before moving further south into their wintering range (2015). Blackpoll Warblers spend the non-breeding season throughout the Amazon Basin in Bolivia, Brazil, Colombia, Ecuador, Peru, and Venezuela (NatureServe 2024). Northward migration occurs at a more leisurely pace with movement occurring over land after shorter overwater flights from South America (DeLuca et al. 2015). It is during this spring migration that Blackpoll Warblers most often occur in South Carolina.

The Wood Thrush is distributed statewide in South Carolina with higher concentrations of breeding in the Piedmont and Mountain regions (Cely 2003). Partners in Flight estimates the current range-wide population to be 12,000,000 individuals (2023). Wood Thrush breed throughout the Eastern United States and Southeastern Canada from New Brunswick to Ontario south to Texas and north Florida. During August and September, individuals leave their northern breeding grounds to fly southward. Overwintering occurs in central America from southeastern Mexico to western Colombia. Northward migration occurs in April and May and is 2-6 times faster than the move south. Migrants generally cross the Gulf of Mexico while moving in both directions (Evans et al. 2020).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Black-billed and Yellow-billed Cuckoo are both strongly associated with deciduous riparian corridors and can be found in forest edges or forests fragmented by fallow agricultural field, hedgerows, and shrublands (Hughes 2020a and 2020b). While both species can occupy similar habitats, Yellow-billed Cuckoos are thought to prefer more open woodlands and lower elevation areas than Black-billed Cuckoos (Hughes 2020a). In the Florida coastal plain, Yellow-billed Cuckoos are present in hardwood hammocks and other moist forested habitats (Stevenson and Anderson 1994b). North American cuckoos are occasional intra- and interspecific brood parasites but often build a nest and raise their own young. Nest sites are usually located in deciduous forest groves, but Black-billed Cuckoos tend to nest in areas with greater forest cover and often in coniferous trees (Hughes 2020a and 2020b).

Blackpoll Warblers breed throughout Canadian and Alaskan boreal spruce forests in riparian areas or transitional zones between taiga and tundra. Overwintering habitat in South America consists of deciduous forest, rainforest, cloud forest, mangrove forest, and galley forests. Migratory stopover habitats are highly diverse, covering a vast latitudinal range. Blackpoll Warblers can be found in nearly any forested habitat during migration (DeLuca et al 2020).

Wood Thrush breeding habitat consists of edge and interior of mature deciduous or mixed forests, with preference for mesic, upland habitat. Ideal Wood Thrush nesting habitat contains diverse deciduous tree species, with a developed midstory that creates a shaded, open forest floor covered in leaf litter. Nest site selection favors larger tracts, but nesting does occur in smaller fragments and in residential areas or parks. Overwintering occurs in closed-canopy, semi-evergreen tropical forests. Migration habitat use for Wood Thrush is not well understood (Evans et al. 2020).

CHALLENGES

Forest fragmentation is one of the biggest problems for area-sensitive deciduous forest birds, such as the Wood Thrush, which may have reduced breeding success or abandon areas in response to shrinking patch sizes (Evans et al. 2020). Roads and edges which split or isolate forest fragments may also attract native and non-native predators, such as rodents and feral cats, or the Brown-headed Cowbird (*Molothrus ater*), a common nest parasite, into the forest interior (Lowther 2020). While Wood Thrush often select nest sites that contain edge or early successional habitat, this disproportionately exposes them to disturbance or nest parasitism by Brown-headed Cowbirds (Evans et al. 2020). Both Black- and Yellow-headed Cuckoos may also be sensitive to fragmentation, degradation or damming of water sources, and land use changes associated with removal of forest or ground cover (Hughes 2020a and 2020b).

The species included in this guild are neotropical migrants, and thus susceptible to collisions with stationary objects on migration routes (DeLuca et al 2020; Evans et al. 2020; Hughes 2020a; Hughes 2020b). Communication towers, wind turbines, cars, and buildings all pose a threat to migrating birds, with up to 900 million killed annually by window collisions alone (Elmore et al. 2021). The Wood Thrush has been noted by multiple studies as being particularly vulnerable within this guild to window collision mortality (Loss et al. 2014; Elmore et al. 2021). Flocks of Blackpoll Warblers are sometimes killed in at towers, lighthouses and wind turbines,

though this is not believed to be a significant source of population decline since Blackpolls are widespread and often have high population density (DeLuca et al. 2020).

However, Blackpoll Warblers have complex life histories involving long migrations to and from expansive and remote breeding and overwintering grounds. They are widespread and often occur in high population densities. Research is often focused within specific areas, making it difficult to gain a holistic view of the factors contributing to their decline. More widespread research is needed to fully understand Blackpoll Warbler population dynamics (DeLuca et al 2020).

As previously mentioned, Black- and Yellow-billed Cuckoos can be difficult to detect using traditional survey methods such as BBS, due to their secretive and highly mobile nature. Though Johnson and Benson (2022) found in Illinois that broadcast surveys in warm conditions increased the probability that a Cuckoo would be detected, both species exhibited high rates of territory movement during the breeding season, making occupancy estimation difficult.

Additional challenges to deciduous forest species management include introduced fugal diseases or parasites, such as sudden oak death (SOD; *Phytophthora ramorum*) and the Hemlock Woolly Adelgid (*Adelges tsugae*), which negatively impact the health of forested ecosystems.

CONSERVATION ACCOMPLISHMENTS

Deciduous forest types, including upland oak-hickory and bottomland oak-gum cypress, account for approximately 33% of total forest cover in South Carolina (South Carolina Forestry Commission 2021). In the northwest region of the state, SCDNR manages the approximately 43,000-acre Jocassee Gorges Wilderness Area, which contains critical tracts of uninterrupted mature hardwood. As of 2015, Jocassee Gorges included at least 1,200 acres of hardwood forest 60 years and older, with some patches older than 80 years (M. Hall, SCDNR, pers. comm.). The purchase of this tract of land by the state in 1997 ensures protection and management of habitat that benefits interior forest bird species.

Completion of Partners in Flight plans for Physiographic Area #03: South Atlantic Coastal Plain, Physiographic Area #23: Southern Blue Ridge, and Physiographic Area #29: Piedmont serve as helpful sources when reviewing priority bird species in these ecoregions, as well as for guiding population and habitat improvement objectives.

CONSERVATION RECOMMENDATIONS

- Identify and protect forest interior and unbroken large tracts of deciduous forest habitat.
- Determine the best sites for conservation and/or restoration projects by conducting a landscape-level spatial analysis. Utilize spatial models as a basis for land acquisition and delivery of private lands programs in order to locate areas where opportunities for conservation are the greatest.
- Promote existing and develop new partnerships to facilitate increased land acquisition.

- Maintain migratory stopover habitat in coastal areas and river bottoms for Wood Thrush and other Neotropical migrants.
- Continue to promote partnerships to implement forest health measures to prevent, detect, and suppress outbreaks of SOD and hemlock woolly adelgid on public and private lands.
- Reduce communication tower collisions. These measures will be particularly beneficial to species that are common subjects of tower mortality during migration, such as the Blackpoll Warbler (DeLuca et al 2020). Recommendations set forth by Shire (2000) include removing aviation lights on towers that are less than 199 ft tall, removing old towers that are no longer in operation, and conducting environmental assessments to determine the impact a new tower will have if placed within a migratory pathway.
- Introduce policy that seeks to reduce bird-building collisions in South Carolina. Improved building design and window placement in new structures, the addition of window deterrents in existing buildings, conscientious tree and shrub placement, and stricter urban light usage are all measures that should collectively decrease the number of building collisions in urban and suburban areas (Loss et al. 2019; Van Doren et al 2021). Wood Thrush, which are particularly vulnerable to window strikes (Evans et al. 2020), and other neotropical migrants will benefit from these measures.
- If found to be causing an impact in certain areas, the removal of feral cats (*Felis catus*) from public lands through live trapping should be implemented.
- Develop and implement monitoring programs to better assess population dynamics, breeding success, minimum habitat area requirements, and migratory behavior of deciduous forest species. Measures will need to be developed to integrate state monitoring results into regional- and national-level databases.
- Breeding Bird Survey routes should continue annually. The number of routes in under-sampled areas of South Carolina should increase, and new research on improving detection of cryptic species (such as Black- and Yellow-bellied Cuckoos) should be incorporated into survey protocol.
- Promote the participation of volunteers and agency personnel to collect survey and monitoring data.
- Radar ornithology should be continued in order to monitor bird-habitat associations at migration stopover sites. Understanding migratory stopover use of habitat in South Carolina would allow for more targeted projects that would benefit migrants like the Blackpoll Warbler.
- Continue participation in the Atlantic Coast Joint Venture at the management board and science committee levels.

MEASURES OF SUCCESS

Habitat improvement and restoration projects should result in higher breeding populations and nesting success rates. Objectives outlined in Partners in Flight Physiographic Region plans should help guide these measures.

DESCRIPTION

Taxonomy and Basic Description

The family *Accipitridae* contains 59 species of eagles worldwide (Grossman and Hamlet 1964). Sea and fish eagles account for 11 species comprising 3 genera, of which 8 are in the genus *Haliaeetus*. The Bald Eagle is the only species of sea eagle to regularly occur on the North American continent. Two subspecies of *leucocephalus* are described based on size and weight. These are of questionable merit because of a continuous gradient in size from north to south throughout the range (Buehler 2022); therefore, the subspecies *leucocephalus* and *alascanus* are not recognized in this report.

Adult Bald Eagles are large raptors with a distinctive white head and tail that contrasts with the dark brown body. They also possess a bright yellow bill and feet with unfeathered lower legs. Their eyes are large and yellow. Juveniles have a dark head and tail in addition to the dark body. The eyes and bill are dark but the feet and legs are like those of the adults. As the juvenile ages, its body plumage becomes mottled with white and in 4-5 years will reach adult plumage.

South Carolina's nesting population of Bald Eagles is smaller in stature than their northern counterparts with a mean wingspan of 188 cm (6 ft., 2 in.) and a mean weight of 3.27 kg (7.14 lbs.). Bald Eagles from the northern portion of their range can be twice as heavy. Bald Eagle chicks are full grown when they leave the nest and frequently weigh more than adults.

Golden Eagle / Tom Koerner - USFWS

The Golden Eagle is a large, dark brown raptor with a wingspan of 185 – 222 cm (6 - 7 ft.) and a dark bill that fades to yellow at the cere. Females tend to be larger by weight than males (3,000 – 6,000 g (6.61-13.23 lbs.) vs. 2,400 – 4,500 g (5.29-9.92 lbs.). The sexes share plumage characteristics as adults (Katzner et al. 2020). Plumage differs in younger birds, which tend to have white on their inner primary remiges and rectrices, though the amount of white present differs between individuals and decreases with age. Subadult Golden Eagles and Bald Eagles can be difficult to distinguish, but the Golden Eagle can be identified by its head and bill, which are smaller and slimmer than those of a Bald Eagle. Because this species' range extends across the Northern Hemisphere, 6 geographically distinct subspecies are recognized (Katzner et al. 2020).

Status

Bald Eagles and Golden Eagles are protected under the Eagle Protection Act (16 U.S.C. 668-668d) of June 8, 1940, as amended on October 23, 1972. Bald Eagles below the 40th parallel were listed as endangered on March 11, 1967, and subsequently received protection under the Endangered Species Act of 1973 (16 U.S.C.1531-1543). On February 14, 1978, listing status was changed to endangered throughout the contiguous United States except for Washington, Oregon, Minnesota, Wisconsin and Michigan, where the Bald Eagle was designated as threatened. Bald Eagles were reclassified as threatened in all lower 48 states on July 12, 1995 (50CGR Part17). The Bald Eagle was removed from the Endangered Species list in June of 2007 and receives protection by the Eagle Protection Act under the Office of Migratory Birds at the US Fish and Wildlife Service. It continues to be listed under the South Carolina Nongame and Endangered Species Conservation Act as a state endangered species. In South Carolina, the Bald Eagle is considered a vulnerable species (S3B,S3N) and the Golden Eagle is considered critically imperiled (S1N; Nature Serve 2024). On September 11, 2009, a final rule was published in the Federal Register on two permit regulations that allow for take of Bald Eagles and their nests during the course of conducting otherwise lawful activities to protect human safety (74 FR 46836). The current management guidelines and conservation measures can be found at this website: National bald eagle management guidelines | FWS.gov.

POPULATION SIZE AND DISTRIBUTION

During the early 1960s, the nesting Bald Eagle population was estimated at about 412 pairs in the 48 contiguous states (Sprunt and Ligas 1963). In 1982, the number of nesting pairs was up to 1,482 (Green 1985). By the early 2000's there are 7,066 nesting pairs of Bald Eagles in the lower 48 states. The current population estimate for the US and Canada is 200,000 individuals (Panjabi

et al. 2021). The population has both a long-term and short-term increasing population trend, 784.80% and 261.64% respectively (Panjabi et al. 2021). Bald Eagles nest in every state except Hawaii and Vermont. In 1977, there were 13 occupied nesting territories in South Carolina, and by 2009 the State's population had increased to 251 pairs (Figure 1). In 2023, there were at least 350 nesting pairs in South Carolina.

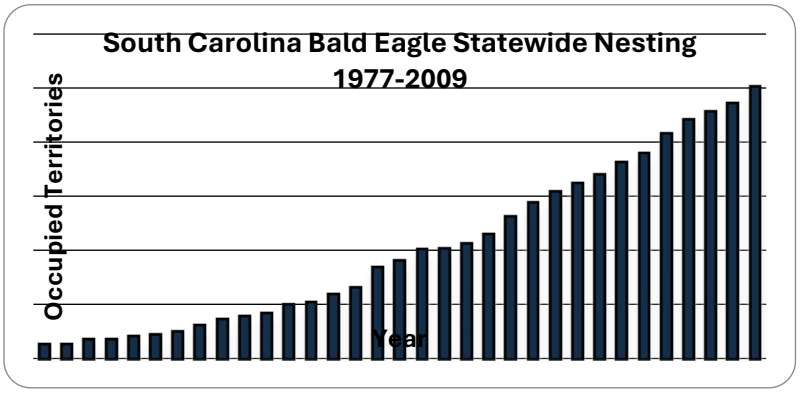

Figure 1: Nesting

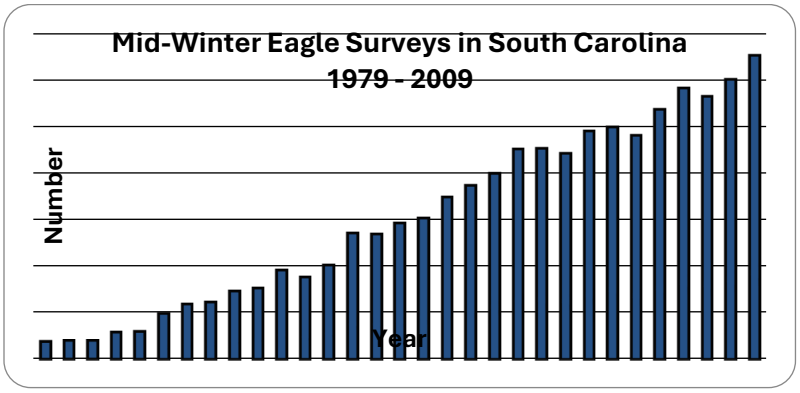
Since 1979, mid-winter surveys of adult and juvenile Eagles in South Carolina have been conducted as part of a national effort. The 2009 survey resulted in 652 Eagles counted during mid-winter (Figure 2), up from 36 during the first survey.



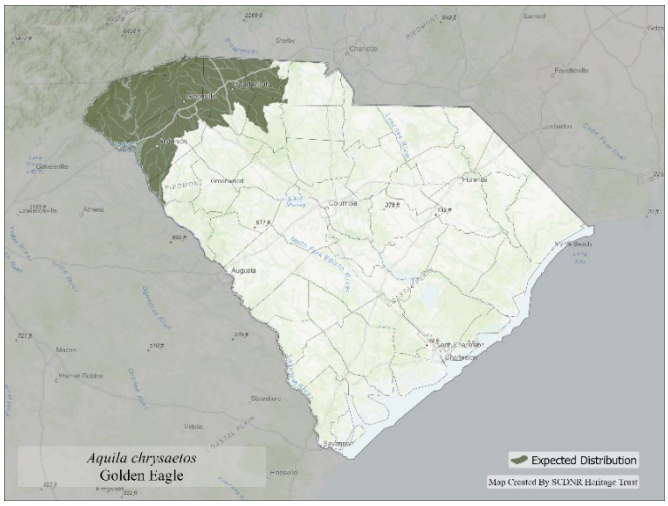


Figure 2: Surveys

The Golden Eagle is found globally, with resident populations in the western US and Canada. The species is a winter migrant to the southeast and has historically been recorded in South Carolina in the Appalachian foothills, with increasing frequency in the coastal plain (Vukovich et al. 2015). Golden Eagles appear to be increasing in number. The US population estimate for the species is 40,000 individuals (PIF 2023), with an approximately 6% increase in population size between 1970 and 2014 (Rosenberg et al. 2016). Based on Breeding Bird Survey data, the annual growth rate in the US is 0.2% (Ziolkowski et al. 2022).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Bald Eagles require large trees with an open limb structure for nesting and are usually located on the forest/marsh ecotone within 1 km (0.62 mi.) of open water. Large trees allow for large nests that can support nesting for many years without falling. The large size may also reduce fratricide or premature fledging. The open limb structure provides easy access and a clear view of foraging habitat. Nesting habitats initially selected by Bald Eagles usually have limited disturbance, although Bald Eagles show remarkable adaptability when confronted with moderate habitat alterations, often due to development in established territories. Trees suitable for perching and future nesting sites are also important components of stable nesting territories. Nonbreeding habitat includes large canopy trees suitable for resting and roosting near foraging sites (Buehler 2022).

Fresh, brackish, and marine habitats provide suitable foraging sites and include open water, marsh, and riverine types. Prime habitats are characterized by having shallow, slow moving water with abundant fish and bird prey. Preferred sites have suitable perches and roosts with minimal disturbance. Large manmade reservoirs in South Carolina have provided 240,000 ha (592,800 ac.) of new inland Bald Eagle foraging habitat. Concentrations of Bald Eagles may be found below hydroelectric dams where they forage on injured fish. Impounded marsh managed for waterfowl is preferred foraging and nesting habitat.

In eastern North America, wintering Golden Eagles are associated with areas of minimal human disturbance and higher forest cover compared with their breeding range in the western US (Katzner et al. 2020). There is evidence that migratory Golden Eagles return to the same wintering areas over consecutive years (McKinley and Mattox 2010; Katzner et al. 2020). This species hunts in flight and will primarily target small and mesomammals for live prey, but eating carrion is also common in the winter. Golden Eagles can be found in the Appalachian Plateau in the very northwest corner of South Carolina, but they are also observed occasionally in the Coastal Plain using forested habitat and managed coastal wetlands (Millsap and Vana 1984).

Eight individual eagles were observed over a 3-year period via carrion-baited camera traps at Savannah River Site in Aiken County (Vukovich et al. 2015). The authors suggested there are likely more eagles wintering in the Southeastern Coastal Plain than originally thought, and that longleaf pine savannas and feral pig carcasses may be important winter resources for them.

CHALLENGES

Shooting has historically been the most significant cause of mortality for Bald Eagles and Golden Eagles. Between 1961 and 1965, 62% of Bald Eagles found dead were shot. More recently, the percentage of Bald Eagles that died as a result of illegal shooting has declined to under 20%. This is undoubtedly one major reason for Bald Eagle recovery. Illegal take is also a concern for Golden Eagles, which are trafficked for their feathers or killed incidentally in mammal traps (Katzner et al. 2020).

Chemical contamination of eagle habitat has long been a problem for these top carnivores. Bald Eagles have been shown to be sensitive to a variety of toxins, particularly persistent organo-chlorine pesticides, such as DDT. Pesticide poisoning has been greatly reduced and is another reason for recovery of the species. However, even with many new products on the market, contamination problems persists. Lead poisoning in Bald and Golden Eagles has been identified as a significant problem (Pattee 1981; Katzner et al. 2020) and there is a chronic issue with barbiturate poisoning of Bald Eagles at landfills where they feed on euthanized animals. Deposition of mercury in foraging habitat also poses a potential threat to the health of Bald and Golden Eagle populations. Currently, the primary diseases affecting Bald Eagles are West Nile virus (WNV), Avian Vacuolar Myelinopathy (AVM), and High Pathogenic Avian Influenza (HPAI) have been identified as notable sources of mortality. Recovery of the Bald Eagle population will result in higher population density and less fit individuals as a result of competition, which may lead to an increased risk of disease.

Since Bald Eagles have been removed from the Endangered Species list, they lost some of the habitat protection previously afforded to the species and their nesting territories no longer require annual monitoring. These factors may lead to habitat degradation and decreased compliance with land management recommendations, which may make current and future nesting habitat unsuitable. Finally, other sources of mortality in Bald and Golden Eagles include electrocution at power lines and trauma sustained from collisions with wind turbines, cars, and other structures.

CONSERVATION ACCOMPLISHMENTS

Conservation accomplishments directly and indirectly affecting the Bald and Golden Eagle are varied. Through public education and effective law enforcement, shooting mortality in Bald Eagles has declined from 62% (Mulhern 1970) to less than 20% of diagnosed mortalities (Locke 1982). A ban on widespread use of DDT was implemented in 1972 and non-toxic shot has been required for waterfowl hunting. Additionally, an array of effective pesticides has been developed that have limited impacts on non-target species. A variety of raptor-safe powerline

configurations have been developed and implemented, and wind turbine collisions have decreased in frequency due to changes in turbine design (Katzner et al. 2020).

Bald Eagle management guidelines for nesting territories have been developed, with reproductive effort and fledgling success of South Carolina nesting Bald Eagles have been documented on an annual basis for 33 years. Adult mortality rates of 12% per year have been calculated based on banded Bald Eagles at nesting territories between 1977 and 2009. Currently, SCDNR surveys Bald Eagle nests by dividing the state into three sections and surveying one section each year so that the entire state is surveyed every three years.

CONSERVATION RECOMMENDATIONS

- Periodic monitoring to evaluate the effects of habitat alterations on the long-term viability of Bald Eagle nesting territories.
- Monitor a different portion of the state annually to keep an index of known Bald Eagle territories so SC can participate in the federal delisting monitoring plan.
- Monitor the causes of injury and mortality of Bald Eagles to document effects of delisting.
- Continue to work with DHEC, veterinarians, and landfill operators to eliminate barbiturate poisonings of Bald Eagles at landfills.
- Work with the Clemson Institute of Environmental Toxicology, Southeastern Cooperative Wildlife Study group (UGA), and the USFWS Wildlife Health Laboratory to monitor contaminants in Bald Eagles.
- Determine the etiology of AVM; document the current extent of the disease; evaluate the potential for future disease; and develop management strategies to minimize impacts. Conduct postmortem examination of fresh dead Bald Eagles to evaluate impacts of AVM, WNV, and HPAI.
- Identify important overwintering areas for Golden Eagles using baited camera traps, following methods in Vukovich et al. (2015).
- Continue monitoring the level of shooting mortality and react with increased active and proactive law enforcement in the event of an increase.
- Continue to implement raptor-safe powerline configurations with a variety of power companies and cooperatives.
- Continue to partner with the International Center for Birds of Prey to provide public education, raptor rehabilitation, and to document the causes of injury and death of Bald and Golden Eagles.
- Continue to ship suitable carcasses to the National Feather Repository for distribution to Native Americans.

MEASURES OF SUCCESS

The Bald and Golden Eagle are species with deferred maturity, low annual reproductive potential, and sensitivity to environmental contaminants. Therefore, utilizing adaptive management to implement conservation actions is important. An indicator of success for both

species is high annual survivorship. Maintaining annual survivorship greater than 85% can best be accomplished by minimizing anthropogenic sources of mortality such as shooting, barbiturate poisoning, and AVM disease. Management of Bald Eagle nesting territories should maintain 1.0 young per occupied territory by minimizing human disturbance and providing adequate perch and nest trees. Bald Eagle mortality and reduced reproduction by contaminants should be prevented by reducing environmental contamination of territories and important prey base species. A better understanding of Golden Eagle distribution in South Carolina will help facilitate protection of suitable habitat and contaminant reduction in key overwintering areas.

Nightjar Bird Guild

Chuck-Will's-Widow *Antrostomus carolinensis*
Common Nighthawk *Chordeiles minor*
Eastern Whip-Poor-Will *Antrostomus vociferus*

Contributor (2013): Janet Thibault (SCDNR)
Reviewed and edited (2024): Sarah Stewart (SCDNR)

DESCRIPTION

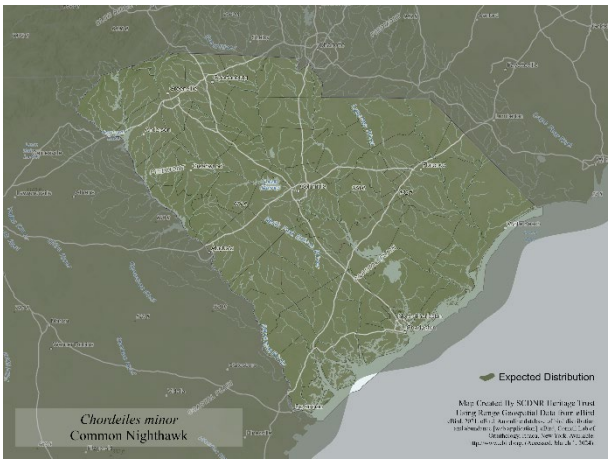
Taxonomy and Basic Description

The nightjar family (*Caprimulgidae*) is a group of insectivorous birds characterized by their nocturnal or crepuscular (dusk and dawn) activity patterns and cryptic appearance. Three nightjar species, the Chuck-will's-widow, Common Nighthawk, and Eastern Whip-poor-will, are known to breed in South Carolina.

All species have mottled brown plumage and share morphological features such as large eyes, wide mouths, and short bills with long rictal bristles around their gapes. Chuck-will's-widows are the largest nightjar in North America with an overall length of 28-32 cm (11-13 in.) and a mass of 110 g (3.9 oz.). They are a reddish-brown color with black patterning on the breast (Straight and Cooper 2020). Common Nighthawks are smaller (22–24 cm or 8.5-9.5 in; 65–98 g or 2.3-3.5 oz) with distinct barring on the abdomen and underside of wing, as well as bright white patches on the primary feathers (Brigham 2020). The Eastern Whip-poor-will is a similar length to the Common Nighthawk (22-26 cm or 8.5-10 in) but is the smallest in body mass of the three (43-64 g or 1.5-2.3 oz) and has more gray and brown patterning with a dark throat contrasted with a white necklace and pale underparts (Cink 2020).

Because of their cryptic appearance and nocturnality, nightjars are typically identified by their vocalizations. The Chuck-wills-widow and Eastern Whip-poor-will are distinguished by their onomatopoetic songs. Chuck-will's-widow songs begin with a low first note followed by 3 notes in which the middle syllable is emphasized ('chuck-wills-WID-ow'), while Eastern Whip-poor-will songs

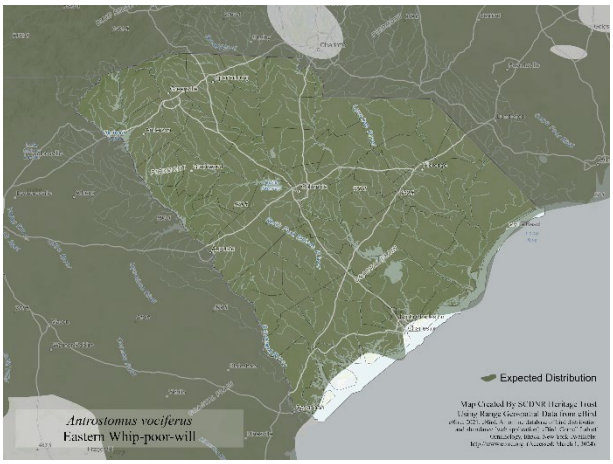
Top to bottom: Chuck-will's-widow (Tony Castro), Common Nighthawk (David Youngblood), and Eastern Whip-poor-will (Mykola Swarnyk).



are 3-noted with the first and last notes accented ('WHIP-poor-WEEL'). Common Nighthawks do not have a distinct song, but often make a nasal '*Peent'* call in flight. Additionally, breeding males perform diving displays that produce a loud booming sound (Brigham 2020).

Status

The Chuck-will's-widow, Common Nighthawk, and Eastern Whip-poor-will are each in steep decline across their ranges (Rosenberg et al. 2016; Ziolkowski et al. 2022). Population declines within other aerial insectivore guilds indicate this may be influenced by long-term changes in the quality and availability of insect prey (Spiller and Detmers 2019); however, specific factors leading to nightjar declines are unclear. Estimated range-wide population change between 1970 and 2014 is -63% for Chuck-will's-widows, -58% for Common Nighthawks, and -69% for Eastern Whip-poor-wills (Rosenburg et al. 2016). In South Carolina, the annual rate of decline is 0.5% for Chuck-wills-widows, 6% for Common Nighthawks, and 1.6% for Eastern Whip-poor-wills (Ziolkowski et al. 2021).



All three species are protected under the Migratory Bird Treaty Act, though none receive special federal status. The Chuck-will's-widow and Common Nighthawk are considered common birds in steep decline by Partners in Flight (PIF), while the Eastern Whip-poor-will is on the PIF Yellow Watch List, specifying greater urgency for the species (Rosenberg et al. 2016; PIF 2023). Regionally, PIF lists the Chuck-will's-widow and Eastern Whip-poor-will as conservation priority species for forests of the Atlantic Coast.

POPULATION SIZE AND DISTRIBUTION

Although there are limitations which increase uncertainty in surveying these species, global estimates of population size are roughly 5.4 million for Chuck-will's-widow, 16 million for Common Nighthawk, and 1.8 million for Eastern Whip-poor-will (Rosenberg et al. 2016). In South Carolina, population estimates are 330 thousand, 8.2 thousand, and 210 thousand, respectively (PIF 2023). The Chuck-will's-widow and Eastern Whip-poor-will have overlapping distributions throughout the Eastern United States and parts of the Midwest. The Chuck-will's-widow's breeding range extends north to Virginia, west to Iowa and Texas, and south to Florida (Straight and Cooper 2020). Eastern Whip-poor-wills breeding range is more northward, extending north to Ontario and New England, west to the Mississippi River, and south to northern Georgia and Alabama (Cink 2020). Both species winter in the

Caribbean and Central America, though the Eastern Whip-poor-will is also a frequent winter resident along the southeast and gulf coasts. Common Nighthawks are a more broadly distributed species and can be found breeding throughout North America, from northern Canada to central Mexico and the Caribbean, and wintering in South America (Brigham 2020).

In South Carolina, the Chuck-will's widow is a summer resident, and confirmed breeding records exist for Barnwell, Charleston, Edgefield, Greenville, Georgetown, Saluda, and Williamsburg counties (Cely 2003) as well as Lexington County (A. Huckabee Smith, pers. comm.). Common Nighthawks are also summer residents, with confirmed breeding records for Chesterfield, Hampton, Jasper, Lexington, and Spartanburg counties. While the Eastern Whip-poorwill is a winter resident along the South Carolina coast, it migrates northwest in April (Sprunt and Chamberlain 1970). Breeding records have been confirmed in Chesterfield, Lee, Spartanburg, and Union counties. There is evidence that Eastern Whip-poor-wills are expanding their breeding range to lower parts of the state; Hamel et al. (1980) reported hearing vocalizations of both species in the Coastal Plain at Beidler Forest in Dorchester County and Congaree Swamp in Richland County during May and June.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Nightjars are insectivorous and forage primarily at night, dusk, and dawn. The Chuck-will's-widow feeds aerially, flying just above the ground and capturing moths and flying beetles with sensory aid from its rictal bristles. They have also been documented consuming small birds and bats opportunistically (Straight and Cooper 2020). The Eastern Whip-poor-will forages at dusk and dawn and during times of bright moon phases, utilizing moonlight to improve prey detection. It often captures insects by sallying from perches and can capture large moths in its enormous gape (Cink 2020). Based upon a selection of qualitative and quantitative diet analyses, Chuck-will’s-widows and Eastern Whip-poor-wills seem to select for moths and flying beetles while foraging (Straight and Cooper 2020; Souza-Cole et al. 2022). Common Nighthawks exhibit more diversity in foraging times and prey selection; while they typically forage at dusk and dawn, they will also opportunistically forage during the day. Their diet encompasses a wide variety of flying insects, including moths, beetles, ants, wasps, mayflies, and caddisflies (Brigham 2020).

The Chuck-will’s-widow and Eastern Whip-poor-will are both considered forest species, but Chuck-will’s-widows appear to use forest gaps, riparian areas, and pastures at a greater rate than Eastern Whip-poor-wills, which prefer areas with more forest cover (Straight and Cooper 2020). Chuck-will's-widows can occur in mixed, pine, and oak-hickory forests while Eastern Whip-poor-wills prefer dry deciduous or mixed forests, open pine, or scrub oak with little or no underbrush. These species are never found in dense forests. Common Nighthawks are considered habitat generalists, though they are typically found in open habitats, including coastal sand

dunes, grasslands, pine savannas, and even urban areas if there are gravel rooftops available for nest sites. Water sources may also play a role in habitat suitability, as Common Nighthawks will exploit them for their insect abundance (Brigham 2020).

Nightjars are ground-nesters but do not create a nest structure, opting to lay their eggs directly on the ground. All three species tend to lay 2-egg clutches. Adults are attentive incubators, with their cryptic plumage serving as nest concealment against the selected ground cover (often deciduous leaf litter for Chuck-will's-widow and Eastern Whip-poor-will). Nightjar young are considered semi precocial and have open eyes and the ability to walk within a day of hatching but are still reliant on adults for physical protection and provisioning for multiple weeks.

CHALLENGES

Nightjars' nocturnal nature and cryptic appearance make these species difficult to detect and survey. Thus, there are knowledge gaps in the life history of Chuck-will's-widows, Common Nighthawks, and Eastern Whip-poor-wills that need to be filled before adaptive management is possible. A significant barrier to understanding nightjar declines is the lack of empirical research on the relationship between industrial pesticide use and abundance of preferred insect prey. While there is anecdotal evidence that indiscriminate mosquito control reduced Common Nighthawk populations in Saskatchewan (Wedgwood 1991), further analysis is needed to understand the influence of pesticides on nightjar ecology. Land use changes over the last century, particularly industrial agriculture, urbanization, and forest succession, likely play a role in loss of breeding habitat for Chuck-will's-widows and Eastern Whip-poor-wills. Collisions with automobiles on gravel roads and along forest edges may also negatively affect adult survival of all three species (Brigham 2020; Cink 2020; Straight and Cooper 2020).

CONSERVATION ACCOMPLISHMENTS

No specific conservation accomplishments have been noted for Chuck-will's-widows, Common Nighthawks, or Eastern Whip-poor-wills. However, significant strides have been made to fill knowledge gaps on the ecology of all three species; a plethora of studies focusing on their migration pathways, nest survival, habitat use, and diet have been published in the last 10 years. Additionally, the Nightjar Survey Network (www.nightjars.org), a U.S.-based network of nightjar survey routes and volunteers, has compiled a database of nightjar occurrence in 40 states since 2007. These data may help identify changes in population status or areas of high conservation priority.

CONSERVATION RECOMMENDATIONS

Priorities for continuing and future research on Chuck-will's-widows, Common Nighthawks, and Eastern Whip-poor-wills include:

- Conduct species-specific surveys for each within their ranges utilizing the United States Nightjar Survey Network to determine breeding distribution and density.

- Determine breeding habitat preferences of each species in South Carolina, as well as winter habitat preferences for the Eastern Whip-poor-will.
- Conduct insect and soil sampling where nightjars are present to assess how pesticide use may impact nightjar's preferred prey species.
- Investigate nest survival and juvenile dispersal patterns for each species.

MEASURES OF SUCCESS

Basic habitat characteristics, population surveys, and nest survival data should be collected before any adaptive management occurs for these species. Success parameters will be outlined pending research findings.

Whooping Crane

Grus americana

Ryan Hagerty/USFWS, Public Domain

Contributors (2024): Mikayla Thistle (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Whooping Crane (*Grus americana*) is a large crane (Family *Gruidae*, Order *Gruiformes*), native to North America. The Whooping Crane and the Sandhill Crane, with which it sometimes forms mixed flocks, are the only crane species in continental North America. Whooping Crane populations can be migratory or non-migratory. Standing almost 1.5 m (4.9 ft), it is also the tallest bird in North America. Males (7.3 kg [16.1 lbs]) are on average larger than females (6.4 kg [14.1 lbs]). Males and females appear similar. Adults have white plumage except for black primary feathers that are only visible when the wings are outstretched. They also have a dark gray-black patch on the nape and sparse bristly black feathers on a red cap and moustache. Adults have a yellow iris. Their long legs are gray-black and bill is olive-gray, lightening during the breeding season. Hatchlings are cinnamon in color. Juveniles begin to develop white feathers at approximately 120 days.

Whooping Cranes are a long-lived species. In the wild, Whooping Cranes on average live to be 22-24 years old (Binkley and Miller 1983) and potentially reach a maximum of 30 years (Mirande et al. 1993). In captivity, they can reach an age of 35-40 years (Moody 1931, McNulty 1966). However, they are slow to reach maturity which contributes to recovery challenges. On average, Whooping Cranes do not produce an egg until 5 years of age (Kuyt and Goossen 1987) and captive birds often are not productive for at least ten years (USFWS 2012).

Status

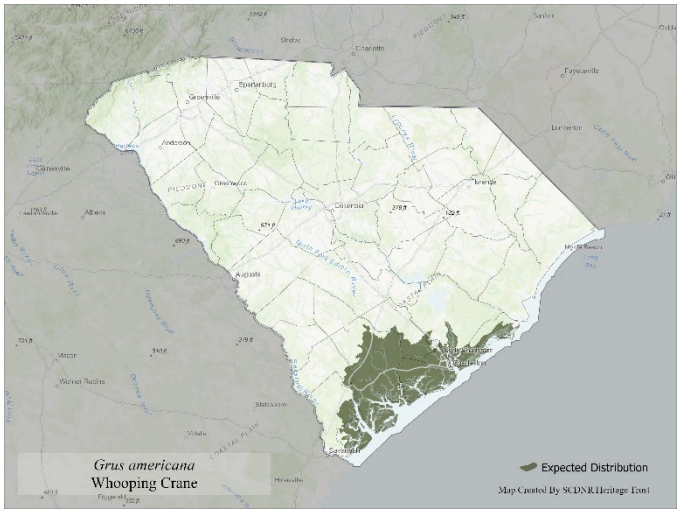
In 1941, only 21 Whooping Cranes remained in the wild and two in captivity. The Whooping Crane was determined to be threatened with extinction in 1967 and endangered in 1970 under that Endangered Species Preservation Act of 1966. The Whooping Crane maintained its endangered status under the Endangered Species Act of 1973 and critical habitat for the species was designated in 1978. In Canada where the only self-sustaining population breeds, the Whooping Crane was listed as endangered in 1978 by the Committee on the Status of Endangered Wildlife in Canada and listed as endangered under the Species at Risk Act in 2003. NatureServe ranks Whooping Crane as a G1 (Critically Imperiled) Global Status due to only having one self-sustaining population and two reintroduced populations, decreased distribution, low population numbers, habitat degradation, and problems due to collisions with man-made objects such as power lines. Nature Serve also ranks Whooping Crane as a S1 (Critically Imperiled) State Conservation Status for South Carolina. Whooping Crane is not listed on the official State List of Endangered Wildlife Species of South Carolina.

With ESA protection and successes with captive rearing, Whooping Crane populations are increasing. However, only one self-sustaining population that breeds at Wood Buffalo National Park in Canada and winters at Aransas National Wildlife Refuge in Texas remains. As of 2023, the long-term growth rate of this population averaged 4.34% (McAbee and Conkin 2024). Today, Whooping Crane maintains its endangered listing. As of 2024, Whooping Crane is undergoing a 5-year status review by the USFWS.

The first objective listed in the species International Recovery Plan is to "establish and maintain self-sustaining populations of whooping cranes in the wild that are genetically stable and resilient to stochastic environmental events," with the goal of downlisting Whooping Crane from endangered to threatened status (CWS and USFWS 2007). In addition to the one self-sustaining Aransas-Wood Buffalo Population (AWP), there have been four efforts to establish new self-sustaining populations starting in 1975, 1993, 2001, and 2011. These experimental reintroduction populations include a migratory population in the Rocky Mountains for which management was discontinued in 1997 and the last crane disappeared in 2002, a non-migratory population in central Florida (Florida Population [FP]), a population that breeds in Wisconsin and winters between Indiana and Florida (Easten Migratory Population [EMP]), and a non-migratory population in Louisiana (Louisiana Population [LP]). However, success with these programs has been limited.

The second objective listed in the species recovery plan is to "maintain a genetically stable captive population to ensure against extinction of the species" (CWS and USFWS 2007). If self-sustaining populations cannot be established elsewhere through captive rearing and reintroduction, it is estimated that the AWBP must reach a size of 1,000 individuals to be genetically stable and meet criteria for downlisting to threatened.

POPULATION SIZE AND DISTRIBUTION



It is estimated that Whooping Crane populations historically reached over 10,000 individuals (USFWS 2012). This declined to about 1,400 individuals by the mid-1800s (USFWS 2012). After reaching a low of 15 or 16 Whooping Cranes wintering at Aransas National Wildlife Refuge in 1941, populations have increased due to conservation efforts (CWS and USFWS 2007). In the winter of 2023, it was estimated that 699 individuals, of which there are 139 breeding pairs, exist in the wild whooping crane populations. As of March 31, 2023, there are 134 individuals in captivity (McAbee and Conkin 2024).

The AWBP breeds primarily in Wood Buffalo National Park and surrounding areas in Canada. This population migrates through Alberta, Saskatchewan, eastern Manitoba, eastern Montana, North Dakota, South Dakota, Nebraska, Kansas, and Oklahoma before reaching wintering grounds in a roughly 50 km stretch of the Texas coast. The AWBP winters primarily at Aransas National Wildlife Refuge and surrounding areas including San Jose and Matagorda Islands. The spring migration corridor is the same as the fall migration corridor. Aerial surveys conducted on wintering grounds in January 2023 were used to estimate the population size at 536 individuals (McAbee and Conkin 2024). The non-migratory FP generally resides at and around Kissimmee Prairie in Osceola and Polk Counties. At the time that the Florida Fish and Wildlife Conservation Commission ended intensive monitoring of the reintroduced Whooping Cranes in June 2012,

there were 18 individuals. Opportunistic monitoring continues and there has been observed breeding success after the intensive monitoring period (McAbee and Conkin 2024). The population estimate as of June 2023 is 5 individuals. The EMP breeds in central Wisconsin at and around Necedah National Wildlife Refuge. The EMP migrates through and winters in various wetland and agricultural areas between Indiana and Florida. Originally, the EMP wintered primarily along the Gulf Coast of Florida; however, wintering grounds have shifted northwards. As of March 1, 2024, the population size of the EMP is 72 individuals (Thompson 2024). Whooping Cranes were reintroduced to White Lake Wetlands Conservation Area, Louisiana. The LP ranges through southwestern Louisiana and occasionally into Texas. As of 2023, there were 85 birds in the LP (McAbee and Conkin 2024). On March 31, 2023, there were 134 Whooping Cranes held in captivity in breeding centers and zoos as part of the American Zoological Association Saving Animals From Extinction program (McAbee and Conkin 2024).

Whooping Cranes were historically present in South Carolina. Fossil evidence demonstrated that Whooping Cranes ranged from the Arctic south to central Mexico, extending from Utah in the west and New Jersey, South Carolina, Georgia, and Florida in the east (Allen 1952). Until 1950, the Waccamaw River served as a wintering ground for Whooping Cranes (Allen 1952, CWS and USFWS 2007). Within the last few decades, Whooping Cranes that have appeared in South Carolina during the winters have been part of the experimental EMP. This wild population is part of a reintroduction effort by the Whooping Crane Eastern Partnership. Starting in 2001, eggs from the breeding population were hand reared at breeding facilities. The chicks are then brought to Necedah NWR in central Wisconsin in the summer. In the fall, the chicks, guided by an ultralight aircraft, migrate to wintering grounds at Chassahowitzka National Wildlife Refuge in west-central Florida. Some birds from this population wintered at the Hiawassee Wildlife Refuge in central Tennessee, Wheeler NWR in northern Alabama, and the ACE Basin in coastal South Carolina (USFWS 2012) although wintering grounds have been shifting northward during the past decade.

In the winter of 2004-2005, seven Whooping Cranes from the experimental EMP wintered in South Carolina. In May 2005, five subadult cranes were detected in South Carolina. These birds were part of the experimental FP and were likely dispersing from drought conditions. Two to four cranes wintered in South Carolina from 2006-2012 (Urbanek et al. 2014b, Thompson et al. 2022). Whooping Cranes were last detected in South Carolina in 2014 when a pair wintered in the ACE Basin (Thompson et al. 2022). Starting in the winter of 2007-2008 and continuing to the present, Whooping Cranes in the EMP have been wintering further north, from Florida up to Indiana. Suspected causes for this shift include warmer winter temperatures, information about norther wintering grounds being passed from older to younger individuals, fewer cranes being guided by aircraft, and use of crops as a

food source on northern agricultural lands (Urbanek et al. 2014a, Teitelbaum et al. 2016, Mengden et al. 2023).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Whooping Cranes generally spend all life history stages in wetland habitat, including coastal marshes and estuaries, inland marshes, lakes, ponds, wet meadows and prairie, rivers, and sometimes agricultural fields (CWS and USFWS 2007, Urbanek and Lewis 2020). The AWBP typically nests in and around Wood Buffalo National Park in Canada in shallow diatom ponds dominated by bulrush, but also use depressions with cattail, sedge, musk-grass, and other aquatic plants (Timoney 1999, CWS and USFWS 2007, Urbanek and Lewis 2020). On wintering grounds at Aransas National Wildlife Refuge in Texas, Whooping Crane typically use salt marshes and tidal flats dominated by salt grass, saltwort, smooth cordgrass, glasswort, and sea ox-eye daisy (CWS and USFWS 2007).

The EMP breeds in central Wisconsin in and near Necedah National Wildlife Refuge. The EMP winters between Indiana and Florida. Wintering sites include wetland complexes with shallow water (brackish marshes, moist soil management units, restored wetlands), riverine systems, flooded agricultural river bottoms, and wetlands on cattle ranches (Thompson 2018, Urbanek and Lewis 2020). The EMP also use agricultural lands, such as cornfields, while overwintering. However, this is more common at northern overwintering sites (Urbanek 2014a, Thompson 2018). Whooping Cranes generally select areas with short vegetation (Thompson 2018). In South Carolina, Whooping Cranes have been documented using managed wetlands such as those common in the ACE Basin.

The FP breeds and winters in central Florida, primarily in or around Kissimmee Prairie. This area is a floodplain to the Kissimmee River and contains freshwater marsh, natural grasslands, and livestock pasture used by the FP (CWS and USFWS 2007). The LP breeds and winters in southwestern Louisiana. Historically, Whooping Cranes in Louisiana used coastal tallgrass prairie. However, this region has experienced drastic land use conversion. The reintroduced population now primarily uses natural shallow freshwater wetlands and working wetlands including fields in rice and crawfish agriculture (Pickens et al. 2017, Vasseur et al. 2023).

Whooping Cranes are omnivores and forage by probing and gleaning food items in the water, soil, and vegetation (Urbanek and Lewis 2020). Their diet is fairly opportunistic, consisting of small aquatic animals, (e.g. fish, frogs, crabs, clams, shrimp, and insects), tubers, acorns, and berries. Migratory individuals often consume waste grain on migratory routes and northern wintering grounds (Urbanek and Lewis 2020).

Stan Bousson/USFWS, Public Domain

CHALLENGES

Range-wide, population declines were originally caused by hunting, egg collection, wetland drainage, and loss of habitat due to agricultural use (CWS and USFWS 2007). Today, Whooping Cranes are still occasionally killed by gunshot when they are mistaken for Sandhill Cranes or through acts of vandalism. Power line collisions and collisions with other manmade objects are threats are additional causes of direct mortality. Every three years, Whooping Cranes undergo a flightless molt period. During this time, adults experience a higher risk of predation.

In captivity, Whooping Cranes face threats such as disease outbreaks and loss of genetic diversity. As Whooping Cranes are slow to mature and typically average fewer than one chick per year, populations are slow to recover (CWS and USFWS 2007). Low reproductive success is a challenge in all populations, but especially in experimental populations where older individuals often fail to breed naturally. In captive populations, many fertile eggs often fail to hatch.

Climate change poses challenges to Whooping Crane conservation, particularly in the wintering grounds. Sea level rise poses a threat to populations wintering in coastal habitat. Whooping Cranes typically use wetlands with water levels <20 in (51cm) deep and sea level rise could limit the availability of suitable wetlands (USFWS 2012). The EMP faces additional threats due to increased drought frequency. Droughts change salinity levels and reduce food sources in wintering grounds, particularly in Florida (Spalding et al. 2009).

The EMP experiences multiple challenges to population growth. One of the largest challenges in the EMP is biting insects. Black flies on the breeding grounds are a large cause of nest abandonment and failure (Urbanek et al. 2010). To help solve this problem, eggs are being collected to encourage renesting after black flies have subsided (McAbee and Conkin 2024). Additionally, cranes are now being released at wetlands in the Eastern Rectangle of Wisconsin where black flies are less of a threat (Thompson et al. 2022). In recent years, the population size of the EMP has started to decline as management objectives shifted from releasing captive reared cranes (Thompson et al. 2022). Reproduction does occur in the wild but natural recruitment in this population remains low (Thompson et al. 2022).

CONSERVATION ACCOMPLISHMENTS

Due to intensive management and captive breeding efforts, total population numbers have increased from a low of 21 individuals to approximately 699 individuals in the wild (CWS and USFWS 2007, McAbee and Conkin 2024). Three additional experimental populations are currently being managed or still have cranes remaining from the management programs. Still, Whooping Cranes, particularly those in experimental populations, are highly dependent on human intervention for population growth. Although no reintroduced population has become self-sustaining, lessons have been learned from each attempt which are applied to improving rearing and release strategies.

Matt Strausser/USFWS, Public Domain

There have been limited direct conservation actions for Whooping Cranes taken in South Carolina as Whooping Cranes have only been an occasional visitor since reintroduction to eastern North America and have not been present in the state for ten years (Thompson et al. 2022). However, multiple partnerships and organizations are working towards rebuilding Whooping Crane populations throughout their range. The reintroduction of the EMP is supported by work from over 9 agencies and private organizations that form the Whooping Crane Eastern Partnership. In 2006, the first wild chick fledged in the EMP (Urbanek et al. 2014b). Initially, chicks were hatched in captivity and reared by staff in costume. The young were then either led by ultralight plane to wintering grounds in Florida or released directly into the population of adult cranes (direct autumn release) in Wisconsin. The ultralight program ended in 2015 as more natural direct autumn release and parent rearing strategies became favored (Thompson et al. 2022). Since the reintroduction program started, 167 ultralight-led, 92 direct autumn release, 52 parent reared, and 37 wild hatched Whooping Cranes have been added to the EMP (Thompson et al. 2022).

Researchers studying the EMP are currently investigating ways to improve management for reintroduced Whooping Cranes. Current goals include refining habitat management, particularly on breeding grounds, to increase reproductive success and better understanding the effects of rearing strategies on behavior, such as parenting abilities and predator aversion, in order to increase survival. Color bands, VHF transmitters, and GPS transmitters are also placed on Whooping Cranes in the EMP in order to monitor the species' movements, breeding ecology, and survivorship (Thompson et al. 2022).

CONSERVATION RECOMMENDATIONS

- Support work being conducted by the Whooping Crane Eastern Partnership to continue growing the EMP to where it is self-sustaining.
- Continue preserving and managing vast, largely undisturbed wetland complexes, such as those found in the ACE Basin. Maintain or increase the acreage and quality of available habitat for Whooping Crane.
- Maintain health of coastal wetlands and managed tidal impoundments. Maintain native vegetation.
- Monitor and protect Whooping Cranes that do arrive in South Carolina. Protect individuals from disturbance by controlling visitation in areas used by Whooping Cranes.
- Research resource use in South Carolina wintering areas if Whooping Cranes repopulate.
- Maintain functional managed tidal impoundments. Wetlands with increased water level control may protect food resources in times of drought.
- Start a public outreach campaign if Whooping Cranes reinhabit South Carolina.

MEASURES OF SUCCESS

Whooping Cranes are likely not dependent on habitat in South Carolina for population growth. Recent shifts in winter ranges are likely not driven by the amount quality habitat for Whooping Crane in the state. Success could be measured by maintaining or increasing the amount of quality habitat for Whooping Cranes in South Carolina if wintering ranges shift back into South Carolina. If Whooping Cranes do winter in the state again, success would be measured in low overwinter mortality rates, successful migration from wintering grounds, and breeding success in reproductive individuals in the following summer. Increased occupancy would only be considered a success if it were due to abundant resources in the state and not due to a decrease in quality habitat elsewhere in their range.

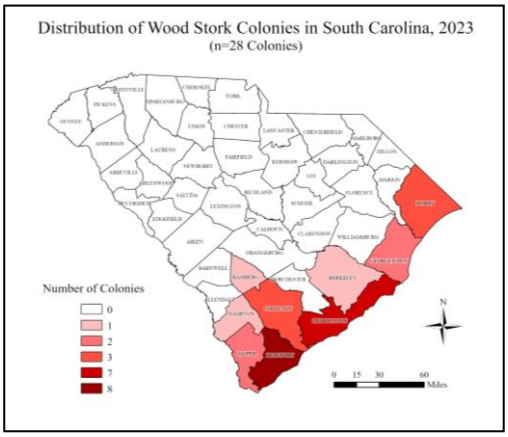
Photo of an adult and an immature Wood Stork by C. Hand, SCDNR

DESCRIPTION

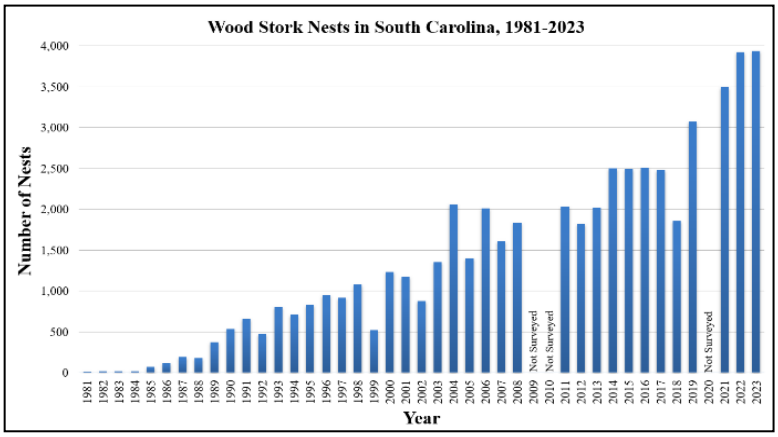
Taxonomy and Basic Description

The Wood Stork is the only stork species that breeds in the United States. Worldwide, there are 19 species of storks in the family Ciconiidae, 4 of which belong to the genus *Mycteria*. Wood Storks are morphologically indistinguishable across their range, and no subspecies have been proposed (Coulter et al. 2020).

Wood Storks have a wingspan of 150 to 165 cm (59 to 65 in) and a head-to-tail length of 85 to 115 cm (33 to 45 in) (Coulter et al. 2020). They are the largest wading birds that breed in South Carolina. Unlike herons and egrets, storks fly with their neck and legs extended. Wood Storks are mostly white, but their primary and secondary wing feathers and their tail feathers are glossy black with a greenish tinge. Adults have dark, unfeathered necks and heads and long, dark bills. At the onset of the breeding season, adults have pinkish feathers under their wings, fluffy feathers under their tails, dark legs, and pink feet. Their legs and feet fade to gray during the nonbreeding season. Immature Wood Storks look similar to adults but have grayish feathers on their necks and heads as well as yellow bills. Storks gradually lose their neck feathers as they mature. They reach maturity at 3 to 4 years of age (Coulter et al. 2020).



Status



Wood Storks were listed as Endangered on February 28, 1984, pursuant to the Endangered Species Act of 1973, as amended (USFWS 1984). The status of the Wood Stork was reviewed by the U.S. Fish and Wildlife Service (USFWS) in 2007, and in 2010, a petition was filed to reclassify Wood Storks as Threatened rather than Endangered (USFWS 2010). A decision on the reclassification was announced in June 2014 and the bird was down-listed to Threatened. A reclassification to Threatened does not alter any of the protections Wood Storks receive under the Endangered Species Act, but it is a step toward delisting the species. In 2023, a petition was filed to delist the Southeast U.S. distinct population segment of the Wood Stork due to recovery and threats being sufficiently managed (USFWS 2023). After delisting, Wood Stork populations will be monitored for at least five years to ensure that they remain stable or continue to increase. Wood Storks are listed as endangered under the South Carolina Nongame and Endangered Species Conservation Act. The Wood Stork is considered a species of Least Concern by the International Union for the Conservation of Nature (2024). Globally, the Wood Stork is ranked

as Apparently Secure (G4). In South Carolina, it is ranked as Imperiled (S2) (NatureServe 2024). The North American Waterbird Conservation Plan (Waterbird Conservation for the Americas, Version 1) listed the Wood Stork as a species of high concern (Kushlan et al. 2002).

POPULATION SIZE AND DISTRIBUTION

The breeding range of the Wood Stork extends from the southeastern part of the United States through Mexico, Central America and the Caribbean, to central South America. In the United States, storks breed in Florida, Georgia, South Carolina, and North Carolina. The breeding population of Wood Storks in the United States was initially listed as Endangered after nesting pairs declined from between 15,000 and 20,000 in the 1930s to 2,500 pairs by 1978. The low number in 1978 was a combination of a decrease in the regional population and poor conditions for nesting that particular year (USFWS 1996).

Historically, Wood Storks have used South Carolina as a post-nesting foraging area during the summer and fall (Murphy 1995). In 1981, the first successful Wood Stork nests were documented in South Carolina. SCDNR estimates that the number of nests in South Carolina have increased from 11 in 1981 to 3,935 nests over 28 colonies in 2023. The highest counts of Wood Stork nests were recorded over the past five years, omitting 2020 due to survey constraints, and nest counts have nearly doubled over the past decade. This is likely due to increased habitat management and a trend of nesting colonies moving northward. Partners in Flight estimate the global population size of Wood Storks to be 450,000 individuals, with 16,000 in the United States.

Photo by C. Hand, SCDNR

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Wood Storks typically nest in the upper branches of black gum (*Nyssa biflora*) or cypress (*Taxodium distichum*) trees that are in standing water. Standing water deters mammalian predators and is an essential element of colony sites. Storks require open access to nest trees and are frequently found in trees adjacent to

open water areas. Range-wide, there has been a trend towards the use of manmade wetlands as colony sites in recent years as these sites are not totally dependent on rainfall for water (Rodgers 1996). In South Carolina, colony sites are typically surrounded by extensive wetlands, in particular palustrine forested wetlands (Mitchell 2002).

Wood Stork chicks are altricial, which means that they are completely dependent on their parents for temperature regulation and food when they hatch. At least one parent is usually at the nest caring for the chicks during the first three weeks after they hatch. Wood Stork chicks require parental care for a long period of time (over two months) before they can depart from their nests and feed themselves. In order for Wood Storks to nest successfully, prey must be abundant and available throughout their nesting season. A small colony of Wood Storks (100 pairs) requires over 15,000 kg (33,070 lbs) of food during the nesting season (Coulter et al. 2020). Storks time their nesting activity so that chick rearing coincides with receding water levels in wetlands, which allow them to capture prey more efficiently. In South Carolina, storks typically nest from March through August. When adequate food is not available throughout the entire nesting season, adult storks abandon the colony and the remaining eggs and chicks do not survive.

Photo by C. Hand, SCDNR

Unlike herons and egrets, which hunt visually, Wood Storks use tactolocation, which means that they hunt by feeling for fish, crustaceans, and other prey. Storks wade through the water with their bills open, and when their sensitive lower mandible comes into contact with prey, their bill snaps shut. A snapping reflex is used to close their bills in as little as 1/40th of a second (Coulter et al. 2020). Storks sweep their bills back and forth through the water and pump their feet up and down to startle prey. This feeding strategy requires high concentrations of prey in water that is shallow enough (less than 50 cm or 20 in) (Coulter et al. 2020) for storks to wade through it. Storks can feed in the dark and in water that is murky since they do not rely on visual cues to locate prey. Tactolocation also allows storks to feed in large aggregations that stir up sediment into the water. Forested riverine floodplains, diked marsh impoundments, ponds, ditches, and tidal creeks are important feeding habitats. Use of these habitats is enhanced by receding water which concentrates prey items.

Photo by C. Hand, SCDNR

CHALLENGES

Wood Storks are particularly vulnerable to habitat degradation and to unpredictable weather conditions because of their specialized feeding behavior and because their chicks require care for a long period of time before becoming independent. Loss of feeding habitat from alteration of natural hydroperiods in the Everglades has resulted in abandonment of nesting colonies or widespread nesting failures in south Florida. Development, lowered water tables, and disturbance also degrade nesting sites. As habitat in their historic breeding range has become degraded, South Carolina has become an important breeding area as well as an important feeding area during the nonbreeding season. The impounded backwaters and managed impoundments of South Carolina likely provide more stable habitat and food resources for Wood Storks while in other areas of their range, such as south Florida, resources may be more unstable. However, these impoundments are at risk because sea level rise and increasing storm intensity may damage impoundment infrastructure.

Thick mat of Cuban bulrush in wading bird habitat by C. Hand, SCDNR

The presence of invasive Cuban bulrush (*Oxycaryum cubense*) in rookeries is an emerging threat to wading bird colonies that warrants future study. Cuban bulrush forms thick, buoyant mats that outcompete native aquatic plants, reduce water quality, and allow terrestrial predators such as racoons to access nesting sites. Thick mats of Cuban bulrush may also restrict alligator movement. Alligator presence attracts wading birds to nesting colonies (Burtner and Frederick 2017) as they reduce the number of mammalian predators. In turn, alligators benefit from consuming nestling carcasses (Nell and Frederick 2015). SCDNR is developing strategies to manage Cuban Bulrush from Donnelley Wildlife Management Area and other ACE Basin properties used by colonial nesting wading birds.

CONSERVATION ACCOMPLISHMENTS

A regional Wood Stork working group has been organized to facilitate information exchange and to set research and management priorities. Regional management guidelines for Wood Stork nesting, feeding, and roosting habitats have been developed. Standardized surveys of nesting efforts have been completed for the Southeastern United States. A revised Wood Stork Recovery Plan was completed in 1997 which has informed management guidance in South Carolina. In 2001, a brochure to inform landowners of conservation and management needs of storks was completed as a joint production of the USFWS and the University of Georgia Savannah River Ecology Laboratory. This brochure can be found at: https://www.dnr.sc.gov/wildlife/species/wadingbirds/docs/WOST_Management_Landowners_brochure.pdf (Accessible as of August 30, 2024).

SCDNR has been monitoring Wood Stork populations in the state since 1981. In 2014, SCDNR banded 100 Wood Stork chicks as part of a research effort throughout the southeast to understand Wood Stork movement, demography, and longevity. Satellite transmitters were also placed on nine Wood Storks in South Carolina to identify foraging and roosting habitat, monitor productivity, and monitor survivorship. Monitoring currently includes on the ground nesting surveys at index colonies (to best estimate nesting success) and statewide aerial surveys. Nest success exceeded the recovery criteria of 1.5 fledglings per nest during 12 of the 13 years when monitoring has been completed. South Carolina has seen nest counts in South Carolina climb from 11 in 1981 to 3,935 nests in 2023. This increase reflects a commitment to management that supports Wood Storks by private and public land managers in South Carolina as well as a northward shift in the Wood Stork breeding range. Additionally, updated colony location and species composition data from surveys are added to the SCDNR Heritage Trust Database which is used by permit reviewers, land use planners, conservation easement advocates, landowners, consultants, and other agencies and individuals who are interested in considering wading bird conservation in their land use decisions.

At a few sites, intensive efforts have been made to create habitat for Wood Storks. Techniques for management of fresh water ponds to enhance stork use have been developed and implemented at the National Audubon Society's Silver Bluff Plantation Sanctuary in Jackson, South Carolina. At Harris Neck National Wildlife Refuge (NWR), artificial nesting platforms have been developed to enhance stork nesting at colony sites with limited vegetation for nest construction. In recent years, the storks at Harris Neck NWR have moved from the artificial platforms to trees that were grown to provide nesting habitat.

CONSERVATION RECOMMENDATIONS

- Conduct aerial surveys annually to locate new Wood Stork nesting colonies and to determine which colonies should be visited from the ground.
- Conduct complete ground counts of Wood Stork nests at colony sites in South Carolina each year.
- Provide permitting agencies with current information on Wood Stork colonies by updating distribution maps every year.
- Monitor a sample of nests each year to quantify nesting success.
- Determine survivorship of fledgling, immature, and adult Wood Storks using mark and recapture (band resighting) and satellite telemetry.
- Document important habitat for Wood Storks during the nonbreeding season.
- Determine if the amount of foraging habitat limits species recovery. Study foraging ecology and habitat use in South Carolina.
- Participate in and contribute to the regional Wood Stork working group.
- Integrate management for Wood Storks into traditional waterfowl management of currently impounded wetlands by timing draw downs during key feeding periods (post fledging).
- Provide technical guidance and assistance to owners and managers of land where storks nest, feed, and roost.
- Develop a fund that can be used by SCDNR to manage habitat for storks on private lands (with the consent and cooperation of the private landowners). SCDNR manages aquatic

vegetation in colonies on public land, but funding is not currently available for SCDNR to purchase herbicide and apply it on private land.

- Acquire, or assist conservation organizations to acquire, and manage important nesting and feeding sites to benefit Wood Storks.
- Continue maintaining a SCDNR web page on Wood Storks and other wading birds for public outreach and information exchange with existing and potential management partners.
- Develop management strategies to eradicate and prevent the spread of Cuban bulrush.
- Monitor the effects of invasive Cuban bulrush and Cuban bulrush removal on wading bird nesting success

MEASURES OF SUCCESS

During the past several decades, Wood Stork nesting has shifted northward and is significantly changing management of the species. Efforts to restore wetlands in south Florida may significantly affect wintering and nesting Wood Storks in the future. The USFWS recovery goal for the Wood Stork is a minimum of 10,000 breeding pairs with annual regional productivity greater than 1.5 chicks per nest/year (USFWS 1996). This goal has been met in all breeding regions except for the South Breeding Region which has had lower productivity (USFWS 2021). However, the Northeast, Northwest, and Central Breeding Regions have all met the productivity goal and the increased importance of the northern breeding regions in population recovery provide support for delisting. In South Carolina, management for Wood Storks will be considered successful if the distribution of nesting colonies in the state expands, number of nests continue to increase across years, and annual regional productivity is maintained at greater than 1.5 chicks per nest/year.

Acuminate Crayfish

Cambarus acuminatus

Contributor (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Cambarus acuminatus was described from the Saluda River but is known to be part of a species complex, known as the *Cambarus* sp. C. complex that ranges from South Carolina to Pennsylvania. *Cambarus acuminatus sensu stricto* appears to be restricted to the Saluda River basin in SC (Williams et al. 2019).

Status

Cambarus acuminatus appears to be stable, but development and land use change threaten this species. Populations in the South and North Fork of the Saluda River within the Enoree District of the Sumter National Forest appear to be robust.

POPULATION SIZE AND DISTRIBUTION

The Broad River Spiny Crayfish is restricted to the Broad River Basin, see Williams et al. 2019 for a map of its distribution. It is rare at sites where it is found (Eversole 1995, Loughman and Williams 2020). Simmons and Fraley (2010) completed surveys in the Broad River basin and found *C. spicatus* at 4 of 27 sampled sites. Russ and Fraley (2014) documented *C. spicatus* at eight of 43 sites in the Broad River basins. The historic distribution is the Broad, Little, Pacolet, Saluda and Tyger River basins in South Carolina. Survey efforts from 2017 to 2018 found *C. spicatus* from the Little River and Cedar Creek in lower portions of the Broad River, and in Obed Creek in the Pacolet River basin. No animals were collected from historical locations in the Tyger River system, indicating that these populations are likely extirpated.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

This species is often collected from third, or higher, order streams throughout the upper Saluda River basin at or above the fall line. Substrate of cobbles, slab boulders, and boulder clusters, as well as leaf packs, root wads, and undercut banks (Williams et al. 2019).

CHALLENGES

The presence of invasive crayfish, stream degradation and sedimentation, and lack of connectivity all represent significant challenges to this crayfish that is known to be locally rare when it is present. The spread of *P. clarkii*, in particular, within the Saluda River drainage poses a serious threat to long term existence of *C. acuminatus*.

CONSERVATION ACCOMPLISHMENTS

Surveys by Williams et al. (2019) provided critical information on the status of this species.

CONSERVATION RECOMMENDATIONS

- Additional surveys throughout the entire study area for undocumented populations as well as documenting the spread of invasive *F. rusticus* and *P. clarkii* populations is needed.
- Given the disjunct nature of the known populations, population genetics would be warranted to better understand population connectivity and genetic structure.

MEASURES OF SUCCESS

An increase or no net decrease in numbers of individuals collected in future surveys would be considered a sign of success.

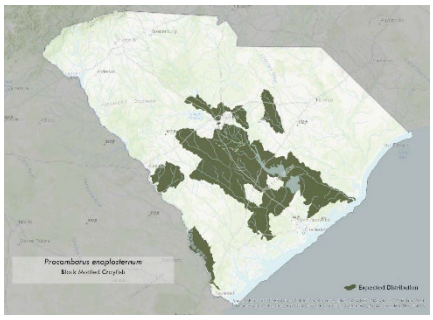
Black Mottled Crayfish

Procambarus enoplosternum

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Zanethia Barnett (USFS)

DESCRIPTION

Taxonomy and Basic Description



There is a great deal of geographic variation in the coloration of *P. enoplosternum*. Patterns vary and may be charcoal or black and orange, cream, or yellowish-cream. Sometimes, it may have black stripes or cream-colored tubercles. The antennae may be cream or have pinkish irregular spots. The chelae are olive tan or cream to orange-tan with black tubercles (Hobbs 1981). This species may be confused with the Cedar Creek crayfish, *P. chacei*. Therefore, questions have been raised regarding the taxonomic distinctness between these two species (Hobbs 1981, 1989).

Status

NatureServe (2024) currently identifies *P. enoplosternum* as vulnerable (S3) in South Carolina, while it is listed as apparently secure/secure in Georgia (S4/S5) and globally (G4/G5). Taylor et al. (2007) listed the species as currently stable in Georgia and South Carolina.

POPULATION SIZE AND DISTRIBUTION

P. enoplosternum occurs in South Carolina counties below the fall line from the Santee River basin in Berkely County to the Savannah River basin into eastern Georgia's Ogeechee, Altamaha, and Oconee River Basins (Eversole and Jones 2004; Skelton 2010; Z. Barnett, USFS, pers. comm. 2024). It is believed to be fairly widespread in South Carolina, but due to taxonomic confusion between *P. enoplosternum* and *P. chacei*, the exact range is difficult to determine (Hobbs 1981).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

P. enoplosternum occurs in a variety of habitats including slow to moderately flowing streams and impoundments (Hobbs 1958). It can be found in shaded streams often in dense beds of macrophytes or occasionally in shallow lentic habitats such as roadside ditches (Hobbs 1981). Little is known of its specific habitat requirements.

CHALLENGES

Because little is known of the specific habitat requirements specifically for *P. enoplosternum*, surveys should be conducted to determine these requirements. Additionally, taxonomic work is necessary to clarify the relationship between this species and *P. chacei*. Until more information is available, it is difficult to identify specific challenges to *P. enoplosternum*.

CONSERVATION ACCOMPLISHMENTS

Stream surveys from 2022-2024 on the Francis Marion National Forest collected 106 *P. enoplosternum* from 5 sites in Berkely County (Z. Barnett, USFS, pers. comm.).

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the range, population densities, and habitat requirements for *P. enoplosternum*.
- Conduct taxonomic studies to determine the relationship between *P. enoplosternum* and *P. chacei*.

MEASURES OF SUCCESS

The collection of data that better describes the habitat requirements, distribution, and population densities for *P. enoplosternum* may be considered a measure of success. Additionally, completion of taxonomic studies to determine the relationship between *P. enoplosternum* and *P. chacei* would be considered a sign of success.

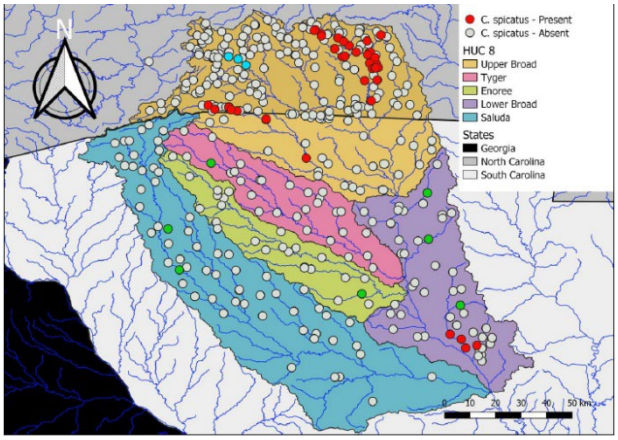
Broad River Spiny Crayfish

Cambarus spicatus

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



The Broad River Spiny Crayfish is a moderate-sized tertiary burrowing crayfish with cream, pink, purple, and brown highlights. The chelae are green with orange tips and a double row of tubercles (NCWRC 2005) with spination in the hepatic region of the carapace, and along the ventral and dorsolateral region of the carpus and merus and with prominent hepatic spines. The rostrum has marginal spines and two prominent rostral tubercles, and the chelae are broad with long fingers. The holotypic, allotypic and morphotypic specimens ranged from about 60-78 mm (2.4-3.1 in.) in length (Hobbs 1956a).

Status

Taylor et al. (2007) recommended that the Broad River Spiny Crayfish be listed as vulnerable in both North and South Carolina. The National Museum of Natural History considers it to be of special concern. NatureServe (2011) currently identifies this crayfish with a ranking of imperiled (S2) in North Carolina and vulnerable (S3) in South Carolina. Recently, the Broad River Spiny Crayfish was included on a list of 404 species being petitioned for consideration as candidates for federal protection (United States Fish and Wildlife Service 2011). The IUCN classifies *C. spicatus* as data deficient (IUCN, 2010).

POPULATION SIZE AND DISTRIBUTION

The Broad River Spiny Crayfish is restricted to the Broad River Basin. It is rare at sites where it is found (Eversole 1995, Loughman and Williams 2020). Simmons and Fraley (2010) completed surveys in the Broad River basin and found *C. spicatus* at 4 of 27 sampled sites. Russ and Fraley (2014) documented *C. spicatus* at eight of 43 sites in the Broad River basins. The historic distribution is the Broad, Little, Pacolet, Saluda and Tyger River basins in South Carolina. Survey efforts from 2017 to 2018 found *C. spicatus* from the Little River and Cedar Creek in lower portions of the Broad River, and in Obed Creek in the Pacolet River basin. No animals were collected from historical locations in the Tyger River system, indicating that these populations are likely extirpated.

Loughman and Williams (2019): SEAFWA SEARS Grant #2016-02. *C. spicatus* locations are documented in red points.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The streams in which the Broad River Spiny Crayfish has been found exhibit signs of flash flooding, including sand deposits and log jams. This species is usually found in leaf packs/debris, artificial cover, and associated with undercut banks (Eversole 1995; Loughman & Williams 2020). Siltation limits suitable habitat (Simmons and Fraley 2010; Russ and Fraley 2014).

CHALLENGES

The presence of invasive crayfish, stream degradation and sedimentation, and lack of connectivity all represent significant challenges to this crayfish that is known to be locally rare when it is present.

CONSERVATION ACCOMPLISHMENTS

Surveys by Loughman & Williams (2020) provided critical information on the status of this species.

CONSERVATION RECOMMENDATIONS

- Additional surveys throughout the entire study area for undocumented populations as well as documenting the spread of invasive *F. rusticus* and *P. clarkii* populations is needed.
- Given the disjunct nature of the known populations, population genetics would be warranted to better understand population connectivity and genetic structure.

MEASURES OF SUCCESS

An increase or no net decrease in numbers of individuals collected in future surveys would be considered a sign of success.

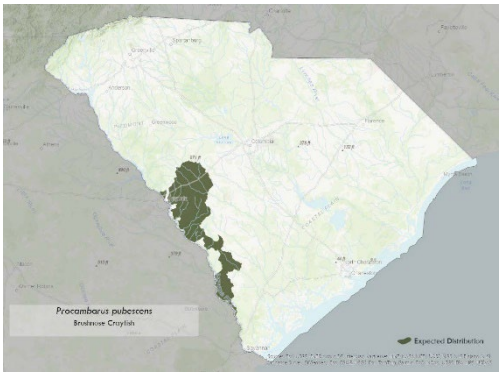
Brushnose Crayfish
Procambarus pubescens

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Graham Wagner and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



Procambarus pubescens is found in two color phases. One is predominantly blue, grey and black; and the other is brown, tan, orange, and black with a median longitudinal orange-tan stripe and black spots. The rostrum has marginal spines, and the chelipeds have tubercles (Hobbs 1981).

Status

NatureServe (2024) currently identifies this species as ranked of apparently secure (S4/S5) in Georgia and vulnerable (S3?) in South Carolina. It has a global rank of apparently secure (G4). Taylor et al. (2007) listed the Brushnose Crayfish as currently stable in Georgia and South Carolina.

POPULATION SIZE AND DISTRIBUTION

The Brushnose Crayfish is found in the Coastal Plain and the eastern edge of the Piedmont Plateau in the Savannah River Basin of South Carolina and Georgia. In South Carolina, it is documented in Edgefield, Aiken, and Barnwell counties and is expected to occur at least as far south as Hampton County (A. Eversole pers. comm., SCDNR data). This species is abundant in aquatic plant beds in Stevens Creek Reservoir (W. Poly pers. obs.). It is a peripheral species in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

P. pubescens has been found in a variety of streams in the Coastal Plain, ranging from very small, shallow streams to small rivers. It can be found in both densely vegetated streams and well-shaded streams lacking in vegetation. Some of the streams in which it has been found are slow-flowing with muddy bottoms, while others have sandy or rocky substrates and are rapidly flowing (Hobbs 1947b).

CHALLENGES

Little is known about the Brushnose Crayfish. Survey work and research on its habitat association and life history are needed.

CONSERVATION ACCOMPLISHMENTS

Surveys were conducted with positive records of this species confirmed, but there are no other significant conservation accomplishments specifically for *P. pubescens* at this time.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the habitat requirements and life history for *P. pubescens.*

MEASURES OF SUCCESS

The collection of data that better describes the habitat requirements and life history of *P. pubescens* may be considered a measure of success.

Chattahoochie Crayfish (*Cambarus* sp. "A" cf. *howardi*)

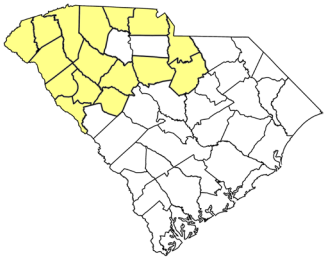
Cambarus howardi

Contributors (2024): Eric Ng and Kathryn Schulz
(West Liberty University) and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and basic description

Cambarus howardi was described by Hobbs and Hall in 1969 from Cobb County, Georgia. However, the species has more recently been reported to occur in South Carolina as *Cambarus* species "A" (*C. cf. howardi*), due to characteristics this species shares with the description of *C. howardi*. Both Eversole and Jones (2004) and Alderman (2005) identified the species occurring in South Carolina tentatively as *Cambarus howardi*. To address this issue, Eversole (2014), and Poly and Eversole (2015) recommended a taxonomic revision of *C. cf. howardi* as a research objective.



According to Eversole (2014), *Cambarus* species "A" resembles the description of *C. howardi*. *C. howardi* is an olive-green base color with scarlet-red rostral margins, suborbital and postorbital ridges. The abdomen is a greenish tan and possesses a scarlet band on the caudal portion of each segment. Eyes are large and well-developed. Chelae have alternating patches of tan and green with scarlet-red accenting on each segment. The mesial margin of the palm has a single row of tubercles and the fingers of the chelae have developed longitudinal ridges. The cervical groove of the carapace has small tubercles, but no spines. The total carapace length of mature, form I males can range between 27.6mm (1.09 inches) to 31.8mm (1.25 inches), while females can reach 34mm (1.34 inches) maximum (Hobbs & Hall, 1969).

Status

Because of the systematic concerns of *Cambarus cf. howardi* in South Carolina, there is no status rank for *Cambarus* species "A" in the state. A formal taxonomic review of *C. cf. howardi* needs to occur in order to establish a status rank for the species in South Carolina (Poly & Eversole, 2015). Under NatureServe (2024), the type Chattahoochee Crayfish (*C. howardi*) is ranked imperiled (S2) in Georgia and Alabama and vulnerable (G3) globally.

POPULATION SIZE AND DISTRIBUTION

The range of *Cambarus* sp. "A" consists of 16 counties located within the upper piedmont region of South Carolina. They are restricted to the Savannah, Saluda, Broad and Catawba river basins (Eversole, 2014). Individuals have been found in North Carolina as well under the name of *Cambarus sp. cf. howardi*, and are found within the Broad, Catawba, and Yadkin-Pee Dee River basins (LeGrand, 2022).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Chattahoochee Crayfish typically inhabits water with moderate to fast flowing currents that contain a high dissolved oxygen rate. They prefer streams and rivers with gravel and rocky

substrate where they can seek shelter in interstitial burrows among the rocks (Hobbs & Hall, 1969).

CHALLENGES

Due to the limited information pertaining to *Cambarus* species "A" in South Carolina, future surveys are recommended to discern the exact range, threats, and life history of the species. Eversole (2014), lists this species in 16 counties across South Carolina, not placing it currently in a need for conservation concern. However, due to their sensitivity to low oxygenated water systems (Hobbs & Hall, 1969), habitat loss is still a concern for this species.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the *Cambarus* species "A" at this time.

CONSERVATION RECOMMENDATIONS

- Initiate the process to refine the taxonomy of *Cambarus* sp. "A" in South and North Carolina.
- Continue to conduct surveys to monitor the abundance of *Cambarus* sp. "A".
- Based on surveys, establish a conservation rank for *Cambarus cf. howardi* in South Carolina.

MEASURES OF SUCCESS

The collection of data that better describes the natural history and population status of the *Cambarus* sp. "A" may be considered a measure of success. An updated taxonomic revision of the species would also be considered a sign of success.

Carolina Needlenose Crayfish

Cambarus aldermanorum

Credit: Michael Perkins/NCWRC

Contributor (2024): Graham Wagner (SCDNR) and Bronwyn Williams (NCMNS)

DESCRIPTION

Taxonomy and Basic Description

The Carolina needlenose crayfish is olive colored or green-gray with bluish highlights. The rostrum is long and narrow, not delineated by tubercles or spines (Cooper and Price 2010). The tips of the chelae are a yellowish-cream color. There is a strong longitudinal ridge on the dorsal surface of both fingers, and a double row of tubercles on the mesial margin of the palm. Individuals may or may not display hepatic spines.

Status

NatureServe (2024) identifies the rank as Vulnerable (S3) in South Carolina, but there is no global status rank.

POPULATION SIZE AND DISTRIBUTION

The Carolina Needlenose Crayfish occurs in the Catawba basin in South Carolina, with an apparently disjunct population in the Saluda River basin; the species also occurs in North Carolina in the Catawba basin. There are no current estimates of population size.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Little is known about the preferred habitat and environmental requirements of the Carolina Needlenose Crayfish. There have been no studies of the life history of this species (Cooper and Russ 2013).

CHALLENGES

Little is known about the life history of this species (Cooper and Russ 2013). Additionally, it has a relatively small range, and is therefore at risk of impacts from anthropogenic habitat alterations as well as nonnative species.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the Carolina Needlenose Crayfish at this time.

CONSERVATION RECOMMENDATIONS

Conduct thorough surveys to determine the range and distribution of the Carolina Needlenose Crayfish, as well as its habitat preferences and abundances.

MEASURES OF SUCCESS

An increased understanding of the distribution and population status of the Carolina Needlenose Crayfish would be considered a measure of success.

Carolina Sandhills Crayfish

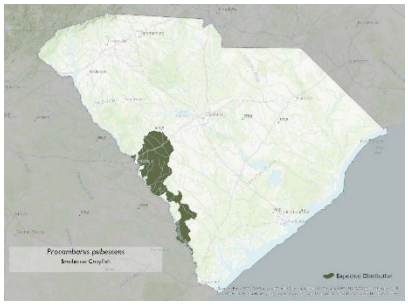
Procambarus pearsei

Credit: Kendrick/SCDNR

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



The Carolina Sandhills Crayfish is a small species, cylindrical in shape, and light brown in color with pastel highlights and often with dark speckles. The chelae are large but not robust (NCWRC 2005). Adult specimens examined in the process of writing the original description of the Carolina Sandhills Crayfish ranged from approximately 48-58 mm (1.9-2.3 in.) in length (Creaser 1934). A re-description of the Carolina Sandhills Crayfish was published (Cooper 2011b).

Status

NatureServe (2011) currently identifies the ranking of the Carolina Sandhills Crayfish as vulnerable (S3) in South Carolina and apparently stable (S4) in North Carolina. Taylor et al. (2007) listed the species as currently stable in North and South Carolina.

POPULATION SIZE AND DISTRIBUTION

The majority of the range of the Carolina Sandhills Crayfish is in North Carolina, but it does extend into the Waccamaw and Lumber-Little Pee Dee River Basins of South Carolina (Cooper 2011). It has been found in 5 counties in South Carolina and also might be expected to occur in other nearby counties (SCDNR stream data, Cooper 2011).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Generally, the Carolina Sandhills Crayfish is found in lentic waters and subterranean burrows. It is a secondary burrower (NCWRC 2005). Hobbs (1989) listed it as being found in streams, so it may be able to inhabit a wide variety of habitats.

CHALLENGES

Our experts recommend that the Carolina Sandhills Crayfish be designated as a species of special concern in South Carolina due to an apparently restricted distribution. More research is needed on the habitat associations and distribution of this species before it can be determined if this ranking is appropriate.

CONSERVATION ACCOMPLISHMENTS

A re-description of the species, update of its distribution, and limited life history information was recently published (Cooper 2011b).

CONSERVATION RECOMMENDATIONS

- Conduct research on the life history and habitat requirements of the Carolina Sandhills Crayfish.
- Investigate the need to initiate the process to achieve special concern status for the Carolina Sandhills Crayfish in South Carolina.

MEASURES OF SUCCESS

The collection of data that better describes the life history and habitat requirements for the Carolina Sandhills Crayfish may be considered a measure of success.

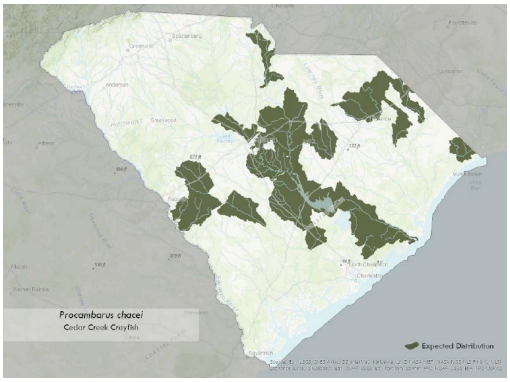
Cedar Creek Crayfish
Procambarus chacei

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION



Taxonomy and Basic Description

This species has been synonymized with the Waccamaw Crayfish (*Procambarus braswelli*; Kendrick and Williams (In Review)). *Procambarus chacei* is also similar to the Black Mottled Crayfish (*Procambarus enoplosternum*) and there is concern that the two species may also be synonymous (Hobbs 1981, 1989).

The chelae of *P. chacei* are slender and elongate and covered in tubercles. The fingers of the chelae are not gaping and have well-developed longitudinal ridges on the upper and lower surfaces. Intensity of color markings can vary, but color patterns are fairly consistent. This species is greenish-tan in color with darker specks on the rostrum and black saddle-like markings. The chelae are greenish tan with dark and light spots and reddish fingers, while the legs are pale greenish-cream (Hobbs 1958). Body pigmented, eyes well developed, strong postorbital ridge, strong marginal spines, strong postorbital ridge spine; lacks median carina. Fingers without gape, without dense setae at opposable bases. Mesial margin of palm with or without serrate tubercles (Kendrick and Williams *In Review*).

Status

NatureServe (2024) has identified *P. chacei* as imperiled (S3) and apparently secure (G4) globally. The Cedar Creek Crayfish was considered to be currently stable in Georgia and South Carolina by Taylor et al. (2007), but has not been recognized by GADNR due to its taxonomic similarity uncertainty regarding *P. enoplosternum*.

POPULATION SIZE AND DISTRIBUTION

P. chacei is found in streams from all major drainage Basins in South Carolina to the Ogeechee and Canoochee River Basins in eastern Georgia.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

This species is found in Coastal Plain streams (Hobbs 1989). *P. chacei* frequents swamps, ponds, lakes, roadside ditches, springs and streams, including lentic and lotic habitats and burrows (Kendrick and Williams In Review).

CHALLENGES

Procambarus clarkii is spreading across much of South Carolina's coastal plain, with potential impacts on native crayfishes such as *P. chacei* (Kenderick et al. 2024). Additional morphological

and genetic work are needed to understand how *P. chacei* relates to *P. enoplosternum* (Hobbs 1981, 1989; Kendrick and Williams In Review).

CONSERVATION ACCOMPLISHMENTS

Significant distribution records of *P. chacei* have been gathered from the South Carolina Stream Assessment (2006–2011) and recent morphological and genetic data have led to the synonymy of the Waccamaw Crayfish *Procambarus braswelli* with the Cedar Creek Crayfish *Procambarus chacei*. This information has considerably expanded the species' known range in South Carolina and clarified important taxonomic questions.

CONSERVATION RECOMMENDATIONS

- Conduct taxonomic studies to determine the relationship between *P. enoplosternum*.
- Determine how the non-native *P. clarkii* may be impacting *P. chacei*.

MEASURES OF SUCCESS

Describing the range, population densities, and habitat associations for *P. chacei* may be considered a measure of success. Additionally, completion of taxonomic studies to determine the relationship between *P. enoplosternum* and *P. chacei* would be considered a sign of success.

Chauga Crayfish
Cambarus chaugaensis

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2024): Eric Ng and Kathryn Schulz (West Liberty University) and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Cambarus chaugaensis was described by Prins and Hobbs in 1972. Upon description, the Chauga Crayfish was designated to the former subgenus Punticambarus. However, after subsequent phylogenetic revision of the subgenera of the genus *Cambarus*, the designation to Punticambarus was eliminated (Breinholt et al., 2012; Crandall & De Grave, 2017).

The Chauga Crayfish is olive-green with dark olive-brown mottling, orangish or yellowish to red fingertips, and robust, well-developed chelae. It has large, well-developed eyes. The chelae have two rows of tubercles along the mesial surface of the palm and the fingers have well-defined longitudinal ridges. Mature males range in size from approximately 50-78 mm (2-3.1 in.), while females range from 50 mm (2 inches) to 70 mm (2.8 inches) in total length (Hobbs 1981).

Status

NatureServe (2024) currently designates the Chauga Crayfish an imperiled in both South Carolina (S2S3) and North Carolina (S2) and a vulnerable (G3) global ranking. However, Simmons and Fraley, 2010 suggest an imperiled (G2) global status for the Chauga Crayfish. In 2011, it was petitioned among 404 species for consideration as a candidate for federal protection (United States Fish and Wildlife Service 2011). The species has shown an apparent decline of approximately 50%, although it remains uncertain whether this decline is genuine or a result of insufficient surveying efforts (NatureServe, 2024).

POPULATION SIZE AND DISTRIBUTION

In South Carolina, the Chauga Crayfish is restricted to the upper Savannah River Basin, particularly the Chauga and Chattooga River Basins in Oconee County. They can be found in 3 counties in North Carolina. NatureServe (2024) reports that it has been found across 22 localities across South Carolina and North Carolina, using a 2km separation distance between sites. Most of its range in South Carolina lies within Sumter National Forest. The reduced range of the Chauga Crayfish no longer places them in Georgia. (Eversole et al. 2002, NCSM records, NatureServe, 2024).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Chauga Crayfish is found at sites with medium to large cobble and boulders as substrate and little sediment accumulation. The Chauga Crayfish is found in both high and low order streams, but it is more abundant in higher order streams (Eversole et al. 2002). These crayfish are particularly prevalent in high-gradient streams within the Blue Ridge ecological zone (Eversole, 2014).

CHALLENGES

Because of its extremely restricted distribution, the Chauga Crayfish is in need of protection. Even though the Chauga River population appears to be fairly stable, this very small distribution is cause for great concern. Although the river basin in which this species occurs is within the Sumter National Forest and is currently relatively pristine, the Chauga Crayfish seems particularly sensitive to sedimentation, since it inhabits rocky sites free of sediment accumulation (Eversole et al. 2002). This species faces threats from industrial pollution along and upstream of the Savannah River, as well as industrial development operations in the surrounding region (Cordeiro et al., 2010).

CONSERVATION ACCOMPLISHMENTS

The majority of the distribution of the Chauga Crayfish lies within Sumter National Forest land, and the US Forest Service has funded survey efforts for this species (Eversole et al. 2002). In addition, the Chauga Crayfish has achieved 'species of concern' status in the state and is now indicated to be a species of highest priority for South Carolina's SWAP.

CONSERVATION RECOMMENDATIONS

- Continue to conduct surveys to monitor the abundance of the Chauga Crayfish.
- Continue to work with the US Forest Service to ensure that operations on Sumter National Forest do not negatively impact habitat for the Chauga Crayfish.

MEASURES OF SUCCESS

An increase or no net decrease in numbers of individuals collected in future surveys in the Sumter National Forest would be considered a sign of success.

Cinnamon River Shrimp

Macrobrachium acanthurus

Credit: Torati et al 2011

Contributor (2024): Graham Wagner (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The cinnamon river shrimp can be differentiated from other *Macrobrachium* species by its long and slender claws and carpus with felt-like setae. It also has only two teeth on its rostrum behind the eye. It is generally an olive green color with some blue coloration on the abdominal pleura and uropods. A brown-orange stripe runs down the middle of the dorsal surface of the abdomen. They can be fairly large, measuring 120-150 mm, and the chelipeds themselves can measure 180-225 mm, meaning an adult specimen can measure approximately 380 mm including chelipeds (Hedgepeth 1949).

Status

NatureServe (2024) identifies the global rank for the cinnamon river shrimp to be secure (G5); however, at the state level, it has not been assigned a rank.

POPULATION SIZE AND DISTRIBUTION

The cinnamon river shrimp occurs along the western Atlantic from North Carolina to Brazil, including the Gulf of Mexico and the Caribbean (Holthuis 1980). There are no estimates of population size.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The cinnamon river shrimp uses rivers, estuaries, and small lagoons during its life cycle, including moving up to ~300km inland (Coelho 1963). It has a migratory lifecycle in which it can move between fresh and salt water. They tend to seek out structure such as rocks, fallen trees and aquatic vegetation (Coelho 1963).

CHALLENGES

We are unaware of specific challenges to the cinnamon river shrimp. It is considered a species of concern because there is little information regarding its life history, and the contemporary distributions of this species are incomplete. In theory, its migratory life cycle make it susceptible to dams and other human-induced modifications to waterways. Due to its large size, this species has aquaculture potential (Kutty et al 2000), but a lack of understanding of reproductive biology and life history prevents large-scale aquaculture.

CONSERVATION ACCOMPLISHMENTS

No conservation accomplishments are currently known for the cinnamon river shrimp in South Carolina.

CONSERVATION RECOMMENDATIONS

Compile records of the cinnamon river shrimp in South Carolina to determine its range and habitat requirements.

MEASURES OF SUCCESS

The completion of a thorough survey of the systems where the cinnamon river shrimp has been found and the determination of its habitat requirements will be indicative of success.

Coastal Plain Crayfish

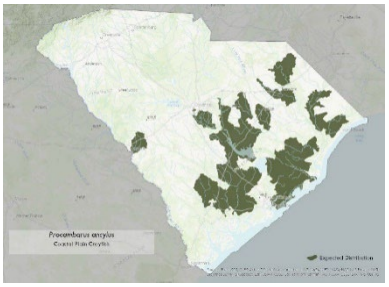
Procambarus ancylus

Credit: B. Williams

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



The Coastal Plain Crayfish is a small and cylindrical in shape. It is reddish-brown or chocolate in color with a narrow red-orange dorsal stripe and slender chelae (NCWRC 2005).

Status

NatureServe (2011) currently identifies the Coastal Plain Crayfish as vulnerable (S3) in North Carolina and apparently secure/secure (S4/S5) in South Carolina. The Coastal Plain Crayfish was listed as currently stable by Taylor et al. (2007).

POPULATION SIZE AND DISTRIBUTION

The Coastal Plain Crayfish is only found in the Coastal Plain of the Carolinas. In South Carolina, it is found in 13 Coastal Plain counties. It is less widespread in North Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Coastal Plain Crayfish is found in both lentic and lotic waters and burrows (Hobbs 1989).

CHALLENGES

Because so little is known about the Coastal Plain Crayfish, this species is in need of surveys, research on habitat associations, and taxonomic investigations. The taxonomic status of this species across its currently understood range is unclear.

CONSERVATION ACCOMPLISHMENTS

Limited life history observations on egg number and size were reported by Poly (2007).

CONSERVATION RECOMMENDATIONS

- Conduct targeted surveys to determine the range and distribution of the Coastal Plain Crayfish. During these surveys, collect data about habitat requirements.
- Cooperate with the North Carolina Museum of Natural Sciences to determine whether additional taxonomic studies are necessary.

MEASURES OF SUCCESS

Collection of data that better describes the range and distribution of the Coastal Plain Crayfish may be considered a measure of success.

Digger Crayfish

Creaserinus fodiens

Contributor (2024): Graham Wagner (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Digger Crayfish has a cylindrical body shape, short antennae with very small spines on the second and third segments, a moderate length rostrum that is broadly triangular, and no lateral spines.

Status

NatureServe (2024) identifies the rank for the Digger Crayfish as secure (S5) in South Carolina and secure (G5) globally. Taylor et al. (2007) considered the species to be currently stable.

POPULATION SIZE AND DISTRIBUTION

The digger crayfish has a relatively large distribution in eastern and central North America, stretching from Ontario down through the midwestern states, and east from Pennsylvania to Florida. Its range excludes much of the Appalachian Mountains (Hobbs 1989, Guiasu 2007, Taylor et al. 2007, Loughman and Simon 2011, Loughman et al. 2018, Guiasu 2021). The western extent of its range is Oklahoma. Occurrences in Texas, however, are no longer ascribed to this species (Johnson et al 2021). In South Carolina, it occurs in all river drainages in the eastern portion of the state in the coastal plain, including Bamberg, Lexington, Marion, Sumter, and Williamsburg counties (Eversole and Jones 2004).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The digger crayfish is a secondary burrowing species, meaning it spends much of its life in a burrow. This species requires clay soils in order to dig their burrows. They can sometimes be found in small streams, but even modest currents can wash them downstream (Bouchard 1974, Maude and Willimas 1983). Often, burrows are made in roadside ditches, and can be identified by vertical mud “chimneys.” These burrows can be several meters deep.

CHALLENGES

The digger crayfish is an obligate burrower; as such, collecting specimens and *in situ* studies of its biology are difficult. It is susceptible to anthropogenic impacts such as habitat loss and pollution (Guiasu 2007). Additionally, due to its wide distribution, the digger crayfish could be impacted by interspecific competition with nonnative crayfishes (Guiasu 2007).

CONSERVATION ACCOMPLISHMENTS

No conservation accomplishments are currently known for digger crayfish in South Carolina.

CONSERVATION RECOMMENDATIONS

Surveys to determine the distribution of digger crayfish would benefit the understanding of this species. Studies of the impacts of pollutants and habitat degradation and loss would improve the conservation of this species.

MEASURES OF SUCCESS

A contemporary understanding of the distribution and microscale habitat preferences of this species in South Carolina would be considered successful. Additionally, an understanding of how this species is impacted by nonnative *Procambarus clarkii* would be a success.

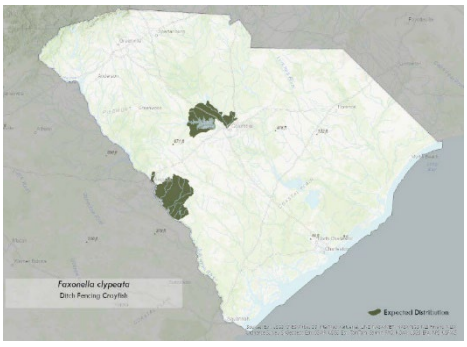
Ditch Fencing Crayfish
Faxonella clypeata

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



The Ditch Fencing Crayfish is very small and occurs in 2 distinctive color patterns: the first is olive tan to reddish brown with a pale creamy-tan stripe extending from rostrum to rear the margin of carapace; the second pattern lacks the stripe and is pinkish-brown. There are substantial differences in size between populations, but adults are generally 27 to 50 mm (1.1 to 2 in.) in total length (Hobbs 1981).

Status

NatureServe (2011) currently lists the Ditch Fencing Crayfish with a ranking of imperiled (S2). It is more common in other states and has a global ranking of secure (G5). It was listed as currently stable by Taylor et al. (2007).

POPULATION SIZE AND DISTRIBUTION

The Ditch Fencing Crayfish is found appears to have two disjunct population centers in SC. A cluster of occurrences is apparent in the coastal plain of Aiken and Barnwell Counties along tributaries to the Savannah River. Another cluster of occurrences appears in the Piedmont at the northern ends of Lexington and Richland Counties.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Ditch Fencing Crayfish is reported to inhabit slow moving streams, ditches, cypress ponds, and vegetation in clear, sandy-bottom streams (Hobbs 1981).

CHALLENGES

We are unaware of specific challenges to the Ditch Fencing Crayfish. We have included it as a species of concern because there is little information on its abundance and distribution in South Carolina.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the Ditch Fencing Crayfish at this time.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to determine the range and habitat requirements of the Ditch Fencing Crayfish.

MEASURES OF SUCCESS

The completion of a thorough survey of the drainages where the Ditch Fencing Crayfish has been found and the determination of its habitat requirements will be indicative of success.

Eastern Red Swamp Crayfish

Procambarus troglodytes

Credit: Kendrick/SCDNR

Contributor (2024): Gregory Rothman (SCDNR)
and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

LeConte (1856) made the original description of *Procambarus troglodytes* from specimens collected in rice fields in Georgia, describing individuals as having: a slightly concave rostrum with a small, blunt, acumen; a coarse and sparsely punctate cephalothorax; and a narrow areola. Additionally, the chelae of *P. troglodytes* are described as being broad and tuberculate with a toothed inner margin. Specimens can vary in coloration, but typically are of a reddish-brown coloration, with an occasional dark lateral line. Specimens of *P. troglodytes* can often be confused with individuals of their sister taxa, *P. clarkii,* due to their close resemblance morphologically. A few key differences when identifying individuals of *P. troglodytes* include a downward curvature of the rostrum, and, as a more definitive feature in males, having the caudal margin of the cephalic process of first pleopod being rounded, instead of angled as featured in *P. clarkii* (Eversole & Jones, 2004).

Status

NatureServe (2024) identifies the rank of *P. troglodytes* as apparently secure/secure (S3/S4) in both South Carolina and Georgia. The species was listed as currently stable by Taylor *et al*. (2007) and assessed as secure by Simon (2011).

POPULATION SIZE AND DISTRIBUTION

The known distribution of *P. troglodytes* occurs from the Altamaha River in Georgia to the Pee Dee rivers in South Carolina, primarily being found along the coastal plain of both states (Hobbs, 1989). Spawning of *P. troglodytes* is thought to primarily occur in the fall, coinciding with increases in rainfall along the coastal plain (SCDNR, climatology data). This fall spawn is represented in collection data from 2017 – 2023, that shows the highest proportion of reproductively active male *P. troglodytes* caught in the fall, while in the winter, the majority of individuals caught are juveniles (SCDNR, unpublished data).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Procambarus troglodytes can be found in both lotic and lentic environments, and has been considered a tertiary burrower (Hobbs, 1989). Originally described specimens were collected from ditches and rice fields in Georgia; however, *P. troglodytes* has been collected in several different environments from streams to seasonally flooded wetlands, and typically in high abundances where present (Price & Welch, 2009).

CHALLENGES

The introduction of the sister species to *P. troglodytes,* the non-native crayfish *P. clarkii*, may pose threats to the population status of *P. troglodytes*. These species often occur within the same habitat (SCDNR unpublished data), and *P. clarkii* has been known to alter native crayfish species

richness and abundance in areas of South Carolina in which they are present (Kendrick *et al.,* in press). Additionally, the genetic relatedness of these two species presents a concern for introgression between these species, lessening genetic diversity.

CONSERVATION ACCOMPLISHMENTS

Opportunistic sampling over the last decade along the coastal plain of SC has shown that *P. troglodytes* is widespread in its distribution, and apparently high in abundance where present (SCDNR, unpublished data); however, much about the life history of this crayfish or its place within ecosystems is still unknown. An examination on the impacts of the non-native *P. clarkii* on native crayfish populations including *P. troglodytes* in the Lower Pee Dee, Waccamaw and Winyah watersheds was completed, highlighting the concerns for the introduction of this non-native species (Kendrick *et al.,* in press). Additionally, recent work has been completed comparing both the genetic relatedness of, as well as parasite communities, between *P. clarkii* and *P. troglodytes* living in sympatry. These efforts hope to identify how *P. clarkii* may be directly impacting populations of *P. troglodytes* in areas of which they are known to coexist (SCDNR, unpublished data).

CONSERVATION RECOMMENDATIONS

- Conduct research to determine current distributions, abundances, and population densities of *P. troglodytes*.
- Investigate the life history of *P. troglodytes*, particularly in regards to how this may be impacted by the introduction of non-native crayfish, like *P. clarkii*.

MEASURES OF SUCCESS

The collection of data to better understand any aspects of the life history of *P. troglodytes*, as well as threats to populations may be considered a measure of success.

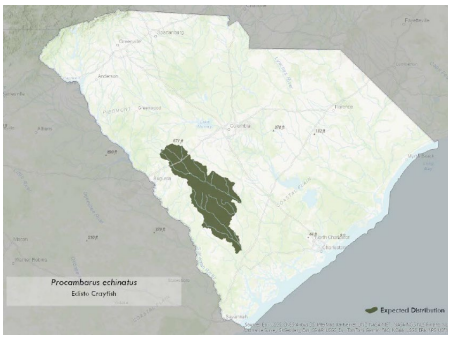
Edisto Crayfish
Procambarus echinatus

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Greg Rothman and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



This is a large species with the holotypic male measuring 64 cm in carapace length, which is roughly equal to 128 mm (5.1 inches) in total length. The carapace of *Procambarus echinatus* Hobbs 1956, is olive-green dorsally, fading ventrally to creamy-white with ridges edged in black. The abdomen is greenish with a bright blue caudal section bearing red and reddish-purple markings. The chelae are reddish-black with white tubercles. There are well-developed spines on the carapace and chelae. This species exhibits large amounts of variation between individuals in the number of spines and the size ratios of various body parts (Hobbs 1956b).

Status

NatureServe (2024) identifies the rank of *P. echinatus* as vulnerable (S3) in South Carolina. The species was listed as vulnerable by Taylor *et al*. (2007) and conferred by Simon (2011).

POPULATION SIZE AND DISTRIBUTION

P. echinatus is endemic to South Carolina and known only from the headwaters of the Edisto and the Salkahatchie/Combahee River drainages. It has been recorded in at least five Coastal Plain counties (Eversole 1995, Poly 2009). In an extensive survey during 1988 and 1989, Eversole (1995) found that the species had a restricted distribution but was abundant at some sites. It is often abundant where it occurs based on recent surveys (Poly 2009).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

P. echinatus is known to inhabit good quality, fast-flowing, dark water streams, usually with sandy substrates. It is often found in grass beds dominated by *Sparganium* and *Saururus* or in submerged rootwads along stream banks (Eversole 1995, Poly 2009).

CHALLENGES

The restricted distribution of *P. echinatus* and its apparent dependence on good water quality streams warrant considerable protection both for the species and its habitat, particularly with increases in urban development and impacts of climate change. Current surveys indicate that this species has a very limited distribution. Therefore, updated surveys are necessary to better determine its status. Additionally, the rarity of *P. echinatus* indicates that its status should be reviewed in South Carolina. The introduction of non-native species, like *Procambarus clarkii*, may also pose threats to the population status of *P. echinatus*, as distributions of the species may overlap (SCDNR unpublished data). Species like *P. clarkii* have been known to alter native

crayfish species richness and abundance in areas of South Carolina in which they are present (Kendrick *et al.,* in press).

CONSERVATION ACCOMPLISHMENTS

Distribution, abundance, and life history of this species have been studied recently, resulting in a slight extension of the known range into two other counties.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the range, population densities, and habitat associations for *P. echinatus*.
- Based on surveys, investigate the need to assign special concern status for *P. echinatus* in South Carolina.

MEASURES OF SUCCESS

The collection of data that better describes the range, population densities, and habitat associations for *P. echinatus* may be considered a measure of success.

Eastern Grass Shrimp

Contributor (2024): Michael Kendrick (SCDNR)

Credit: Aguilar, Wikimedia Commons

DESCRIPTION

Taxonomy and Basic Description

The eastern grass shrimp *Palaemon paludosus* a member of the family Palaemonidae. The eastern grass shrimp is characterized by not having a hepatic spine present (as compared with members of the genus *Macrobrachium*). The eastern grass shrimp may grow up to 2.5 cm (1 in.) long.

Status

The eastern grass shrimp *Palaemon paludosus* is S4 in SC and G5 (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The eastern grass shrimp is native to the Atlantic coastal plain from southern New Jersey to Florida (Thorp and Covich 2010), but the population size in SC is unknown.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The eastern grass shrimp has been identified as a keystone species with some vertical migration patterns that prefers aquatic vegetation, presumably due to the protection it provides from predators (Wessell et al. 2001).

CHALLENGES

The population size of the eastern grass shrimp in SC is unknown and deserves additional attention.

CONSERVATION ACCOMPLISHMENTS

Increasing attention on this potentially important species in South Carolina will aid in gathering additional information on how the importance of this species to native environments in SC.

CONSERVATION RECOMMENDATIONS

- Examine the ecological role of the eastern grass shrimp in riverine systems in South Carolina.
- Establish baseline data on population size, distribution, and habitat requirements of the eastern grass shrimp in South Carolina waters.
- Examine how anthropogenic river modifications and reduced floodplain connectivity may impact the eastern grass shrimp as well as other riverine species.

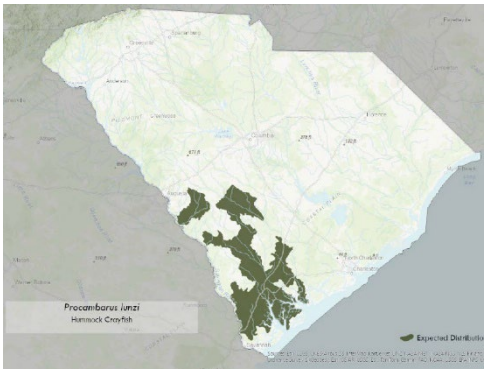
Hummock Crayfish

Procambarus lunzi

Credit: Kendrick/SCDNR

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Graham Wagner and Michael Kendrick (SCDNR)

DESCRIPTION



Taxonomy and Basic Description

Procambarus lunzi is reddish-brown with orange, tan, and black markings. The thoracic and abdominal sections have longitudinal stripes flanked by lighter pink stripes while the ventral surface is cream. The chelae are greenish cream to olive color with tubercles (Hobbs 1981).

Status

NatureServe (2024) identifies this species with a rank of vulnerable (S3) in Georgia and critically imperiled (S1) in South Carolina. Globally, it is apparently secure (G4). The Hummock Crayfish was considered to be currently stable in Georgia and South Carolina by Taylor et al. (2007).

POPULATION SIZE AND DISTRIBUTION

The Hummock Crayfish is found primarily in lentic waters within the Coastal Plain of South Carolina and Georgia (Hobbs 1989). In South Carolina, it has been collected in Beaufort, Colleton, Hampton and Jasper Counties. This is the only crayfish species that has been found in a survey of South Carolina hammock/hummock islands (McCord et al. 2004). Hobbs (1989) also lists Aiken and Bamberg counties as part of the range of *P. lunzi*, but these locations have not been confirmed by recent collections. This species is common at some sites including those in the Francis Marion National Forest.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

P. lunzi is found in lentic and sluggish lotic environments and sometimes burrows (Hobbs 1989). According to Hobbs (1981) this is a secondary or tertiary burrower.

CHALLENGES

The Hummock Crayfish should be considered a research priority because little is known about its distribution and habitat requirements. Additionally, as an inhabitant of low-lying hammock/hummock islands in South Carolina and Georgia, it is critically affected by the impacts of climate change, such as sea level rise and increased storminess. Development and urbanization of these same habitats also presents a threat to *P. lunzi* in the form of habitat loss.

CONSERVATION ACCOMPLISHMENTS

The hammock island where *P. lunzi* is found is protected as a South Carolina Heritage Preserve (McCord et al. 2004). A survey of North and South Williman Islands in South Carolina in 2024 recorded only *P. lunzi* and no non-native crayfish species (SCDNR unpub. data).

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the range, distribution, and habitat requirements for *P. lunzi*.

MEASURES OF SUCCESS

The collection of data that better describes the range, distribution, and habitat requirements for *P. lunzi* may be considered a measure of success.

Keeowee Crayfish

Cambarus sp. nov. "B" cf. *longirostris*

Credit: Sartore/National Geographic

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Cambarus sp. nov. "B" appears to be a new species that was formerly misidentified as *Cambarus longirostris*. Although *C. longirostris* was previously thought to have been introduced to South Carolina, further examination of specimens indicates that *C. longirostris* does not occur in the state (D. Jones, pers. comm., 2004). However, the species was included as an invasive species (as C. longirostris) in South Carolina by McLaughlin et al. (2005) and Taylor et al. (2007), although the latter source indicated that *C. longirostris* was a species complex under investigation. Adults of this species average about 58 mm (2.3 in.) in total length. The body of this species is buckskin to dark tan with the tips of the chelae white and the joints of the legs pale blue. The posterior terga of the abdomen bears a thin, transverse, burgundy line, and there is usually a dark brown or black saddle following the cervical groove. The fingers of the chelae are very long and form a noticeable gap when closed (D. Jones, Clemson University, pers. comm. via e-mail message on March 10, 2005).

Status

Because this is possibly a new species of crayfish, no status information exists for Cambarus sp. nov. "B."

POPULATION SIZE AND DISTRIBUTION

Cambarus sp. nov. "B" has been collected in medium-sized rivers in the Savannah drainage in Pickens and Oconee Counties in South Carolina. Efforts to locate the species in Georgia have been unsuccessful; it appears to be endemic to South Carolina. It has only been found recently at 3 sites, 2 on Flat Shoals River and 1 on Oconee Creek. The site on Oconee Creek appears highly affected by sedimentation and is the site where the species is least abundant (D. Jones, pers. comm., 2004).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Cambarus sp. nov. "B" prefers riffles and fast flowing sections of streams and rivers with coarse gravel and cobble overlaying fractured bedrock. Females carrying juveniles can be found under boulders in deeper pools of water downstream from the riffles. Specimens are primarily found in crevices in boulders and under rocks 45 cm (18 in.) or more in diameter (D. Jones pers. comm. 2004).

CHALLENGES

The case of the Keeowee crayfish Cambarus sp. nov. "B" cf. longirostris, which was mistaken for an introduced species, is an excellent example. It has previously been treated as an introduced population of C. longirostris in South Carolina (McLaughlin et al. 2005; Taylor et al. 2007), and as of October 2023 this species remains undescribed. Formal description of this species is sorely needed to ensure its conservation status.

Cambarus sp. nov. "B" appears to be highly sensitive to sedimentation due to its need for coarse substrates. Therefore, development or forestry activities in the vicinity of this species' habitat could adversely impact *Cambarus* sp. nov. "B." Oconee Creek, one of the three locations from which this species is documented, appears to have been negatively affected by a high sediment loading and supports the smallest population. Additionally, much of the suitable habitat for this species has been inundated by reservoirs. *Cambarus* sp. nov. "B" is no longer found at several sites where specimens were once taken prior to inundation by Lake Jocassee (D. Jones pers. comm. 2004).

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the *Cambarus* sp. nov. "B" crayfish at this time.

CONSERVATION RECOMMENDATIONS

- Complete the taxonomic description of *Cambarus* sp. nov. "B."
- Develop a landowner education program to promote sound land stewardship practices that result in the reduction of sedimentation in waterbodies.
- Conduct a stream restoration project at Oconee Creek to stabilize streambanks and reduce sediment loads. Revisit the site and conduct additional surveys to determine the affect of the restoration project on the population of *Cambarus* sp. nov. "B."
- Conduct additional surveys to determine the range for the *Cambarus* sp. nov. "B" crayfish.
- Based on surveys, determine the need to obtain special concern status for the *Cambarus* sp. nov. "B" crayfish.
- Review any new proposals for dam construction to determine whether habitat for *Cambarus* sp. nov. "B" is not affected by inundation. Work with appropriate

MEASURES OF SUCCESS

An increase or no net decrease in numbers of individuals collected in future surveys would be considered a sign of success. An increase in the numbers of individuals identified in surveys at the location of stream restoration would also be considered to be a success. Monitor the number of individuals that are reached through the landowner education program and survey those individuals to determine whether they implement stewardship practices conveyed in that program.

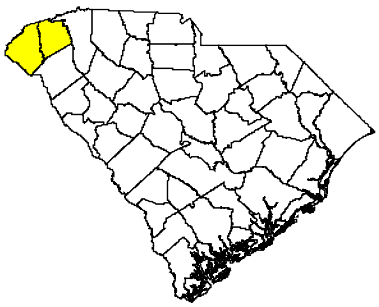
Knotty Burrowing Crayfish
Cambarus nodosus

Contributors (2024): Kathryn Schulz and Eric Ng (West Liberty University) and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Cambarus nodosus was described by Bouchard and Hobbs in 1976. The Knotty Burrowing Crayfish was initially described under the subgenus Jugicambarus. However, after phylogenetic revision of the subgenera of the genus *Cambarus*, the designation to Jugicambarus was eliminated (Breinholt et al., 2012; Crandall & De Grave, 2017). The closest relative of *C. nodosus* is *Cambarus carolinus* and can be separated by multiple morphological traits.



The Knotty Burrowing Crayfish is mainly blue grey on the body and abdomen. Dark brown stripes can sometimes be present on the abdomen of adults but are more prominent in juveniles. The chelae are blue grey with orange to yellow on the distal portion of the fingers. The eyes are reduced and pigmented. The rostrum is blunt and truncated, lacking spines or tubercles on the rostral margins. The chelae have a single row of cristiform tubercles on the mesial margin of the palm with a second row of reduced tubercles. Mature males can grow to be larger than 26.8mm (1.06 inches), with females also being a very similar size (Bouchard & Hobbs, 1976).

Status

In South Carolina, NatureServe (2024) designates the Knotty Burrowing Crayfish as critically imperiled to imperiled (S1/S2), critically imperiled (S1) in North Carolina, imperiled (S2) in Georgia, apparently secure in Tennessee, and secure (G4) globally. Threats to the species in the state are minimal, however the range in South Carolina is narrow (Eversole & Jones, 2004). Taylor et al., 2007 suggested *C. nodosus* to be currently stable (CS) and apparently secure globally (G4).

POPULATION SIZE AND DISTRIBUTION

In South Carolina, the Knotty Burrowing Crayfish is restricted to a single river system in the upper Savannah River Basin, particularly the Keowee River Basin in both Oconee and Pickens Counties (Eversole and Jones, 2004). There are 7 known populations of *Cambrus nodusus* in South Carolina, with a majority of them belonging in Pickens County (Eversole and Jones, 2004). NatureServe (2024) reports that the species can also be found in seepage areas and head water tributaries within Georgia, Tennessee, and North Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Knotty Burrowing Crayfish is a primary burrowing crayfish and is considered a generalist in terms of habitat preference. They tend to reside in pools, seepage areas, roadside ditches and occasionally in the riffle areas of streams (NatureServe, 2024). They can be found near the headwaters and tributaries of the Savannah River basin (Eversole and Jones, 2004)

CHALLENGES

The Knotty Burrowing Crayfish faces no significant threats and demonstrates resilience in challenging habitats (NatureServe, 2024). However, due to the lack of recent surveying for the Knotty Burrowing Crayfish, future surveys are recommended to identify any localized threats to this species. Although the Savannah River population appears to be stable, its restricted range is cause for great concern. If the distribution of *Cambarus nodosus* is as restricted as it appears, any developmental project in the vicinity of its range could result in localized extirpation of this species.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for the Knotty Burrowing Crayfish at this time.

CONSERVATION RECOMMENDATIONS

- Conduct more surveys to establish the full extent of the range in South Carolina.
- Create a contemporary map of the updated area of occurrence in the state.
- Monitor the response of the crayfish to local, fine-scale threats to ensure the security of persisting populations.

MEASURES OF SUCCESS

Data collection that better defines the distribution, population, and threat status of *C. nodosus* in South Carolina would be considered a measure of success. Gaining protection in areas where *C. nodosus* is found would also be considered a measure of success.

Lean Crayfish

Cambarus strigosus

Contributor (2024): Zanethia Barnett (USFS)

Credit: Zachary Graham/West Liberty University

DESCRIPTION

Taxonomy and Basic Description

Cambarus strigosus is mostly olive to dark bluish green fading to pale orange tan with dark brownish to dark olive and orange markings. The eyes are small but well-developed. There are 5 to 8 tubercles on the mesial margin of palm on chela, and cervical tubercles on the carapace. There is also a single spine on both sides of the telson (Hobbs 1981).

Status

NatureServe (2024) currently ranks *C. strigosus* as critically imperiled in South Carolina (S1) and imperiled in Georgia (S2) and globally (G2). Taylor et al. (2007) recommended listing it as a threatened species, but at the time its known distribution was only in Georgia.

POPULATION SIZE AND DISTRIBUTION

Cambarus strigosus is a primary burrowing crayfish that is endemic to the Piedmont region of the Savannah River Drainage in South Carolina and Georgia (Barnett et al. 2024). It has a limited range, but has been collected from McCormick, Edgefield, Abbeville, and Aiken counties in South Carolina (Barnett et al. 2024), as well as Wilkes, Oglethorpe, and Elbert counties in Georgia (Skelton 2016).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Cambarus strigosus is a habitat specialist found in low-elevation terrestrial habitats associated with infrequently managed open fields and riparian forests, as well as ecotones between these two habitats (M. Stubbs, WLU, unpublished data). It has also been collected from roadside ditches and adjacent to spring-runs in Georgia (Hobbs 1981). *Cambarus strigosus* has been collected in sandy-clay to clay-loam soils (Hobbs 1981; M. Stubbs, WLU, unpublished data).

CHALLENGES

Little is known about the distribution, population size and microhabitat requirements of *C. strigosus.* It's association with infrequently managed open fields may indicate that it used to utilize prairie habitats and forest succession may threaten these populations. We are currently unsure if *C. strigosus* in South Carolina use roadside ditch or spring habitats as they do in Georgia.

CONSERVATION ACCOMPLISHMENTS

Crayfish surveys on the Long Cane Ranger District of the Sumter National Forest from 2020-2023 identified 6 new locations for *C. strigosus*, with over 90 individuals encountered (Barnett et al. 2024). These encounters of *C. strigosus* led to the investigation of the species presence in South Carolina and uncovered two historical records in the state from the 1980s.

The US Forest Service may be able to maintain suitable habitat for *C. strigosus* by managing wildlife openings, protecting riparian zones, as well as, reducing ditch maintenance during winter and spring months when *C. strigosus* are active within them.

CONSERVATION RECOMMENDATIONS

- Conduct additional surveys for *C. strigosus* throughout the Piedmont region of the Savannah River Drainage to assess its distribution.
- Conduct additional surveys to assess *C. strigosus* habitat requirements and population size.
- Continue to work with the US Forest Service to ensure that operations on Sumter National Forest maintain suitable habitats.

MEASURES OF SUCCESS

Collection of data that better describes the distribution and habitat requirements for *C. strigosus* may be considered a measure of success. Conservation of suitable habitats may be considered a success.

Freshwater, Marine and Terrestrial Leeches Guild

New England Medicinal Leech *Macrobdella sestertia*
"A terrestrial leech" *Haemopis septagon*
Appalachian Leech *Placobdella biannulata*
Nuchal Leech *Placobdella nuchalis*
Translucent Leech *Placobdella translucens*
"A marine leech" *Branchellion ravenelii*

Contributors (2024): Bronwyn W. Williams (NC Museum of Natural Sciences), William E. Moser (Smithsonian Institution National Museum of Natural History)

New England Medicinal Leech
Macrobdella sestertia

The New England Medicinal Leech was described in 1886 from eastern Massachusetts. It took nearly a century, in 1976, to be collected a second time (Smith 1977), and nearly two decades more to be collected a third time (Smith and Hanlon 1997), in Maine. In 2008, 9 specimens of *M. sestertia* were collected in southwestern South Carolina (Poly 2011), representing a significant expansion of its historically reported New England distribution. Two additional specimens of the species from South Carolina were found in the collections of the Charleston Museum and North Carolina Museum of Natural Sciences (NCSM) (Poly 2018); these specimens are currently housed in the NCSM Non-molluscan Invertebrates (NMI) Collection. Carlson and Phillips (2020) presented an extinction model for *M. sestertia* throughout its patchy and disparate range, concluding that the species may have gone extinct, but urging for surveys and a focus more generally on leech conservation. Ironically, this paper was in press when Dr. Bronwyn Williams, joined by Dr. Anna Phillips, collected several *M. sestertia* specimens in southern New Hampshire; Dr. Williams had also collected a handful of *M. sestertia* specimens in South Carolina the previous year. In South Carolina, the New England Medicinal Leech is known to occur only in Edgefield County. *Macrobdella sestertia* has a Global Status of imperiled (G2) and is currently considered Possibly Extirpated in Massachusetts. It has no current status rank in South Carolina (NatureServe 2024). Nearly nothing is known about the local and range-wide distribution of this species or any aspect of its natural history; fewer than 30 individuals have been collected since its description over 140 years ago.

"A terrestrial leech"
Haemopis septagon

The terrestrial leech, *Haemopis septagon*, was described in 1976 from Durham County, North Carolina. Its known distribution ranges from New Jersey south into Georgia throughout coastal plain and lower Piedmont habitats. While it is truly a terrestrial species, *H. septagon* occupies damp riparian areas and microhabitats containing an abundance of earthworms, its primary prey. A substantial amount of information about the natural history of this species has been recently gleaned through collecting and husbandry efforts by a handful of herpetologists in the southeast. That said, *H. septagon* remains poorly documented in South Carolina, reported only from Georgetown, Charleston, and Lee Counties (Sawyer and Shelley 1976, NCSM NMI Collection

database). Basic surveys, ideally coincident with efforts focused on amphibians, are needed to assess the distribution and abundance of this species in South Carolina (Sawyer 1979). It was recommended for Special Concern status by Sawyer (1979). This species is currently unranked (NatureServe 2024).

Appalachian Leech
Placobdella biannulata

This species is found free-living and as a parasite on salamanders of the genus *Desmognathus*. Formerly known by the name *Oligobdella biannulate*, it is known to occur in South Carolina only in the Blue Ridge Ecoregion in Oconee, Pickens, and Greenville Counties (Sawyer and Shelley 1976; Moser et al. 2005). Sawyer (1979) recommended Special Concern status for the species. In its entirety, the species occurs in a relatively small area encompassing mountainous portions of Georgia, North Carolina, South Carolina, and Tennessee (Moser et al. 2005). This species has no current status rank in South Carolina (NatureServe 2024).

Nuchal Leech
Placobdella nuchalis

The nuchal leech was originally described by Sawyer and Shelley (1976) from one site in South Carolina (Orangeburg County) and a few localities in North Carolina. Little is known about the natural history of this species except it being reported as a temporary parasite of fishes (Shelley and Braswell 1981; Klemm, 1982). *Placobdella nuchalis* has been rarely collected since its description. Moser et al. (2017) added new information on its anatomy and a molecular characterization. Poly (2018) discovered individuals of this species to be hitchhikers of a collection of *M. sestertia* in South Carolina. The nature of this association is unknown but warrants further study. This species does not have any conservation rank currently assigned to it, but basic surveys are needed to assess its distribution and abundance.

Translucent Leech
Placobdella translucens

The translucent leech was originally described by Sawyer and Shelley (1976) from Georgetown and Berkeley Counties, South Carolina and from a site in Louisiana. *Placobdella translucens* is infrequently encountered and its range is Alabama, Florida, Georgia, Louisiana, North Carolina, and South Carolina (Sawyer and Shelley 1976; Klemm 1982, 1991). It is most likely a blood feeding leech, but there are no reported hosts for this species. Basic surveys are needed to assess its distribution and abundance of *P. translucens*. It has no current status rank in South Carolina (NatureServe 2024).

"A marine leech"
Branchellion ravenelii

This marine leech was described by Girard in 1850 from Charleston, South Carolina. It is parasitic on rays and skates and occurs along the southeastern Atlantic Coast to the Gulf of Mexico, although reports in South Carolina are exceedingly rare (Sawyer et al. 1975, Sawyer 1979). In 2024, a staff member of the Charleston Aquarium contacted Megan McCuller,

Collections Manager of NMI at the NCSM reporting a *B. ravenelii* on a batoid housed at the facility. If confirmed – and the leech specimen may end up in the NCSM NMI Collection – this would be a welcome recent finding. Sawyer (1979) recommended state endangered status for the species; such a status in turn reflects a conservation focus on the hosts of this leech. *Branchellion ravenelii* is likely present in nearshore areas of South Carolina but may be rare, or appear rare, given this region is the northern extent of its range. Typically, little attention is paid to ectoparasites of marine vertebrates, particularly if the parasites occur in small numbers. As such, this species may be relatively common, but just not reported. *Branchellion ravenelii* has no current status rank in South Carolina (NatureServe 2024).

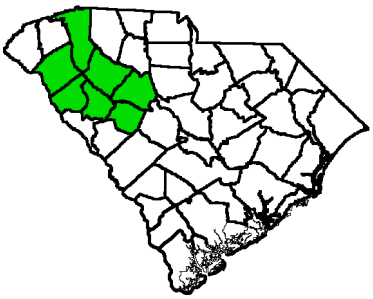
Mimic Crayfish

Distocambarus carlsoni

Photo by Dr. Zackary Graham

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2024): Kathryn Schulz and Eric Ng (West Liberty University)

DESCRIPTION



Taxonomy and Basic Description

Distocambarus carlsoni was described by Hobbs in 1983, shortly after the subgenus Distocambarus was elevated to generic status. The genus was formerly a subgenus of the more basal genus *Procambarus*. The most closely related species are the other members of the retained subgenus *Fitzcambarus*; *Distocambarus youngineri* and *D. hunteri* (Crandall & De Grave, 2017; H. Hobbs, 1983; H. H. Hobbs, 1981). Recent surveys suggest *D. carlsoni to* be a species complex. Outside of the known range, there are populations of a similar species that share physical characters, but also exhibit phenotypic variation. Due to taxonomic complexity within this species, further taxonomic revision is recommended.

The Mimic Crayfish exhibits amazing color variation across its range. The dorsal surface of the carapace is reddish to green or can present as a dark electric blue to grey-blue. The dorsal surface of the thoracic region is also dark, but the ventral surface is a lighter lavender-cream color. The tail is tan and pinkish to dark blue, and the chelae are lavender with a dark brown dorsal stripe and 5 to 7 tubercles on the mesial surface. The rostrum is very broad, lacking tubercles and spines on the margins. The gonopod anatomy of the form 1 male is unlike the other members of the genus, having a blade-like central projection curved to about 90 degrees. The first few adult specimens collected ranged from about 50-62 mm (2-2.5 in.) in total length (Hobbs 1983).

Status

NatureServe (2024) currently identifies the Mimic Crayfish as both globally imperiled (G2) and state imperiled (S2). The Mimic Crayfish was included on a list of 404 species being petitioned for consideration as candidates for federal protection (USFWS 2011).

POPULATION SIZE AND DISTRIBUTION

The Mimic Crayfish is a terrestrial obligate burrower endemic to South Carolina and is known only from 7 counties in the western Piedmont (Hobbs 1989, USNM records). Recent surveys suggest that the Mimic Crayfish may have an expanded range within the Piedmont Region of South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Distocambarus carlsoni is a primary burrowing crayfish that can be found residing in a wide variety of habitat types. Hobbs (1983) described the habitat at the type locality as a swampy area with a water table fluctuating from the surface to 0.8 m (31.5 in.) below. The soil was described as sandy clay, with areas rich in hummus and leaf litter. This species has a strong association with swamp-seepages and can be found in occurrence with *Cambarus carolinus*. The two species

have been known to partition the habitat by *D. carlsoni* occupying static water and *C. carolinus* occupying sites with flowing water (Hobbs, 1983).

CHALLENGES

More research is needed to determine more specifically the distribution and habitat associations of the Mimic Crayfish within this region. The only published paper on *Distocambarus carlsoni* is its original description paper in 1983, making it difficult to discern the exact range and relevant threats this species obtains.

CONSERVATION ACCOMPLISHMENTS

South Carolina Department of Natural Resources is currently undergoing a three-year study to obtain more information on this species. The distribution of the Mimic Crayfish also crosses over into Sumter National Forest, which helps conserve its preferred habitat type. In addition, the Mimic Crayfish has achieved 'species of concern' status in the state and is now indicated to be a species of highest priority for South Carolina's SWAP.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the distribution, habitat associations, and population status of the Mimic Crayfish.
- Develop and conduct landowner and general education programs that stress the unique nature of terrestrial burrowing crayfish and their importance in South Carolina.
- Initiate the process to refine the taxonomic standing of *Distocambarus carlsoni* in South Carolina.

MEASURES OF SUCCESS

The collection of data that better describes the distribution, habitat associations, and population status of the Mimic Crayfish may be considered a measure of success. Assessing participation in education programs would assist in measuring success of the programs. An updated taxonomic revision of the species would also be considered a sign of success.

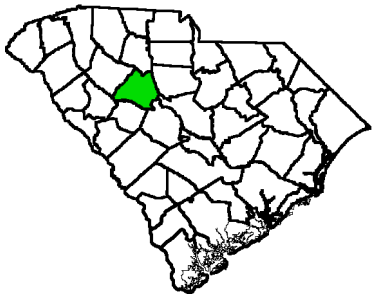
Newberry Burrowing Crayfish

Distocambarus youngineri

Photo by Dr. Zackary Graham

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2024): Kathryn Schulz and Eric Ng (West Liberty University)

DESCRIPTION



Taxonomy and Basic Description

Distocambarus youngineri was described by Hobbs and Carlson in 1985. Before being elevated to full generic status, the genus *Distocambarus* was formerly a subgenus of *Procambarus*. The most closely related species are the other members of the retained subgenus *Fitzcambarus*; *Distocambarus carlsoni* and *D. hunteri* (Crandall & De Grave, 2017; Hobbs & Carlson, 1985; H. H. Hobbs, 1981). Recent surveys suggest *D.* (*F.*) *youngineri* to be a potential species complex. Further taxonomic revision is suggested in order to resolve taxonomic complexity.

The Newberry Burrowing Crayfish is pale blueish to lavender in color uniformly throughout its body. The ventral surfaces are more pinkish cream. There is also some phenotypic variation, with some individuals being blue dorsally and pinkish cream ventrally. The abdomen is greatly reduced in size. The merus of the chelae uniquely has a more tuberculate ventral surface. The rostrum is broad and triangular in shape. The gonopod anatomy of the form 1 males features a blade-like central projection that is short and not bent to 90 degrees. *Distocambarus youngineri* mature males range in size from 12.1mm (0.47 inches) to 29.2mm (1.15 inches), a relatively small species (Hobbs & Carlson, 1985).

Status

NatureServe (2024) identifies *D. youngineri* as critically endangered in South Carolina (S1) and globally (G1), which seems appropriate for such a rare species. Taylor et al. (1996, 2007) recommended listing the species as endangered. The Newberry Burrowing Crayfish was included on a list of 404 species being petitioned for consideration as candidates for federal protection (USFWS 2011).

POPULATION SIZE AND DISTRIBUTION

D. (F.) youngineri is a very rare obligate burrower, endemic to South Carolina. Historically it has only been found in Newberry County, but recent surveys suggest it may also occur in Laurens county. They are primarily found within a portion of the Saluda River Basin and a few sites within the Broad River Basin. One location where this species was found was in Sumter National Forest; however, the majority of its occurrences are found on private land (Eversole 1995; Eversole and Welch 2010). Recent surveys suggest that they may occupy more than one location within Sumter National Forest.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

D. youngineri is found in moist, terrestrial areas with leaf litter and a mixed-hardwood overstory, usually near stream headwaters or intermittent streams (Eversole 1995). Recent studies suggest that it can be found within and near streambanks, having a positive association with water bodies. In areas where *D. youngineri* is found, the soil becomes saturated and may be covered with shallow water during periods of precipitation in the winter, spring, and sometimes into the early summer. Eversole (2010) found them often to occur in soil types that supported a seasonally perched water table. This species appears to have been extirpated from its type locality following a clearcut in the area during 1989 (Eversole 1995). Most of the sites where *D. youngineri* has been recorded are in moist, wooded areas, but it has also been found in a selectively logged pine stand and in grass lawn areas.

CHALLENGES

There is concern that *D. youngineri* may be in decline. Eversole (1995) found the species at only 6 sites despite intensive survey efforts; it now appears to be extirpated from one of those sites. Given the extremely restricted distribution and low population numbers of *D. youngineri*, protections should be put in place. The Newberry Burrowing Crayfish also appears to be more sensitive to habitat disturbance/destruction, raising concerns of range reduction.

CONSERVATION ACCOMPLISHMENTS

D. youngineri is also a species of federal concern, and status surveys funded by the US Fish and Wildlife Service have been conducted for this species. In addition, the Newberry Crayfish has achieved 'species of concern' status in the state and is now indicated to be a species of highest priority for South Carolina's SWAP.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the distribution and population status of *D. youngineri.*
- Collaborate with land trusts as well as other federal, state, and local agencies and private conservation groups to protect areas where *D. youngineri* is located. Protection methods used by SCDNR and/or other groups can include conservation easements or fee-simple land purchases.
- Determine the importance of alterations to the groundwater table to population stability of *D. youngineri*.
- Initiate the process to refine the taxonomy of *D. youngineri* in South Carolina.

MEASURES OF SUCCESS

Collection of data that better determines the distribution and population status of *D. youngineri* may be considered a measure of success. Achieving protection for areas *D. youngineri* is located would also be considered a measurement of success. Completion of groundwater investigations and determination of recommendations to protect this species would also be considered a sign of success. An updated taxonomic revision of the species would also be considered a sign of success.

Ohio river shrimp

Macrobrachium ohione

Credit: Clinton & Charles Robertson

Contributor (2005): Elizabeth Wenner (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Ohio river Shrimp *Macrobrachium ohione* is a member of the family Palaemonidae, characterized by having the first two pairs of legs chelate, the second pair larger than the first, and the carpus of the second leg not subdivided. The Ohio Shrimp is characterized by having a hepatic spine present (as do several other *Macrobrachium*) and enlarged, elongate second pereiopods (though not as large as in other *Macrobrachium*). The rostrum has up to 13 teeth and is upturned with a toothless, daggerlike tip. The Ohio Shrimp may grow up to 10 cm (4 in.) long. Females, which are larger than males, can reach 110 mm in total length and are gray to green in color with light blue spots.

Status

The population of Ohio River Shrimp in South Carolina is not listed as threatened or endangered; however, in parts of its range, the Ohio Shrimp is listed as rare and of long-term concern (Missouri Natural Heritage Program 2004). In some parts of its range, such as Louisiana, the population is abundant enough to provide a fishery. The Ohio River Shrimp has a global rank of apparently stable (G4) but has no state rankings (NatureServe 2011).

POPULATION SIZE AND DISTRIBUTION

This river shrimp occurs in lower salinity and tidal freshwater areas and coastal plain rivers in South Carolina (Cooper 2011a). Its range on the Atlantic Coast extends from Virginia into Florida. The Ohio Shrimp was once common in the Mississippi River below St. Louis, and commercial fisheries for this species previously existed near Chester and Cairo, Illinois. However, Ohio Shrimp have declined dramatically in the Mississippi, most likely due to channelization of the river (Barko and Hrabik 2004). Two specimens collected in 2001 from the Ohio River of Illinois were the first records from the river in over 50 years (Poly and Wetzel 2002). The size of the population in South Carolina is unknown.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Ohio River shrimp is amphidromous such that larvae drift down rivers until they reach high salinity waters and move back to fresh water as adults. Females carrying eggs may also migrate downstream before releasing the larvae to reduce drift times. Ohio Shrimp apparently prefer low velocity water (Conaway and Hrabik 1997); however, open side channels, a preferred habitat of Ohio Shrimp, have flow during normal river elevations (Barko and Herzog 2003). Ohio Shrimp prefer borders of the main channel, especially when the borders are flooded and plant and animal material are available for foraging (Truesdale and Mermilliod 1979). Ohio River Shrimp have been reported to have greater abundance in areas with suspended particulate matter, which may be a predator avoidance response. Ohio River Shrimp occupy low visibility physical habitats that are also occupied by predatory fishes, such as flathead catfish, a species that is not native to South

Carolina (Barko and Herzog 2003). Little is known about the life history of the Ohio Shrimp in South Carolina. In other areas, it has been reported to receive reproductive cues from spring floods and uses flooded terrestrial habitat for reproduction (Hobbs 2001). Aspects of the reproductive biology of Ohio Shrimp in the lower Mississippi and Atchafalaya Rivers were studied recently (Olivier and Bauer 2011). According to Ortmann (1902), the genus Macrobrachium has probably only recently evolved migratory behavior into fresh water. Biological characteristics indicative of this relatively recent adaptation include high hemolymph osmo-ionic concentrations, tolerance of high salinities, dependence on saline water for larval development with many larval stages, and migratory behavior (McNamara 1987).

CHALLENGES

Ohio River Shrimp may have declined as a result of waterway channelization and habitat loss in parts of its range. Changes in river physiography that fragment main channel borders and isolate side channels during moderate to low river elevation can reduce Ohio Shrimp populations (Logsdon 1993; Hobbs 2001; Barko and Herzog 2003). In parts of its range, reduced connectivity with the floodplain—because of levees, closing structures, and wing dikes—has also contributed to Ohio Shrimp declines.

CONSERVATION RECOMMENDATIONS

- Examine the ecological role of Ohio River Shrimp in riverine systems in South Carolina.
- Establish baseline data on population size, distribution, and habitat requirements of Ohio River Shrimp in South Carolina waters.
- Examine how anthropogenic river modifications and reduced floodplain connectivity may impact Ohio River Shrimp as well as other riverine species.
- Protect tidal freshwater habitats in South Carolina from development and modifications to natural freshwater flow regimes by partnering with the appropriate permitting agency to provide better technical information about the potential negative effects of development on aquatic ecosystems.
- Encourage citizens to donate wetland areas to a land trust that will protect it in perpetuity.
- Consider water flow impacts on Ohio River Shrimp when renewing licenses for river dams.

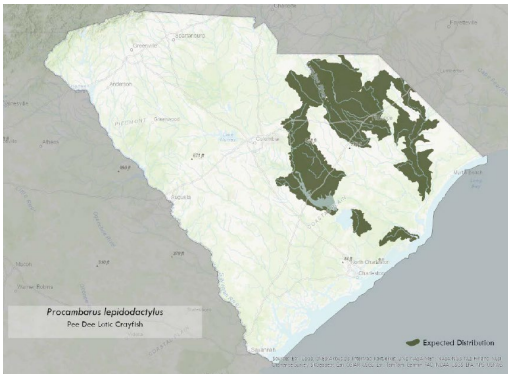
Pee Dee Lotic Crayfish

Procambarus lepidodactylus

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Zanethia Barnett (USFS)

DESCRIPTION

Taxonomy and Basic Description



The Pee Dee Lotic Crayfish is a medium-sized crayfish, approximately 55 mm (2.1 in.) in total length with angulate shoulders covered with acute spines. The body is laterally compressed. The chelae are elongate and the palms studded with squamous tubercles (Hobbs 1947).

Status

NatureServe (2024) ranks the Pee Dee Lotic Crayfish as apparently secure in South Carolina (S4) and globally (G4). Taylor et al. (2007) listed the species as currently stable.

POPULATION SIZE AND DISTRIBUTION

The Pee Dee Lotic Crayfish is endemic to South Carolina (NatureServe 2024). It has been found in the Pee Dee River Basin in Chesterfield, Clarendon, Florence, Darlington, Dillon, Georgetown, Sumter, Kershaw, and Marion counties (Smithsonian Museum of Natural History data set) and in abundance in the Cooper River Drainage in Berkeley County (J. Bulak, SCDNR and Z. Barnett, USFS pers. comm.). However, more research on its distribution, population numbers, and habitat associations are needed to determine if this ranking is accurate.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Pee Dee Lotic Crayfish tends to occur in clear, sandy-bottomed creeks of moderate gradient flowing through swampy areas, often among tree roots along stream banks (NatureServe 2024).

CHALLENGES

It appears that the Pee Dee Lotic Crayfish has a limited and spotty distribution (A. Eversole, pers. comm.). Taylor et al. (2007) listed the Pee Dee Lotic Crayfish as a species complex that is under study.

CONSERVATION ACCOMPLISHMENTS

In a 2006-2011 Stream Survey, 14 occurrences of this crayfish species were found at 9 sites in Sumter and Kershaw counties (A. Eversole, pers. comm.). Additionally, surveys from 2022-2024 on the Francis Marion National Forest collected 40 Pee Dee Lotic Crayfish from 3 sites in Berkely County (Z. Barnett, USFS, pers. comm.).

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the range, distribution, and habitat requirements for the Pee Dee Lotic Crayfish.
- Conduct research to clarify the taxonomy of the Pee Dee Lotic Crayfish.

MEASURES OF SUCCESS

Collection of data that better describes the range, distribution, and habitat requirements for the Pee Dee Lotic Crayfish may be considered a measure of success. Conducting taxonomic research to understand if this species is a species complex may also be considered a measure of success.

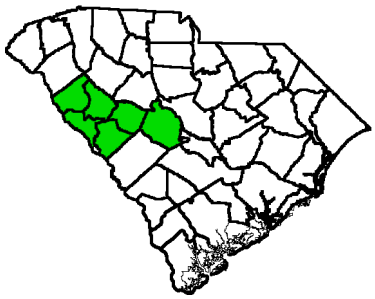
Piedmont Prairie Burrowing Crayfish

Distocambarus crockeri

by Gregory Myers, West Liberty University

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Zanethia Barnett (USFS)

DESCRIPTION



Taxonomy and Basic Description

Distocambarus crockeri is typically dark brown to grayish brown in color with stripes or patterns sometimes present. The chelae are dark tan with brown tubercles. Leucistic (Stubbs et al. 2023) and purple color morphs have been collected (G. Myers, WLU, pers. comm.). The eyes are small but well-developed, and the carapace may have one or several tubercles (Hobbs and Carlson 1983).

Status

NatureServe (2024) currently ranks *D. crockeri* as vulnerable both in South Carolina (S3) and globally (G3). This may be appropriate given that it is moderately abundant but with a restricted distribution. Given the restricted endemic distribution of *D. crockeri*, Taylor et al. (2007) recommended listing it as a threatened species.

POPULATION SIZE AND DISTRIBUTION

D. crockeri is a primary burrowing crayfish that is endemic to South Carolina. It appears to be the most abundant of the *Distocambarus* species. However, none of the species in this genus are particularly widespread. It is found in Abbeville, Edgefield, McCormick, Greenwood and Saluda Counties (Hobbs and Carlson 1983). This species can be found throughout the Carolina Slate Belt between the Savannah and Saluda River Drainage (Eversole and Foltz 2015). Its distribution lies primarily within the Long Cane Ranger District of the Sumter National Forest (S. Welch and Z. Barnett, pers. comm.).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

In the Long Cane Ranger District of the Sumter National Forest, *D. crockeri* is abundant in wildlife openings within the forests. These wildlife openings are grassy fields that were maintained by mowing or disking and resemble Piedmont prairies, which were present throughout much of the Piedmont at the time of European settlement (S. Welch, unpublished manuscript). This species has also been collected in low lying forested areas adjacent to wildlife openings, as well as along the banks of ephemeral streams (Z. Barnett, USFS, pers. comm.). Additionally, during winter and spring months, this species is abundant in roadside ditches and vernal pool habitats (Z. Barnett, USFS, pers. comm.).

Distocambarus crockeri is found primarily on ridgetops and saddles in upland Piedmont areas where there is a perched water table of less than 2 m (6.6 ft.) during the winter and spring. The soils in which *D. crockeri* is found also undergo seasonal drying during the summer and fall (S. Welch, pers. comm.). In the northwestern portion of its range, it is only found near plutonic geologies, which are large, flat, erosion resistant areas that retain fine sediments during rain events and hold water during dry periods (G. Myers, WLU, pers. comm.).

CHALLENGES

The dependence of *D. crockeri* on a perched water table makes it vulnerable to alterations in soil hydrology such as digging a large number of wells or severe drought. Forest succession in prairie areas may also threaten the survival of *D. crockeri* since large populations inhabit these areas (S. Welch, unpublished manuscript). Preliminary taxonomic assessments of the genus suggest that taxonomic clarification of the species may be needed (M. Kendrick, SCDNR, pers. comm.)

CONSERVATION ACCOMPLISHMENTS

The majority of the distribution of *D. crockeri* lies within the Sumter National Forest. The US Forest Service may be able to maintain suitable habitat for *D. crockeri* by managing wildlife openings, restoring prairies, or creating other prairie like environments, as well as, reducing ditch maintenance during winter and spring months when *D. crockeri* are active within them.

Surveys of *D. crockeri* from 2020-2024 has identified over 30 new locations within the Sumter National Forests with over 1,000 individuals encountered.

CONSERVATION RECOMMENDATIONS

- Conduct additional surveys for *D. crockeri* to assess its microhabitat requirements and use of areas outside of prairie-like habitats.
- Taxonomic clarification of species.
- Continue to work with the US Forest Service to ensure that operations on Sumter National Forest maintain suitable habitat for *D. crockeri*.
- Develop and conduct landowner and general education programs that stress the unique nature of terrestrial burrowing crayfish and their importance in South Carolina.

MEASURES OF SUCCESS

Collection of data that better describes the microhabitat requirements (outside of prairie-like habitat) for *D. crockeri* may be considered a measure of success. An update on the taxonomic status of the species would also be considered a measure of success. Assessing participation in education programs would assist in measuring the success of these programs.

Pine Savannah Crayfish

Cambarus reflexus

Credit: Sarah Chinn (CC BY-NC

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick(SCDNR)

DESCRIPTION

Taxonomy and Basic Description

Cambarus reflexus has a reddish-orange-tan carapace, a dark first abdominal segment, and progressively lighter segments approaching the pinkish tail. It has broad, triangular, orange-brown chelae and small eyes (Hobbs 1981).

Status

NatureServe (2024) currently identifies *C. reflexus* as imperiled (S2) in Georgia and vulnerable (S3) in South Carolina. The global ranking of apparently secure (G4) may need to be updated to reflect its rarity in those two states. The species was considered to be currently stable in Georgia and South Carolina by Taylor et al. (2007). According to Welch (2007), the species' current global status of "currently stable" and "vulnerable" in South Carolina likely underestimates its level of imperilment.

POPULATION SIZE AND DISTRIBUTION

Hobbs (1989) lists the distribution as extending to the Santee Basin, but its presence in this basin has not been confirmed by recent collections and there could be some misidentified specimens associated with some of these records or the species may be extirpated from portions of its historical range (Welch 2007).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

C. reflexus is a primary burrower and is restricted to flatwoods longleaf pine forests of the Savannah and Ogeechee River Basins of the Coastal Plain in South Carolina and Georgia (A. Eversole, pers. comm.). In addition to open pine forests, this species can occur underneath logs in low-lying seepage and boggy areas characterized by black soil, and it can be found in mixed hardwood and swamp forests (Hobbs et al. 1976, Hobbs 1981.).

CHALLENGES

Further survey work is needed for *C. reflexus*. This species appears to be rare; with its limited distribution, *C. reflexus* warrants significant habitat protection. However, the species occurs in an area of South Carolina that has a low human population that has decreased, unlike in other areas undergoing urbanization.

CONSERVATION ACCOMPLISHMENTS

A habitat modeling study was done on this species by Welch (2007). The presence of wiregrass was the most important habitat component measured in the study. The importance of wiregrass and stand age indicated that *C. reflexus* was associated with "high quality" fire-maintained pine savannah habitats. Furthermore, the study suggested that *C. reflexus* was limited to these sites and thus could

be included as an invertebrate component used to identify "high quality" pine savanna habitats for conservation and restoration. The species appears to be limited to the Coastal Plain in South Carolina and sensitive to soil surface disturbances.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to determine the extent of the range of *C. reflexus*.
- Conduct research to determine the natural history and population status of *C. reflexus.*
- Determine the importance of alterations to the groundwater table to the population stability of *C. reflexus*.
- Investigate the need to initiate the process of achieving South Carolina special concern status for *C. reflexus*.
- Maintain remnant pine savannah stands containing *C. reflexus* with prescribed burns. Restoration efforts should focus on stands adjacent to *C. reflexus* colonies and restore savannah vegetation structure.
- Develop and conduct landowner and general education programs that stress the unique nature of burrowing crayfish and their importance in South Carolina.

MEASURES OF SUCCESS

The collection of data that better describes the natural history and population status of *C. reflexus* may be considered a measure of success. Completion of groundwater investigations and the determination of recommendations to protect Pine Savannah Crayfish would also be considered a sign of success. Assessing participation in education programs would assist in measuring the success of these programs.

Red Burrowing Crayfish

Cambarus carolinus

Credit: iNaturalist/cporternc

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description

The Red Burrowing Crayfish has a cylindrical body shape and is brick-reddish in color. The chelae have a large row of tubercles on the mesial surface of the palm (NCWRC 2005).

Status

NatureServe (2024) identifies the rank for the Red Burrowing Crayfish as imperiled (S2?) in South Carolina and apparently secure (G4). Taylor et al. (2007) considered the species to be currently stable.

POPULATION SIZE AND DISTRIBUTION

The Red Burrowing Crayfish is an obligate burrower found in the upper Broad, Saluda, and Savannah River Basins (Hobbs et al. 1973; Hobbs 1989, USNM records). Its distribution in South Carolina is spotty and restricted to a few wetlands, seeps, and bogs in the western Piedmont (A. Eversole, pers. comm.). This species is also found in western North Carolina and eastern Tennessee (Hobbs 1989).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Although the Red Burrowing Crayfish is a primary burrower, it is often found in surface waters including springs, seeps, and bogs (NCWRC 2005).

CHALLENGES

Very little is known about its natural history or population status. This species is hard to survey because of its burrowing habit and its colonies are small. It has a limited distribution and small population size (A. Eversole, pers. comm.). It is suspected that any activities likely to alter the water table, such as major road construction or tapping into groundwater for dense suburban development, would threaten this species.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments for the Red Burrowing Crayfish at this time.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the natural history and population status of the Red Burrowing Crayfish.
- Determine the importance of alterations to the groundwater table to population stability of the Red Burrowing Crayfish.

- Develop and conduct landowner and general education programs that stress the unique nature of terrestrial burrowing crayfish and their importance in South Carolina.

MEASURES OF SUCCESS

The collection of data that better describes the natural history and population status of the Red Burrowing Crayfish may be considered a measure of success. Completion of groundwater investigations and determination of recommendations to protect Red Burrowing Crayfish would also be considered a sign of success. Assessing participation in education programs would assist in measuring success of the programs.

Rocky River Crayfish

Cambarus hobbsorum

Credit: Kevin Metcalf

Contributor (2024): Graham Wagner (SCDNR) and Bronwyn Williams (NCMNS)

DESCRIPTION

Taxonomy and Basic Description

The body of the Rocky River Crayfish is dorsoventrally flattened. The thoracic section has punctations and granulations dorsally and cobbled tubercles laterally. Its color is variable but is generally in shades of deep brown, olive, green, blue-green, and black and is highlighted with tan, white, or orangish tubercles. The tips of fingers are orange, tan, or yellowish; the palms of its chelae are inflated and the dorsal surfaces of palms have tubercles (NCWRC 2005). It differs from other members of its subgenus by having a narrow areola, sometimes with long plumose setae on the opposable surface of the fixed finger of the chela of adults, and a disklike caudal knob on the gonopod of form I males (Cooper 2001).

Status

NatureServe (2024) identifies the rank as Vulnerable (S3) in North Carolina and South Carolina, and Vulnerable (G3) globally. Taylor et al. (2007) considered the species to be currently stable.

POPULATION SIZE AND DISTRIBUTION

The Rocky River Crayfish has been reported from the Catawba River basin in South Carolina, and from the middle Yadkin-Pee Dee, and upper Cape Fear and Neuse River basins in North Carolina; Cooper (2001) stated that this species likely has an even wider distribution. However, recent field surveys, coupled with extensive genetic analyses, indicate that the Rocky River Crayfish is restricted to a narrow stretch of the Pee Dee River basin, including the Rocky River, Little River, and Big Mountain Creek drainages (B.W. Williams, NCMNS, unpublished). As such, the species occurs in South Carolina only in Brown Creek, Chesterfield County, north of Pageland. It's presence from this creek has been confirmed (NCSM NMI Collection data)

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Rocky River Crayfish inhabits permanent freshwater creeks and streams (Cooper 2001). Little is known about specific habitat requirements and environmental tolerances of this species.

CHALLENGES

The highly limited distribution of this species in South Carolina makes it vulnerable to impacts from anthropogenic habitat alteration and spread of nonnative species from downstream areas.

CONSERVATION ACCOMPLISHMENTS

An increased understanding of the life history of this species, and assessment of potential threats to Brown Creek, and the species range-wide, would be an important accomplishment.

CONSERVATION RECOMMENDATIONS

Conduct surveys to establish an improved understanding of the entirety of the distribution of this species. Additionally, a study of the life history and microhabitat preferences of the Rocky River Crayfish would benefit the conservation of this species.

MEASURES OF SUCCESS

An increased understanding of the overall distribution and biology of the Rocky River Crayfish would be considered a success.

Saluda Burrowing Crayfish

Distocambarus hunteri

Photo by Dr. Zackary Graham

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2024): Eric Ng and Kathryn Schulz (West Liberty University)

DESCRIPTION

Taxonomy and Basic Description

Distocambarus hunteri was described by Fitzpatrick and Eversole in 1997. The genus was formerly a subgenus of *Procambarus*. The most closely allied species are the other members of the retained subgenus *Fitzcambarus*; *Distocambarus* (*F.*) *youngineri* and *D.* (*F.*) *carlsoni* (Crandall & De Grave, 2017; Fitzpatrick & Eversole, 1997; H. H. Hobbs, 1981). Efforts to delimit this species in the field have proven to be difficult, as the Saluda Burrowing Crayfish closely resembles the Piedmont Prairie Burrowing Crayfish [*Distocambarus* (*Distocambarus*) *crockeri* (H.H. Hobbs, 1983)], despite being more closely related to *D.* (*F.*) *youngineri*. Due to taxonomic complexity within this species and difficulties with morphological delimitation, phylogenetic revision is recommended.

The color of the Saluda Burrowing Crayfish is variable, from lighter brown in recently molted individuals to darker brown in older intermolts with purple occurring on some individuals. The thoracic sections are mottled and fade to reddish-brown posteriorly. The chelae are strongly depressed, and the palm is comparatively long, with the mesial margin of the palm being almost 45% the length of entire chela. The coloring of the chelae is ash-brown with dark brown tubercles and reddish tips. The species has small, pigmented eyes and can rarely have one spine or tubercle on the cervical groove of the carapace. Adult individuals examined in the process of describing this species ranged from approximately 35-58 mm (1.4-2.3 in.) in length (Fitzpatrick and Eversole 1997).

Status

NatureServe (2024) currently lists the Saluda Burrowing Crayfish as both globally endangered (G1) and state endangered (S1). Endangered status was recommended for this species by Taylor et al. (2007).

POPULATION SIZE AND DISTRIBUTION

The Saluda Burrowing Crayfish is a very rare, obligate burrower that is endemic to South Carolina. Historically, there are only 2 populations known, both of which are in the Saluda River Basin in Saluda County (Fitzpatrick and Eversole 1997). However, recent surveys suggest additional populations may occur within Saluda County, South Carolina. The few documented populations occur between the town of Saluda, SC and Lake Murray.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Fitpatrick and Eversole (1997) found both populations of *D.* (*F.*) *hunteri* in roadside drainage habitats with wet, sandy soils that support a high-water table. The dominate forest of the type

locality was an overstory of loblolly pine, red maple, willow oak, and American elm. This species is also known to dig burrows among root mats (Fitpatrick and Eversole 1997). Recent surveys suggest that they can be found in association with juncus, sedge, low-lying depressions and seepage areas.

CHALLENGES

Given its restricted distribution, *D.* (*F.*) *hunteri* should be protected. If the distribution of *D.* (*F.*) *hunteri* is as restricted as it appears, any developmental project in the vicinity of its range could result in localized extirpation of this species. The only published article concerning *D.* (*F.*) *hunteri* is the original description paper from 1997, making it difficult to discern the exact range and relevant threats this species obtains.

CONSERVATION ACCOMPLISHMENTS

South Carolina Department of Natural Resources is currently undergoing a three-year study to obtain more information on this species. In addition, the Saluda Burrowing Crayfish has achieved 'species of concern' status in the state and is now indicated to be a species of highest priority for South Carolina's SWAP.

CONSERVATION RECOMMENDATIONS

- Conduct surveys in the Saluda drainage to look for additional populations of *D.* (*F.*) *hunteri.*
- Investigate the need to initiate the process to achieve South Carolina special concern status for *D.* (*F.*) *hunteri*, based on survey results.
- Initiate the process to refine the taxonomy of *D. (F.) hunteri* in South Carolina.
- Preserve habitat where *D.* (*F.*) *hunteri* is found through conservation easements or land acquisition.

MEASURES OF SUCCESS

An updated taxonomic revision of the species would also be considered a sign of success. In addition, finding more populations of the species with no population losses would be considered a sign of success.

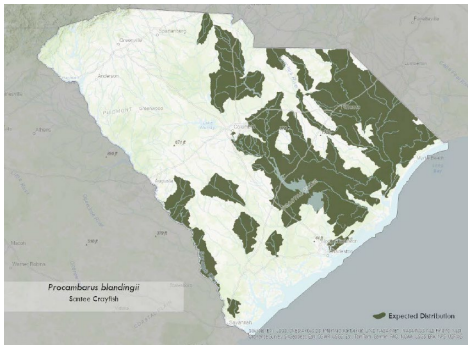
Santee Crayfish
Procambarus blandingii

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Greg Rothman and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



The Santee Crayfish is large and cylindrical in shape. It is tan, brown, and/or green with dark speckles or light mottling and slender chelae (NCWRC 2005).

Status

NatureServe (2024) currently identifies the Santee Crayfish with a ranking of vulnerable/ apparently secure (S3/S4) in North Carolina and apparently secure (S4) in South Carolina. The Santee Crayfish is considered apparently secure in North and South Carolina (Taylor *et al*. 2007; Simon, 2011).

POPULATION SIZE AND DISTRIBUTION

The Santee Crayfish is restricted to the Carolinas and found primarily in lentic waters of the Coastal Plain. Its range extends from the Lumber-Little Pee Dee River Basin in North Carolina to the Wateree-Santee River Basin in South Carolina. It is difficult to determine a detailed range map for this species, because *Procambarus blandingii* (Harlan, 1830) has often been confused with *P. acutus* and it is not known which records are identified correctly.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Santee Crayfish can be found in lentic and slow moving sections of lotic streams. It is usually associated with vegetation or woody debris when found in swamps (NCWRC 2005).

CHALLENGES

The taxonomic status of the Santee Crayfish, primarily in regards to the similarities with *P. acutus*, is one of the larger challenges surrounding this species, leading to little being known about its distribution or life history. Further research is needed on its range, population densities, and habitat associations. Additionally, the introduction of non-native species, such as the Louisiana Red Swamp Crayfish, *Procambarus clarkii*, have been shown to reduce *P. blandingii* abundance in areas of which *P. clarkii* are present (Kendrick *et al.,* in press). This alteration in population status highlights the need to understand how these introductions may impact native crayfish species like *P. blandingii*.

CONSERVATION ACCOMPLISHMENTS

Collections made during the South Carolina Stream Assessment (2006–2011) indicate that the Santee Crayfish is fairly common in the Coastal Plain, but little is known about its life history. Work was also completed examining impacts of the non-native *P. clarkii* on native crayfish

populations including *P. blandingii* in the Lower Pee Dee, Waccamaw and Winyah watersheds (Kendrick *et al.,* in press).

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the range, population densities, and habitat associations for the Santee Crayfish.
- Conduct taxonomic and genetic research comparing *P. blandingii* and the more common *P. acutus*.
- Identify threats posed (*i.e.* disease, resource competition) by the introduction of non-native species, like *P. clarkii*, to the Santee Crayfish.

MEASURES OF SUCCESS

The collection of data that better describes the range, population densities, habitat associations, genetic relatedness to other species of Procambarid crayfish and/or identifies threats to the Santee Crayfish may be considered measures of success.

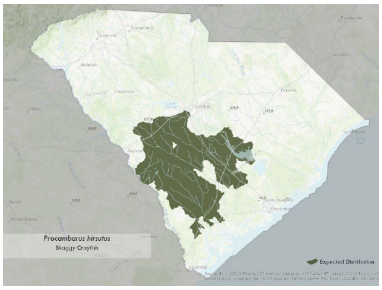
Shaggy Crayfish
Procambarus hirsutus

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Greg Rothman and Michael Kendrick (SCDNR)

DESCRIPTION

Taxonomy and Basic Description



The body of *Procambarus hirsutus* is dark brown with bright orange mottlings. The chelae are brownish-orange with black tubercles on the upper surface, and lighter tubercles on the lower surface. The rostrum of this species has marginal spines and is covered in the dense hairs at the base of the acumen that give the species its name: "hirsutus" means "shaggy" in Latin. The holotypic male measured 68.4 mm (2.7 in.) in length, while the allotypic female and morphotypic male are slightly smaller (Hobbs 1958). Specimens of *P. hirsutus* share many charateristics to specimens of its sister taxa, *P. pubescens*, a tribute to their genetic relatedness, who are often found together in the same environments (Brown, 1981).

Status

NatureServe (2024) identifies *P. hirsutus* with a rank of apparently secure (S4) in South Carolina, but more information is needed to determine if this ranking is appropriate. Taylor *et al.* (2007) and Simon (2011) considered the species to be currently stable in South Carolina.

POPULATION SIZE AND DISTRIBUTION

P. hirsutus is endemic to South Carolina and has been found in the Santee, Edisto, Salkahatchie and Savannah River Basins in Aiken, Allendale, Bamberg, Barnwell, Calhoun, Lexington, Colleton, Orangeburg, and Hampton Counties (Hobbs 1958, SCDNR stream assessment data). During stream surveys (2006–2011) it was abundant at about half of the sites where it occurred.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Procambarus hirsutus is found in clear streams with good flow (Hobbs 1989, W. Poly pers. obs.). Little else is known about its habitat requirements.

CHALLENGES

Little is known about *P. hirsutus*, and research is needed on all aspects of its biology before its conservation status can be determined. The restricted range of this species is cause for some concern, particularly with the potential overlap with non-native species, such as *P. clarkii*. Additionally, development in areas of which *P. hirsutus* are known to occur could alter population status.

CONSERVATION ACCOMPLISHMENTS

Collections of Shaggy Crayfish were made during the South Carolina Stream Assessment (2006–2011), but the known distribution was extended into only one additional county.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the range, distribution and habitat requirements for *P. hirsutus*.
- Identify threats to population status of *P. hirsutus* due to the introduction of non-native species, like *P. clarkii*, habitat alteration, and climate change.

MEASURES OF SUCCESS

The collection of data that better describes the range, distribution, and habitat requirements for *P. hirsutus* may be considered a measure of success.

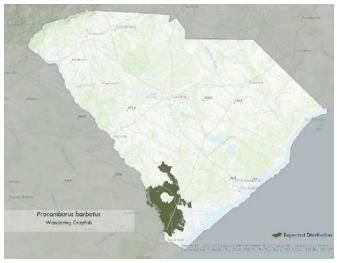
Wandering Crayfish
Procambarus barbatus

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Greg Rothman and Michael Kendrick (SCDNR)

DESCRIPTION



Taxonomy and Basic Description

Two color patterns have been observed for *Procambarus barbatus*. The "striped phase" has a dorsomedian longitudinal light stripe and a background color of light olive, olive-tan, pinkish-tan, or brown. The "speckled phase" has small irregular dark spots scattered over the carapace and dorsum of the abdomen and a background color similar to that of the striped phase. During the breeding season, males have a hairy tuft of setae on the mesial surface of the palm of the chelae (Hobbs 1981). Faxon (1890) examined several specimens that averaged 60 mm (2.4 in.) in length.

Status

NatureServe (2024) currently identifies the species with a ranking of apparently secure (S4) in South Carolina and secure (S5) in Georgia. The species was considered currently stable in Georgia and South Carolina (Taylor et al. 2007; Simon, 2011).

POPULATION SIZE AND DISTRIBUTION

P. barbatus is found in the Lower Coastal Plain from the lower Savannah River Basin in South Carolina to the Altamaha River basin in Georgia (Hobbs 1989). It has been collected in Hampton, Jasper, and Beaufort counties in South Carolina.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

P. barbatus is found in a fairly restricted habitat type: seasonal ponds and ditches in flatwoods. It lives in these lentic waters and will burrow to reach the water table when water levels become low (Hobbs 1981).

CHALLENGES

P. barbatus is fairly common in its preferred habitat but is restricted to ponds in flatwoods, which may be a threatened habitat. The hydrology of these seasonal ponds must remain intact with seasonal saturation of the area with open ground surrounding the pond, not dense vegetation. Anything that alters the hydrology of the soil could adversely affect the habitat of this species. It is possible that an appropriate fire regime is important to maintaining suitable habitat for this species. More research is needed to determine conclusively the soil and vegetation properties needed for this species' habitat and the effects of potential impacts. Based upon the restricted distribution and potential threats to its habitat, this species deserves some protection and should be considered a species of special concern.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments specifically for *P. barbatus* at this time.

CONSERVATION RECOMMENDATIONS

- Conduct research to determine the necessary soil and vegetation properties of the habitat required by *P. barbatus*. Once these properties have been investigated, determine whether their habitat will be adversely impacted by activities in the vicinity of the habitat.
- Conduct additional surveys to determine the distribution and abundance of *P. barbatus*.
- Based on surveys, investigate the need to update the state ranking for *P. barbatus*.

MEASURES OF SUCCESS

Collection of data that better describes the habitat requirements for *P. barbatus* may be considered a measure of success.

Alosines Guild

American Shad *Alosa sapidissima*
Hickory Shad *Alosa mediocris*
Blueback Herring *Alosa aestivalis*

Contributors:
(2005) John W. McCord [SCDNR]

Revised 2015:
Allan Hazel, Bill Post, Brock Renkas, Corbett Norwood, Jarrett Gibbons, and Elizabeth Miller [SCDNR]

Revised 2025:
Claire Benson, Bill Post, Ellen Waldrop, and Joey Ballenger [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The American Shad, Alosa sapidissima belongs to the herring family, Alosidae (Page et al. 2023). It is the largest Atlantic Coast member of the family, with females in South Carolina reaching about 66 cm (26 in.) in total length (TL). Sexually mature female American Shad, often called “roe shad” because of the large, highly prized ovaries, rarely attain more than 3 kg (7 lbs.). Mature male shad, or bucks, are generally smaller than females, rarely exceeding 2 kg (4.5 lbs.). American Shad, like other alosines and most members of the Alosidae, are laterally compressed, with relatively large scales. Scales on the midline of the underside form sharp scutes that produce a saw-toothed ridge. Coloration is dark bluish, greenish, or bronze on the back; silvery on the sides; and white below, and varies depending on color and turbidity of water. The mouth is near the midline of the snout, and a series of several dark spots usually extends backward to below the dorsal fin from near the operculum and pectoral fin. The fins are dark and without spines while the tail is deeply forked.

Most spawning shad in South Carolina are between 3 and 6 years old, with males averaging about a year less than females. Shad migrate several hundred miles or kilometers inland in large river basins and arrive in South Carolina from mid-January through mid-May. Peak spawning activity is water temperature-dependent, but generally occurs during March and April. Shad are sequential or batch spawners, with groups of eggs released as the fish move upriver. Eggs are semi-buoyant and drift in the water column when flows and depth are appropriate. Eggs usually hatch within a few days into tiny larvae that soon transform into small juveniles. Juveniles closely resemble adults but are generally have a more silver color, typically reaching only 10 to 12 cm (4 to 5 in.) TL before they move toward the ocean to complete growth and maturation, usually after about one year of development in the rivers, sounds and bays. However, some

juveniles remain within the Santee-Cooper Lakes at least until the summer of their second year. This is presumably because of difficulties in using out-migration options, some of which are not functional when outflows are limited due to low lake levels (D. Cooke, SCDNR, pers. comm., 2005;USFWS 2017).

Juvenile American Shad feed primarily on small invertebrates, including insect larvae and zooplankton. Adult shad prefer larger zooplankton and rarely feed while in freshwater as they are thought to die after their initial spawning run. Both out-migrating juveniles and adults that survive spawning generally move into the Atlantic and migrate into coastal areas of Maine and southern Canada where they mingle with shad from all Atlantic populations and prey primarily on abundant zooplankton. By fall, the vast conglomerate population migrates south and overwinters off the Mid-Atlantic States. Sexually mature fish then disperse up or down the coast to their respective rivers as late winter and spring water temperatures moderate and become ideal for spawning (Neves and Depres 1979; McCord et al. 1987; Greene et al. 2009).

The Hickory Shad, *Alosa mediocris* (Mitchill 1814), also belongs to the herring family, Alosidae (Page et al. 2023). It is smaller than the American Shad, with females in South Carolina reaching about 55 cm (22 in.) TL. Sexually mature female Hickory Shad, often called “roe jacks”, also carry highly prized ovaries, but rarely attain more than 2 kg (4.5 lbs.). Adult male Hickory Shad are usually smaller than females, rarely exceeding 1 kg (2.2 lbs.). Hickory Shad are shaped much like American Shad and also have large scales. General coloration is greenish or bronze on the back, silvery on the sides, and white below. A small, indistinct spot can usually be seen beneath each lateral scale. The mouth is nearer the top of the snout than in American Shad. Several dark spots usually extend backward to below the dorsal fin from near the operculum and pectoral fins. The fins are dark and spineless while the tail is deeply forked. Juvenile Hickory Shad resemble adults, but are less distinctively marked. Juveniles usually emigrate from inland habitats by early winter at approximately 15 cm (6 in.) TL. Larval and smaller juvenile fishes are primary dietary items for juvenile Hickory Shad.

Adult Hickory Shad migrate and spawn earlier than American Shad and Blueback Herring; Hickory Shad move inland from December through mid-April. Peak spawning for Hickory Shad in South Carolina is during February and early March. Hickory Shad typically spawn along channel edges of tidally influenced freshwater river reaches, usually within 80 km (50 mi.) of the ocean. Otherwise, the general life cycle is similar to the American Shad with a few exceptions. Most Hickory Shad are believed to survive after spawning, presumably because they feed primarily on small fishes that are generally available in inland habitats. Hickory Shad apparently concentrate farther south, principally from Delaware Bay to New England coastal inlets, where they feed primarily on small fishes (ASMFC 1999, Greene et al. 2009).

The Blueback Herring, *Alosa aestivalis* (Mitchill 1814), is the smallest alosine in the Southeast. Adult female Blueback Herring in South Carolina reach about 31 cm (12 in.) TL and weigh 0.3 kg (0.7 lbs.); while the slightly smaller mature males approach 28 cm (11 in.) TL and weighs 0.27 kg (0.6 lbs.). Adult Blueback Herring are shaped and marked much like American Shad. Juveniles, which usually emigrate to the ocean by mid-winter, resemble tiny adults and are about 10 cm (4 in.) TL.

Timing of inland migration, spawning and development of Blueback Herring closely follows patterns for American Shad. However, Blueback Herring typically spawn in freshwater marshlands or small tributaries. Small zooplankton constitute much of the juvenile diet. Post-spawning survival rates are not well known for Blueback Herring, but probably exceed those for American Shad. Migratory routes and timing of Blueback Herring are similar to those for American Shad. During the spawning migration, Herring move inland at distances intermediate to characteristics described for Hickory and American Shad. The distance that Herring move upriver may be partly dependent upon the availability of habitats with suitable substrates for egg adhesion nearer the coast (Loesch and Lund 1977).

During all life stages, alosines contribute greatly to the dynamics of food chains in freshwater, estuarine or marine habitats (Facey et al. 1986; MacKenzie et al. 1985; Weiss-Glanz et al. 1986). While at sea, alosines are prey for many species including sharks, tunas, mackerel and marine mammals, including porpoises and dolphin (Weiss-Glanz et al. 1986; ASMFC 1999). In fresh and brackish waters, both adult and juvenile alosines are consumed by American Eel and Striped Bass (Facey et al. 1896; Mansueti and Kolb 1953; Savoy and Crecco 1995; Walburg and Nichols 1967). Juvenile Herring are high quality prey for Largemouth Bass (Micropterus salmoides); accelerated growth of young bass occurs when Herring consumption is high (Yako et al. 2000). Tissues taken from predatory fish in tidal freshwaters following the residency of migrating alosines had between 35 and 84% of their carbon-biomass derived from marine sources (Garman and Macko 1998; MacAvoy et al. 2000). East Coast alosines, particularly populations in the Southeast where post-spawning mortality is highest, likely provide nutrients and carbon into riverine systems, similar to nutrient dynamics provided by salmon in the Pacific Northwest (Freeman et al. 2003). For example, the James River in Virginia may have received annual biomass input from alosines of 155 kg/ha (138 lbs./ac.) before dams blocked migrations above the fall line (Garman 1992).

More than 40 species of birds and mammals congregate to feed on migrating anadromous fish in southeastern Alaska (Willson and Halupka 1995; Willson et al. 1998). Similar relationships likely occur between East Coast alosines and birds and mammals. Fish-eating birds like Osprey (Pandion haliaetus) and Bald Eagle (Haliaeetus leucocephalus) prey upon alosines (J. W. McCord, pers. obs.) and may have evolved their late winter and spring nesting strategies in response to the availability of food resources supplied by pre and post-spawning alosines. In

addition, nutrients released from carcasses of post-spawning alosines can substantially subsidize aquatic food webs by stimulating productivity of bacteria and aquatic vegetation (Kline et al. 1993; Richey et al. 1975), thereby stimulating the assimilation of marine-derived nutrients into aquatic invertebrates and fish (Bilby et al. 1996).

Status

American Shad, Hickory Shad and Blueback Herring are experiencing coast-wide reductions in all stocks compared to historical populations (ASMFC 2020; ASMFC 2024). Current spawning runs of East Coast North American shad populations have been reduced to 10% of historical sizes and have been extirpated from over 4,000 km (2,500 mi.) of riverine habitat (Limburg et al. 2003). Several alosine stocks (riverine populations) are of unknown status because no directed studies have been conducted. Hickory Shad population status is very poorly known for South Carolina and historical data are virtually absent. The species is apparently not plentiful anywhere within South Carolina. Populations of Blueback Herring in the Waccamaw-Pee Dee and Santee-Cooper are presumably secure, though undoubtedly reduced from historical levels predating dams. Blueback Herring populations for other drainages are perceived to be of poorer status, and perhaps absent. Because of these declines in current stocks, the Atlantic States Marine Fisheries Commission (ASMFC) made the additions of Amendments 2 and 3 to the Shad and River Herring Fishery Management Plan. These amendments state, among other things, that participating states must submit and have approved river-specific sustainability fishing management plans (SMFP) for American Shad and Blueback Herring. These plans must demonstrate, by using targets, how fisheries are sustainable. If sustainability targets are not met or states cannot demonstrate a given river is sustainable, then fisheries on that river must be closed. South Carolina submitted both SFMPs (shad and herring) in 2010 and 2011, and updates for both species again in 2020. Plans and updates have both been accepted by the ASMFC Shad and Herring Board. Sustainability targets, using 75% of the mean in most cases, were set for all rivers where fisheries occur, and those systems where no fishing occur or no data were available have been closed. In addition, on August 5, 2011, the Natural Resources Defense Council submitted a petition to NOAA requesting that the agency consider river herring (Alewife and Blueback Herring) for listing under the Endangered Species Act. In response, NOAA made a determination in 2019 that Alewife and Blueback Herring did not warrant listing under the Endangered Species Act.

POPULATION SIZE AND DISTRIBUTION

American Shad occurs along the Atlantic coast from the Bay of Fundy in Canada to the St. Johns River in Florida. The historical range of Hickory Shad is very similar, from the Bay of Fundy in Canada to the Tacoma River in Florida, but current distribution is uncertain with known occurrence as far north as Connecticut (ASMFC 1999). Blueback Herring are distributed from Nova Scotia to northern Florida, though they are most abundant from the Chesapeake Bay and south (Scott and Scott 1988). In South Carolina, all three species are presumed to occur as unique populations by coastal river system with a minimum of eight populations (presumably for all three species): Waccamaw-Pee Dee, Santee-Cooper, Ashley, Edisto, Ashepoo, Combahee, Coosawhatchie, and Savannah drainage Basins. Relatively unique populations likely occur in the

major tributaries within the Waccamaw–Pee Dee Basin, including Waccamaw, Little Pee Dee, Great Pee Dee, Lynches, Black, and Sampit Rivers.

Historical population estimates are nonexistent, but historical distribution records (USFWS 2001) and anecdotal information on abundance strongly indicates that all populations of alosines in South Carolina are reduced compared to historical levels (early 20th century and before). American Shad and, to a lesser extent Blueback Herring, historically ascended large river basins of the State (Waccamaw-Pee Dee, Santee, and Savannah) well inland of the Fall Line and into North Carolina and Georgia (USFWS 2001).

Trends in American Shad stocks have been primarily monitored by observations in commercial gill-net fishery catch rates since 1979. Based on these trends, American Shad populations in the Waccamaw-Pee Dee Basin and Savannah River have remained relatively stable and healthy over the past 25 years, though almost certainly below levels of a century past and showing some signs of decline within the last 5 years (McCord 2003, Post and Waldrop 2023).

Fortunately, the lowermost dams on both Savannah and Waccamaw–Pee Dee Basins are approximately 300-river km (200 mi.) from the ocean, so spawning habitat is available below primary barriers. However, historical alosine spawning migrations in these basins extended beyond the point of these dams (USFWS 2001). Anecdotal information indicates that both Blueback Herring and Hickory Shad occur in the Savannah in small populations. Dam-locked populations of Blueback Herring now occur in several reservoirs, including Lakes Thurmond, Russell, and Hartwell. Hickory Shad may have also become dam-locked in Savannah Basin reservoirs, but spawning has not been recorded (D. Cooke, SCDNR, pers. comm. 2005).

The Santee-Copper American Shad population has grown substantially since 1985 and is among the largest on the Atlantic coast, with the population likely approaching one million adults annually (McCord 2003). The Blueback Herring population was estimated to average over 6 million in the 5 years following the rediversion of flows (Cooke and Leach 2003), and may be larger now following almost 20 years of increased flows and fish passage. Both American Shad and Blueback Herring populations in the Santee-Cooper Basin have responded well to existing fish passage protocols and increased flows.

Hickory Shad population status is poorly understood; however, based on anecdotal observations, the Santee-Cooper population is among the largest in the State, despite very low passage numbers recorded at St. Stephen Dam (Cooke and Leach 2001).

Among the ACE Basin rivers, Edisto River's shad populations apparently declined dramatically through the early 1990s, with overfishing indicated as a primary cause (McCord and Ulrich 1991). Directed management through restrictive commercial fishery regulations enacted in 1993 and a decline in the number commercial fishers has apparently promoted an increased population as indicated by improved catch rates for gill-net fishers (McCord 2003). However, this stock is considered to be in guarded condition until additional monitoring can better indicate stock status (McCord 2003; Post and Waldrop 2023). The Combahee River shad population was categorized as substantially declined in the late 1990s, presumably from an extended period of overfishing (McCord and Ulrich 1994; McCord 2003). Restrictive commercial fishery guidelines were

established in 2000 and should allow for growth of this stock. The status of the American Shad population in the Ashepoo River, the smallest of the ACE Basin rivers, is unknown. Relatively few records exist for either Hickory Shad or Blueback Herring in the ACE Basin. Both species are presumed to occur in very small populations.

Both Ashley and Coosawhatchie Rivers are small, Coastal Plain drainages that historically supported limited commercial American Shad fisheries. The current status of these populations is also unknown. Commercial fishing activity was restricted substantially for the Ashley and banned for the Coosawhatchie since fishery laws were revised in 2000 in accordance with Act #245 of the 2000 South Carolina General Assembly. Further restrictions to these fisheries occurred as part of requirements in the SC's SFMP for the species (SCDNR 2020). The status of alosine stocks in these small rivers, including whether any Hickory Shad and Blueback Herring are present, is unknown.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Because of the highly migratory nature of alosines, these fishes require access to an expansive variety of high-quality freshwater and marine habitats. Within state waters, adults migrate through nearshore Atlantic shelf waters and enter coastal sounds, bays and inlets to access the river basins in which they spawn. Eggs of American Shad and Hickory Shad require adequate flows (generally 0.15 to 0.9 m/sec. or 0.5 to 3.0 ft./sec.) and sufficiently low sediment loads to keep eggs adrift until hatching (ASMFC 1985; Mansueti 1962; Williams and Bruger 1972). In river reaches where flows and/or water depth are not sufficient to keep eggs suspended, the semi-buoyant eggs sink to the bottom and roll or bounce on hard substrates, but may be suffocated in areas with siltation (Massmann 1951; Williams and Bruger 1972). Successful spawning of Blueback Herring is partly dependent upon the availability of relatively clean vegetation and other substrates outside and at the periphery of river channels for egg adhesion and development with relatively low turbidity or suspended sediments (Christie et al. 1981). Christie et al. (1981) found high utilization of tidal, freshwater breached impoundments, or relict rice-fields as Blueback Herring spawning habitat in the Cooper River Basin.

American Shad require high, but stable flows of high-quality water for spawning and early nursery habitats (Crecco and Savoy 1987). Nursery habitats for American and Hickory Shad include all channel and adjacent out-of-channel submerged habitats from a few kilometers or miles seaward to estuarine sounds and bays of river basin deltas. Larval and early juvenile Blueback Herring are associated more with the floodplain small tributaries and marshlands where spawning occurs, but older juveniles move into the same riverine and estuarine habitats used by American and Hickory Shad (Greene et al. 2009). Where fish passage venues provide access into reservoirs, juveniles of all three species apparently successfully utilize artificial lake and tributary habitats as nursery areas as development continues (D. Cooke, SCDNR, pers. comm. 2005, Post et al. 2023).

Abundant sloughs and flats with submerged vegetation are generally available in reservoirs, providing excellent spawning habitat for Blueback Herring. During fall and winter, juvenile American Shad and Blueback Herring tend to co-occur predominantly in deeper, channel habitats of estuarine systems, while Hickory Shad juveniles are more frequently encountered in shallow

expanses of sounds and bays (J. W. McCord, pers. obs., Post et al. 2023). These variant distributions are likely reflective of differences in food preferences, as small crustaceans used by American Shad and Blueback Herring are generally abundant near the bottom in estuarine channels, and small fishes preferred by Hickory Shad are likely more numerous in shallower habitats adjacent to marshlands.

CHALLENGES

Obstructed access to a diversity of habitats may limit basin-specific alosine populations. Dams prevent upstream migration of alosines and other species (ASMFC 1985; ASMFC 1999; USFWS 2001; USFWS 2017). Atlantic streams from Maine to Florida have undergone a restriction or loss of access for migratory fishes to about 84% of stream habitat within historic ranges from dams alone (Busch et al. 1998;USFWS 2001). The Waccamaw-Pee Dee, Santee-Cooper and Savannah Basins in South Carolina are impacted by dams that restrict migrations of alosines into historical habitats (USFWS 2001). Dams and other impediments to migration have eliminated alosines from many historical habitats in South Carolina (USFWS 2001); the result being a general reduction in alosine populations even in currently accessible river reaches. The ecosystem effects of this loss are difficult to identify (Power et al. 1996), but ecological roles for alosines may be greatly diminished (Garman and Macko 1998). For example, many freshwater mussels are dependent upon migratory fishes as hosts for their parasitic larvae and are presently among the most imperiled freshwater fauna (Neves et al. 1997; Vaughn and Taylor 1999), with about 29 species of conservation concern in South Carolina.

The Santee Basin has the second largest drainage area and total discharge (only the Susquehanna is larger) of all river systems on the East Coast of the US (Hughes 1994). However, this large watershed has been adversely affected by damming to a greater extent than most basins on the Atlantic Coast of North America, with nearly 45 dams in the South Carolina portions of the Basin alone (USFWS 2001). The original Santee-Cooper diversion project, completed in 1942, shifted approximately 88% of the historical Santee River flow into the Cooper River, changing the average Cooper River flow rate from 2 cubic meters per second (cms) or approximately 7 cubic feet per second (cfs) to 442 cms (1,560 cfs) (Kjerfve 1976). Prior to rediversion in 1985, water releases at Pinopolis Dam on the Cooper River were generally continuous. A weekly average flow of 122 cms (430 cfs) has been maintained in the Cooper River since rediversion to protect water supplies (Orlando et al. 1994), but generation time has been restricted to as little as 10 hours per day. Tidal freshwater marshes along the Cooper River (many of which are relic rice impoundments with breached or eroded dikes), which were used extensively as spawning habitat by Blueback Herring prior to rediversion of flows into the Santee River (Christie et al. 1981), are less extensive under reduced flows. Many are now partly dewatered or influenced by brackish water. Available fish passage and commercial fishery data indicate that the Herring population has declined dramatically since flows were rediverted, presumably because of a reduction in the amount, and perhaps quality, of spawning and nursery habitat (Cooke and Eversole 1994).

The original diversion of Santee River historical flows into the Cooper River caused average freshwater flow in the Santee River seaward of Wilson Dam to drop from 525 to 74 cms (1,850 to 260 cfs), and allowed saltwater intrusion (Kjerfve and Greer 1978). The Santee-Cooper Rediversion Project returned about 70% of the Cooper River flow to the Santee, increasing average flow to approximately 367 cms (1,290 cfs) and reducing salinity in the lower Santee (Orlando et al. 1994). However, there is no minimum flow requirement at St. Stephen Dam on the Rediversion Canal (D. Cooke, SCDNR, per. comm., 2005) and the average daily flow from Wilson Dam is only about 18 cms (63 cfs) (Orlando et al. 1994).

During periods of low inflow into the Santee-Cooper Lakes, water releases can be discontinued at St. Stephen Dam (D. Cooke, SCDNR, per. comm., 2005). In contrast, the average daily discharge from Wilson Dam can approximate 500 cms (1760 cfs) during flood-control releases (Orlando et al. 1994). The resulting flow regimens in both the Cooper and Santee Rivers is typically in highs and lows (with more abrupt changes from peaked power generation and flood releases) than are characteristic of more gradual river flow changes that occur in open rivers where waters expand into, and withdraw from, floodplains.

With the construction of the Santee-Cooper Lakes (Moultrie and Marion) in the 1940s, the vast majority of the Santee was closed to migratory fishes (USFWS 2001). Both the Pinopolis navigational lock and St. Stephen fish passage facility are currently used for alosine passage. Passageways at both facilities provide passage for Blueback Herring and American Shad (Timko et al. 2003). The efficiency of passage at St. Stephen Dam for Blueback Herring and American Shad is low (Cooke and Leach 2001;Post and Waldrop 2023).

Fish passage designs and flow protocols currently used at dams on the lower Santee-Cooper Basin were initially designed for passing Blueback Herring into the lakes for forage and do not maximize passage efficiency for alosines in either direction (Cooke and Leach 2001; D. Cooke, SCDNR, pers. comm. 2005). Dams on the Santee-Cooper Basin, that currently incorporate passage for alosines, do not employ methodologies that accommodate timely outmigration and maximized survival of post-spawning adults or emigrating juveniles. Delayed outmigration of juvenile alosines, as occurs in the Santee-Cooper Lakes, may result in increased mortality of juveniles from artificially high predation and from potential capture for bait since fish become concentrated near dams for an extended period of up to several months. In open rivers, juveniles gradually move seaward in groups that are likely spaced according to the spatial separation of spawning and nursery grounds (Limburg 1996; J.W. McCord, SCDNR, pers. obs.;Post and Waldrop 2023). Delayed outmigration not only concentrates juvenile alosines, but extends their stay in freshwater areas until moderating water temperatures of late spring and early summer induce more active feeding behavior for many freshwater piscivores. Delayed outmigration may also increase vulnerability of juveniles to marine predators that would otherwise be absent from coastal waters if juveniles were able to adhere to natural migration patterns. According to the ASMFC Interstate Fishery Management Plan (IFMP) and Amendment 1 to the IFMP, a fish passage program for alosines is only legitimate if downstream passage is an integral part of such operations (ASMFC 1985, 1999).

Dams, and in particular hydropower dams, often produce flow regimens that are not reflective of natural seasonal flows. Pulse flows used for peaking hydropower production can disrupt natural productivity and availability of zooplankton needed for larval and early juvenile forage (Crecco and Savoy 1987; Limburg 1996), can displace eggs and/or larvae from otherwise highly productive habitats, and can disrupt both upstream and downstream migration patterns for adult and juvenile alosines (ASMFC 1985; ASMFC 1999; Limburg 1996; USFWS 2001). Dams may also reduce minimum flows, potentially dewatering otherwise productive habitats, thus causing increased water temperature, or contributing to or exacerbating poor water quality such as reduced dissolved oxygen (ASMFC 1985; ASMFC 1999; NMFS 1998; USFWS 2001). Water releases from deep reservoirs may be poorly oxygenated and/or of below normal seasonal water temperature, thereby causing loss of suitable spawning or nursery habitat in otherwise suitable river reaches (ASMFC 1985; NMFS 1998; ASMFC 1999; USFWS 2001). Further, impounded marshlands in freshwater river reaches prevent access of Blueback Herring to potential spawning and early nursery habitat.

Large concentrations of Double-crested Cormorants (*Phalacrocorax auritus*) and White Pelicans (*Pelecanus erythrorhynchos*) occur immediately below some dams, particularly below those with fish passage and during the winter-spring season of alosine passage (J.W. McCord, SCDNR, pers. obs.; Post and Waldrop 2023). The cormorant population has increased dramatically over the past decade (Wires et al. 2001), and these birds have been shown to feed heavily on alosines (Johnson et al. 1999). Small alosines can comprise up to 64.5% of the cormorant's diet (Johnson et al. 2000). Although the impact of cormorant predation on alosine populations has not been quantified, it appears that cormorants have the potential to negatively impact both upstream passage success for Blueback Herring and out-of-lake passage for all juvenile alosines.

Competition and predation from non-native species, in particular Flathead Catfish (*Pylodictis olivaris*) and Blue Catfish (*Ictalurus furcatus*), may be additive to 'more natural' sources of mortality and may be particularly problematic below dams where catfish density is often high (J.W. McCord, SCDNR, pers. obs). Even adult American Shad have been observed in the diet of large flathead catfish (D. Allen, SCDNR, pers. comm.), and both non-native catfishes are presumed to be problematic to alosines as both competitors and predators (NMFS 1998).

Dredging can also negatively affect alosine populations by producing suspended sediments (Reine et al. 1998). Behaviorally, chronic turbidity from frequent or prolonged dredging can also affect fish migration, spawning, conspecific interactions, and foraging (Coen 1995). Migrating alosines are known to avoid waters of high sediment load (ASMFC 1985; Reine et al. 1998). Suspended sediments have been linked to a variety of lethal and sublethal responses in juvenile and adult fishes that are consistent with oxygen deprivation due to gill clogging (Sherk et al. 1975; Sherk et al. 1974). Filter-feeding fishes such as alosines are particularly susceptible to negative impacts of suspended sediments on gill tissues (Cronin et al. 1970). Siltation from dredging and from agricultural, silvicultural, and other land use practices can reduce spawning success by causing mortality of eggs or by coating substrates needed for attachment of adhesive eggs (NMFS 1998). Suspended sediments, whether caused by dredging or by erosion from land use practices, can also cause reduced feeding success in larval or juvenile fishes that rely on

visual cues for plankton feeding (Kortschal et al. 1991). Larval striped bass (Morone saxatilis) consumed 40 percent less prey when suspended solids exceeded 200 milligrams per liter (mg/L) (Breitburg 1988). Survival of larval alosines decreases as turbidity or suspended sediments increases above 50 mg/L (Auld and Schubel 1978).

Dredging may negatively impact prey availability by removing benthic invertebrates within sediments, by increasing suspended sediments, or by producing changes in salinity or dissolved oxygen regimens (ASMFC 1990). Sediment resuspension from dredging can cause increased turbidity and localized depletion of dissolved oxygen, as well as increased bioavailability of any contaminants that may be bound to these sediments (Clarke and Wilber 2000). The eggs and larvae of estuarine and coastal fishes appear to be among the most sensitive to suspended sediment exposures of all the taxa and life history stages for which data are available (Clarke and Wilber 2000). High concentrations of suspended sediments, as well as relatively low concentrations sustained for several days, have been shown to cause direct mortality, impaired hatching success, reduced larval feeding, and diminished larval growth in several species of estuarine and anadromous fishes (Clarke and Wilber 2000). Waters with high suspended sediment are unproductive for primary and secondary portions of the food pyramid on which juvenile alosines feed, and changes in salinity regimens can dramatically impact prey distribution (ASMFC 1990).

Pollution from point and non-point sources is a primary cause of reduced habitat quality and aquatic species viability in tidal systems. Land use practices such as agriculture and logging, as well as residential, commercial and industrial development, greatly influence the input of chemicals and nutrients into waterways and are the primary sources of increased siltation. All of these factors contribute to eutrophication and a general decline in water quality, including a reduction in dissolved oxygen as previously mentioned. Sediments and pesticides most commonly enter coastal waters in run-off from agricultural and silvicultural lands, and discharges into coastal habitats, thereby causing drastic adverse impacts on aquatic life (Butler 1968). In addition to sediments, run-off from uplands includes nitrates, phosphates, herbicides, pesticides, silt and other chemicals, any of which either acting alone or in combination with other pollutants can be lethal to aquatic life, and particularly to larval forms (Matthews et al. 1980). Chemicals and heavy metals from industrial and other sources that do not cause acute toxicity can be assimilated through the food-chain and can produce sub-lethal effects including behavioral and reproductive abnormalities (Matthews et al. 1980). Pollution from contaminants such as pesticides can directly produce mortality, can lower pH that may reduce egg and larval survival (Klauda 1994), and can contribute to reduced oxygen levels. All of the potential impacts of sediment resuspension and increased turbidity due to dredging (described in detail above) would also apply to sediments derived from upland sources.

Deforestation of swamps potentially leads initially to increased soil and water temperature (Aust and Lea 1991; Perison et al. 1993), siltation from increased erosion and runoff (Aust et al. 1997), decreased dissolved oxygen (DO) (Lockaby et al. 1997), and disturbance of food-web relationships in adjacent and downstream waterways (Batzer et al. 2005). Forestry BMPs for bottomland forests are voluntary. When BMPs are not used, braided streams may be obstructed

by plant material and disturbed soils while excessive ruts may channel eroded sediments into streams. Partially stagnated waters may become nutrient-rich and promote algal growth that can die under extended periods of cloud-cover (J.W. McCord, SCDNR, pers. obs.). Siltation from agricultural, silvicultural, and other land use practices can reduce spawning success by causing entrapment and mortality of semi-buoyant eggs (Mansueti 1961). Siltation also causes increased water temperature and reduced DO, and can result in reduced productivity beginning at lower levels of food-chain relationships on which juvenile alosines are dependent (Mansueti 1961).

Siltation, from erosion due to land use practices or from dredging, physically covers and kills some aquatic life, including submerged aquatic vegetation (SAV) and thereby increases biological oxygen demand (BOD). SAV provides important ecological functions in freshwater habitats. SAV improves water quality (Rybicki and Hammerschlag) and provides habitat for predator avoidance, foraging, and nursery development for many macro-invertebrates and resident and migratory fishes (Maldeis 1970; Killgore et al. 1989; Monk 1988). SAV can also provide important spawning habitat or substrate for Blueback Herring (Christie et al. 1981). SAV is adversely affected by suspended sediments less than 15 mg/L (Funderburk et al. 1991) and by deposition of excessive sediments (Valdes-Murtha and Price 1998).

Dewatering of freshwater streams from irrigation and other water removal projects decreases instream flows and decreases the quantity of both spawning and nursery habitat. Dewatering can also result in reduced water quality from the impacts of more concentrated pollutants and/or increased water temperature (ASMFC 1985). Density-dependent impacts such as predation and competition may also increase. Further, mortality of eggs, larvae, and/or juvenile alosines can occur due to impingement and entrainment in water intakes at water removal projects and in turbines in dams (ASMFC 1985).

By-catch from ‘non-game’ gill-nets may exert excessive mortality on Hickory Shad. Participants in this late winter fishery have reported that numerous Hickory Shad are caught in these nets (J.W. McCord, SCDNR, pers. obs.). Further, Hickory Shad are not generally segregated from American Shad in commercial catches nor are they easily differentiated in fish passage counts. These factors prevent the collection of reliable fishery-dependent and fishery-independent data collection as needed to properly manage Hickory Shad populations. Mortality from directed fisheries and/or from by-catch in other fisheries outside of the State’s jurisdiction may negatively impact South Carolina stocks of alosines, including fisheries within the Exclusive Economic Zone (that portion of the Atlantic Ocean under federal jurisdiction from 3 to 200 mi. offshore) and within Canadian waters (ASMFC 1985; ASMFC 1999).

CONSERVATION ACCOMPLISHMENTS

The first river-specific, restrictive, commercial gill-net fishery regulations (Act # 343 of the 1992 South Carolina General Assembly) were enacted in 1993 for the Edisto River after SCDNR studies indicated overfishing was a major contributor to a perceived trend of population decline (McCord and Ulrich 1991). In 2000, laws and regulations were revised to be more responsive to individual perceived population status by drainage basin or river system (Act #245 of the 2000 South Carolina General Assembly). The Coosawhatchie River shad population received the most

protection, as the river was closed to commercial gill-nets (Act #245 of the 2000 South Carolina General Assembly). The amount of potential gill-net fishery effort was substantially reduced for other small, more imperiled stocks, including those in the Combahee, Ashepoo and Ashley Rivers (Act #245 of the 2000 South Carolina General Assembly).

Coast wide IFMPs has been developed for the alosines under the auspices of the Atlantic States Marine Fisheries Commission (ASMFC 1998). The original ASMFC IFMP for Shad and River Herring was completed in 1985 and was amended in 1999. The 1999 Amendment 1 to the ASMFC IFMP required all member states to close directed fisheries for American Shad in coastal Atlantic Ocean waters by 2005 through a phase-out process initiated in 2000 (ASMFC 1999). Addenda to the IFMP were also approved in 2000 and 2002 (ASMFC 2000; ASMFC 2002). The Atlantic Coastal Fisheries Cooperative Management Act (ACFCMA) of 1993 requires states to adopt management guidelines as mandated by approved ASMFC IFMPs, including the conduct of surveys in selected South Carolina rivers and the monitoring of catch and effort for commercial and recreational fisheries for alosines (ASMFC 1999).

The ASMFC IFMP also required that by the year 2000, states were to limit recreational harvest through the establishment of a possession limit not to exceed an aggregate of 10 American and Hickory Shad per angler per day. Through legislative action, South Carolina established a 10-fish limit in 2000 for all State waters, except for the Santee River and Rediversion Canal, where a 20-fish limit was allowed under a conservation equivalency adjustment.

Additionally, as mentioned above, ASMFC required states' to develop and submit SFMPs for both American Shad and Blueback Herring. Implementation of these plans led to a 50% reduction of allowable fishing gear in all waters of the state and up to a 90% reduction for specific rivers. Legal fishing days during the season were also adjusted earlier to account for and reduce by-catch of sturgeon. This change led to a noticeable reduction in effort later in the season, when water temperatures rise and post release delayed mortality increases.

Passage at all types of dams and other barriers to migration is strongly recommended by the ASMFC IFMP. Many dams in South Carolina are currently, or soon will be, undergoing Federal Energy Regulatory Commission (ERC) re-licensing processes; these processes will include considerations for improved access and migration of aquatic species. Existing passage systems and Herring populations in the Santee River.

CONSERVATION RECCOMENDATIONS

- Conduct statewide surveys of alosine distribution and population size, particularly for small rivers where stock status is unknown or perceived as poor, in order to make prioritized decisions for restoration and passage.
- Determine passage and outmigration efficiency for all alosines at existing facilities so potential changes in protocols or designs can be identified.

- Inventory sources of mortality, including existing outlets providing outmigration through dams and bycatch in commercial fisheries; formulate remedies where practical.
- Improve quality and scope of coverage for mandatory catch and effort records, for both recreational and commercial fisheries.
- Determine how often Hickory Shad is misidentified as American Shad or Blueback Herring.
- Investigate impacts of logging in swamp forests on water quality and habitat, especially as related to Blueback Herring.
- Determine impacts of dewatering of freshwater streams on aquatic species.
- Conduct studies on the energetics and nutrient dynamics related to food-chain relationships and spawning migrations of alosines.
- Determine genetic relationships, or extent of homing, of alosines relative to tributary streams (particularly in the Waccamaw-Pee Dee Basin).
- Determine impacts of competition and predation from non-native species, particularly below dams where alosines passing through existing outmigration routes may become stunned or disoriented, exacerbating predation impacts. To the extent possible, control and prevent further distribution of non-native Blue and Flathead Catfish populations.
- Partner with federal authorities to create on-board observer programs to investigate by-catch of alosines by out-of-state jurisdictional fisheries.
- Partner with appropriate agencies to evaluate State water quality standards and Best Management Practices (BMP) that may impact wetlands to ensure that guidelines are stringent enough to protect alosine habitat.
- Determine impacts of pollution and siltation on life history stages of alosines.
- Determine biotic effects of alosine stocking in habitats where access was previously restricted or absent.
- Determine the relationships of alosines to freshwater mussels on the South Carolina Species of Concern list.
- Determine impacts of biotic and abiotic factors on egg, larval, and juvenile survival and development and how such factors relate to spawning stock recruitment.
- Survey non-gamefish winter gill-net fisheries to determine potential impacts on alosines, particularly on Hickory Shad.
- Determine potential impacts of double-crested cormorant predation on passage of adult Blueback Herring and on all juvenile alosines, particularly at St. Stephen Dam.
- Participate in FERC-relicensing evaluations and partner with appropriate agencies to ensure that cost-effective and efficient designs for providing both upstream and downstream passage of alosines are installed in dams blocking access to suitable spawning and nursery habitats.
- Partner with appropriate entities to improve access to a full diversity of habitats by including fish passage designs, or improving existing designs, at facilities not under FERC jurisdiction.

- Impediments to migration, such as nonfunctional dams, dikes, or causeways should be identified. Investigate the feasibility for these structures to ultimately be removed, breeched, or bypassed through partnerships with the appropriate authorities.
- Build partnerships with NGOs, permitting authorities, and county and local governments to improve and/or implement the use of BMPs in agriculture, silviculture, and urban development activities to reduce siltation and contamination.
- Partner with the appropriate agencies to determine water removal guidelines for agricultural, civil, or industrial purposes that include considerations for migratory fishes.
- Partner with appropriate entities to limit deforestation of river floodplains and swamp forests.
- Partner with appropriate permitting authorities to design dredging protocols that consider the timing of alosine migration.
- Partner with other coastal states to promote protection of the alosines in the Exclusive Economic Zone (EEZ) and in Canadian coastal waters.
- Form an alliance with other state and federal agencies as well as NGOs to implement range-wide conservation and management of alosines as described in the ASMFC IFMP.
- Build partnerships with natural resource agencies in Georgia and North Carolina to manage alosine populations that transcend individual state jurisdictions, specifically populations in the Savannah River and Waccamaw-Pee Dee Basin, respectively.
- Partner with NGOs and other state and/or federal agencies to promote changes in water release protocols for dams that will restore or approximate natural flow regimens and increase minimum flows.
- Partner with appropriate agencies and NGOs to develop or revise river basin plans to identify habitat areas of particular concern (HAPCs), to identify degraded or threatened habitats, and to identify preventative or mitigation actions.
- Partner with appropriate agencies to designate critical coastal areas.
- Develop Memoranda of Understanding (MOUs) with other state agencies for joint review of projects and planning activities to ensure that habitats, particularly HAPCs, are sufficiently protected.
- Develop education and outreach programs that distribute information to governments, civic groups, educational systems and NGOs about critical habitat needs, threats, and potential conservation actions related to alosines.

American Eel
Anguilla rostrata

Contributor (2005): John W. McCord (SCDNR)
Revised and Edited (2012): Allan Hazel, Bill Post, Brock Renkas, Corbett Norwood, Jarrett Gibbons, and Elizabeth Miller (SCDNR)
Revised and Edited (2025): Brock Renkas, Bill Post, Joseph Ballenger, Ellen Waldrop

DESCRIPTION

Taxonomy and Basic Description

The American eel, *Anguilla rostrata* (Lesueur 1817), belongs to the freshwater eel family, Anguillidae. Related species occur throughout the world, but the American eel is the only North American anguillid eel. Eels are snake-shaped and covered with a mucous layer that renders them slimy to the touch despite the presence of minute scales. A continuous, low fin runs from the middle of the back, around the tail, and ends behind the vent. Relatively small pectoral fins originate near the midline and immediately posterior to the head and gill-covers. Coloration varies with stage of maturity and habitat, but eels are generally dark olive, yellowish, or slate-gray above and light below. Eels from dark, tannic acid streams are darker while those from clear streams and estuaries are lighter (J. W. McCord, pers. obs.).

The American eel is catadromous; it spawns in oceanic waters but uses freshwater, brackish, and estuarine systems for most of its developmental life. Sexually mature adults, called silver eels, migrate from freshwater to the sea in fall. Their destination for spawning is the Sargasso Sea, an expansive portion of the central North Atlantic Ocean, east of the Bahamas and south of Bermuda. Adults are thought to die after spawning. The largest females produce nearly 20 million eggs (Barbin and McCleave 1997). Mature females in the southern portion of the eel's range are generally smaller and carry as few as 400,000 eggs (Wenner and Musick 1974). Eggs hatch into a brief pre-larval stage before transformation into the active leptocephalus stage.

Leptocephali primarily drift with ocean currents for about a year before metamorphosing into the glass eel stage (Sheldon 1974). Glass eels are shaped like adults, but are transparent and smaller, reaching lengths of 5 to 7 cm (2 to 3 in.) (Hardy 1978). Glass eels actively migrate across the

continental shelf and move into estuaries and tidal river reaches in late winter and early spring, apparently by detecting temperature gradients and the scents associated with freshwater (Facey and Van Den Avyle 1987). Glass eels feed little or not at all, but within weeks of entering estuaries and tidal rivers, the small eels begin to feed and become pigmented, at which time they are called elvers and resemble miniature adults in coloration and other physical features.

While some elvers move far into inland habitats, others remain in brackish and estuarine areas. Both glass eels and elvers migrate primarily at night and are able to move beyond obstacles that prevent passage of most aquatic species. Small eels can climb vertical walls, including low dams, as long as surfaces are damp and textured.

The final inland resident stage is called the yellow eel and includes all eels greater than 10 cm (4 in.). Yellow eels may gradually move upstream over many years, with most movement occurring during spring and fall when water temperatures are moderate. However, larger yellow eels may settle in specific areas and have been found to occupy distinct home ranges (Gunning and Shoop 1962). Adult females are larger than males and may grow to lengths of nearly 1.0 m (40 in.), but most adults are 0.6 m (24 in.) or less. Maturation occurs from 3 to 24 years of age (ASMFC 2000), with males generally maturing at a younger age and remaining smaller in size than females. Eels as old as age 15 have been recorded in South Carolina (SCDNR SWG 2020).

American eels are opportunistic carnivores, feeding on a vast array of animal life, depending on the size of the eel and the availability of prey within a given habitat. Larger eels feed primarily on small fishes and benthic invertebrates, including crustaceans, aquatic insects, worms, and mollusks. Elvers and small yellow eels feed primarily on aquatic insects, small crustaceans and worms. Elvers collected from the Cooper River consumed mostly midge larvae, cladocerans (zooplankton), amphipods (small crustaceans) and fish parts (McCord 1977). Adults taken from the same study area fed primarily on fish parts, elvers (eels can be highly cannibalistic), and terrestrial isopods (McCord 1977). In estuaries, eels often feed on blue crab (*Callinectes sapidus*) and polychaete worms (Wenner and Musick 1975). Both blue crab and horseshoe crab (*Limulus polyphemus*) are used as bait in trap fisheries for American eel in the Chesapeake Bay and elsewhere.

Elvers are not only preyed upon by larger eels but are also eaten by many fishes, both game and non-game species. Small yellow eels up to 46 cm (18 in.) in length are used as bait for striped bass and cobia. Eels are also consumed by other predatory fishes such as Largemouth Bass (*Micropterus salmoides*) and Bowfin (*Amia calva*) (J. W. McCord, pers. obs.) and are likely preyed upon by opportunistic predatory fish like non-native Flathead Catfish (*Pylodictis olivaris*). American eels are also included in the diets of fish-eating birds and mammals, such as mink (*Mustela vison*) (Sinha and Jones 1967, Seymour 1974). American eels are a valuable part of the many ecosystems they inhabit during various growth stages. Dams and other impediments to migration have eliminated the American eel from many historical habitats in South Carolina (USFWS 2001). The effects of the loss of American eels from aquatic food webs, though not quantified, may be substantial (Freeman et al. 2003).

Status

At a population level, American eels have been on the International Union for the Conservation of Nature's (IUCN) red list since 2014, meaning they are considered globally endangered. The IUCN cited decreased US stocks along with increased commercial fishing on eels in the US, so in 2015 the US Fish and Wildlife Service evaluated the species and announced that despite their historically depleted status, the US American eel stock is stable and does not need protection under the Endangered Species Act. The global status was reassessed by the IUCN in 2017 and again in 2020, with all published results retaining their endangered status. The classification within the red listing is "A2bd" which indicates endangered status based upon "past observations of population decline", and the most recent assessment indicates that the global population trend is still "stable" (Pike et al. 2023).

American eels are managed by the Atlantic States Marine Fisheries Commission (ASMFC) along the Atlantic coast from Maine to Florida. The American eel interstate fishery management plan (IFMP) was implemented in 2000, and has since been modified through seven addenda. The goal of the IFMP is to conserve and protect the American eel resource to ensure ecological stability while providing for sustainable fisheries. Each state is responsible for implementing management measures within its jurisdiction to ensure the sustainability of the American eel population that resides within state boundaries (ASMFC 2023).

Critical to our concerns for the American eel population in the state of South Carolina are the findings of the 2017 assessment report (ASMFC 2017). The only young of the year (YOY) index from South Carolina, a YOY index based on fyke net catches in Goose Creek Reservoir, suggested a significant downward trend in relative abundance (ASMFC 2017). Similarly, the only index of the yellow eel life stage in South Carolina – a statewide upper estuary electrofishing survey – suggested a downward trend in the abundance of yellow eels across the state (Fig. 1 & 2; ASMFC 2017). When combined with other relative abundance data from Florida, Georgia, and North Carolina, there was a clear decline in YOY and yellow eel stage American eels across the four states since 2001 (ASMFC 2017). These results suggested at the meta-population scale, there is even greater concern for the status of American eel in the state of South Carolina and an increasing probability the population is approaching imperiled status.

The most recent stock assessment was an ASMFC benchmark conducted in 2023. The assessment was evaluated and endorsed by an independent panel of scientific experts through the ASMFC external peer review process. The 2023 assessment is the latest and best information available on the status of the coastwide American eel. The 2023 assessment concludes that the stock is depleted, meaning it is at or near historically low levels due to a combination of historical overfishing, habitat loss, food web alterations, predation, turbine mortality, environmental changes, toxins and contaminants, and disease. Based on trend analyses, the stock was also considered depleted in the 2012 and 2017 assessments. The 2023 stock assessment found that the yellow eel population was at lower levels than the previous assessment, and yellow eel harvest should be decreased (Fig. 3; ASMFC 2023).

POPULATION SIZE AND DISTRIBUTION

One genetically similar population of eels is thought to occur along the Atlantic Coast (Williams and Koehn 1984). However, eels become resident as sub-populations in drainage basins throughout the range of the species until they become sexually mature. Accordingly, many sub-populations by drainage basin and region collectively comprise the North American population. The complex life cycle contributes to the difficulty in determining the population status of this species. Furthermore, the American eel has been poorly studied through much of its range. Historical data are scant for most areas of the Atlantic coast; no such information exists for South Carolina. Long-term data sets collected in the northeastern United States and southeastern Canada indicate declines in both recruitment of juveniles and in adult populations (ASMFC 2000). Directed fisheries for silver eels have shown precipitous declines in catch per unit of effort (ASMFC 2000). Long-term data for elvers at Conowingo Dam fish lift on the Susquehanna River, Maryland indicate a declining trend from 1974 through 1996 (ASMFC 2000). Eel migration data from 1984 to 1995 indicates significant negative trends for yellow and/or silver eels in Ontario, Quebec, New York, and Virginia (Richkus and Whalen 2000). Since there is likely a single genetic stock throughout the range, sub-population declines in any region or drainage basin can impact the entire population. The largest declines have been indicated over the past two decades. Dramatic declines in the northern portion of the American eel's range are important since sub-populations in this region carry the highest reproductive potential (Casselman 2003).

The American eel occurs along the Atlantic coast from Canada to Central and South America. Within South Carolina, eels occur from estuaries to the headwaters of coastal streams and at least as far inland as the Fall Line in longer river basins, including the Savannah, Santee and Pee Dee. Although the American eel is capable of traversing obstacles that may completely restrict dispersal of other fishes, both eel distribution and population size may be limited by dams and other impediments to migration. Historical records show that American eels occur in the Santee basin well inland of the fall line and into North Carolina (USFWS 2001). Similar historical distributions occurred for the Waccamaw-Pee Dee Basin and are likely to be present in the Savannah River Basin.

American eel populations within the Santee-Cooper River watershed inland of Pinopolis, St. Stephen, and Wilson Dams are likely well below numbers present prior to impoundment of the Santee-Cooper lakes in the 1940s. Observations from St. Stephen Dam and a eel ramp below the Goose Creek Reservoir indicate rather poor passage success for the American eel (Post and Waldrop 2023). Fish passage at Pinopolis Dam on the Cooper River is provided by navigational lock. Such passage systems are not considered to be particularly effective for American eels because of great fluctuations in water flow that occur during lock operations (Lary and Busch 1997). Dams on the Savannah and Waccamaw-Pee Dee drainages are well inland and probably do not significantly restrict eel distribution.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The American eel is widely distributed in many aquatic habitats including estuarine, brackish and freshwater tidal channels; tidal creeks; coastal impoundments; ponds; lakes; and nearly all accessible freshwater habitats associated within river basins as far inland as the Fall Line and beyond. Males are generally restricted to estuarine and brackish habitats while females are more often found in freshwaters. Among freshwater habitats, eels seem to be most abundant in streams, but occupy all habitats having sufficient food resources and well-oxygenated water. A high density of yellow eels has been observed in the upper South Edisto River, where single channels branch into a braided or intertwined network of small creeks within swamp forest. Yellow eels are also present in high densities in the middle Savannah River in relatively shallow, non-navigable reaches characterized by riffles and pools with rocks and submerged aquatic vegetation (J. W. McCord, pers. obs.). American eels are dependent upon access to such diverse habitats for growth and maturation, as well as free downstream passage for spawning migration. Sexually mature adults are dependent upon the vast expanses of the North Atlantic Ocean and the Sargasso Sea.

CHALLENGES

Because of its complicated life cycle, the American eel population faces a broad range of challenges, some of which are specific to a particular growth stage. Since males and females largely utilize separate habitats, impacts in a given region may affect the sex ratio of the eel population. Dams and causeways obstruct access to a diversity of habitats, which may limit basin-specific and statewide populations. The Pee Dee, Edisto, and Santee coastal drainages have suffered an 83% reduction in unobstructed stream habitat (Busch et al. 1998). Impingement (entrapment in) and entrainment (being carried through) water intakes and turbines are sources of mortality on seaward-migrating eels.

The American eel is sensitive to low dissolved oxygen levels (Hill 1969, Sheldon 1974) in water typically found below dams. Logging in swamp forests may also cause lowered dissolved oxygen by increasing siltation and water temperature. Contaminants such as heavy metals, dioxin, chlordane and polychlorinated biphenyls (PCBs) can bioaccumulate and cause acute toxicity or reduced productivity (Hodson et al. 1994).

Dredging can result in many negative effects to American eels. Physical injury or mortality may result from entrainment of seaward-migrating adults. Increased turbidity or suspended sediments may negatively affect migration of adults, glass eels and elvers. Dredging may also cause changes in salinity regimens that could impact eel distribution and prey availability.
Spawning habitat may be adversely affected due to seaweed (*Sargassum* sp.) harvest in the Sargasso Sea. Spawning habitat and success is also likely to be affected by pollution like oil spills.

Dewatering freshwater streams for irrigation and other water removal projects decreases habitat availability for American eels and exacerbates any existing areas of poor water quality.

Nonpoint source runoff from residential areas, roads, and golf courses can have a negative impact on floodplain ecosystems and impact water quality. Potential overfishing or excessive harvest of juveniles (glass eels and elvers) could negatively impact localized populations. Competition and predation from non-native species, particularly Flathead Catfish (*Pylodictis olivaris*) and Blue Catfish (*Ictalurus furcatus*), is also a problem for American eels. Both of these catfish are piscivorous and opportunistic; they will feed on any fish that can fit in their mouths. Because both species are found in habitats frequented by elvers (J. W. McCord, pers. obs.), predation on eels by these catfish is a concern. Additionally, non-indigenous pathogens or parasites such as the Asian swimbladder nematode (*Anguillicola crassus*), has been shown to have significant negative impacts on the European Eel (*Anguilla anguilla*) and on captive American eels in South Carolina and Texas (ASMFC 2000).

Changes in oceanographic conditions may alter oceanic currents, thereby potentially altering larval transport and recruitment of juveniles across the continental shelf. The cause of these changes is unknown, but global warming may play a part (ASMFC 2000).

CONSERVATION ACCOMPLISHMENTS

An interstate fisheries management plan (IFMP) has been developed for the American eel under the auspices of the ASMFC. The original IFMP for the American eel was completed in 2000 and include five Addenda with another in process. The plan and all Addenda are available at https://asmfc.org/species/american-eel and were established as a framework of recommendations for protecting or enhancing eel sub-populations by state and region.

The IFMP and Addenda require states to control and limit directed effort in both bait and commercial eel fisheries in South Carolina. Beginning in 2001, states were required to collect and monitor catch and effort statistics for American eel commercial fisheries and to limit effort at levels achieved in 2000. As a result, SCDNR capped participation at 10 license holders and capped gear use as well. The permitting system that emerged from the IFMP mandate has greatly enhanced SCDNR’s ability to initiate proactive controls over American eel fisheries. In addition, the plan requires states to limit recreational harvest through the establishment of several regulations: the possession limit is not to exceed 25 eels; the minimum size limit is 15 cm (6 in.); and sale of American eels is prohibited without a license.

SCDNR and Duke Energy partnered to study American eel movement and growth throughout the Santee Basin beginning in 2009. Other partners include SCANA, NWRC, and USFWS. Analysis of annual glass eel migrations in Goose Creek, elver use of the St. Stephen eel ramps, and eel occurrence at a trap in the Wateree Dam provided incentive to gather more detailed data on eel movement rates. As part of this effort, 7,469 eels have been marked.

The question was whether eels passing St. Stephen in April make it through the Santee-Cooper lakes and arrive at the Wateree Dam in the subsequent month of May, or does it take longer periods. The only real way to verify movement speed was to implant uniquely colored elastomer tags under the skin of elvers at St.Stephen, release them upstream into Lake Moultrie, and look for their arrival at the Wateree Dam. Elvers marked with yellow (2010), blue (2011), orange (2012), and white (2013) elastomer tags have been released annually into Lake Moultrie. For

example, in April and June of 2012, SCDNR, along with the USFWS, Duke Energy, and others, tagged 3,377 elvers (young eels) with orange elastomer.

On May 24, 2013, the first tag from the elastomer tagging effort was recovered at the Wateree Hydro eel trap. The elver was 132 mm (5.2 in.). Notes indicate the average length of these 2012 eels was 93 mm (3.7 in.) at tagging so that's almost 40 mm (1.2 in.) of growth. A second orange VIE tagged eel was caught on June 6, 2013 that measured 175 mm (6.9 in.) in length.

Many dams in South Carolina are currently, or are soon to be, undergoing Federal Energy Regulatory Commission (FERC) re-licensing, which includes considerations for improved access by and migration of aquatic species. Therefore, increasing opportunities for passage are possible in the future. After almost 30 years, Santee Cooper received their long-awaited license in 2023. Requirements in the 40-year license include eel monitoring and construction of passage facilities at both the Pinopolis and Santee Dams. Duke Energy also received their license for the Yadkin Pee Dee in 2015. As part of requirements in this license, a eel ladder was installed at Blewett Falls Dam and begun passing fish in 2022. Lastly, Duke Energy received a license for the Catawba Wateree System in 2015. Requirements in this license continued monitoring of an already constructed eel ladder at the Wateree Dam in Lugoff, SC.

Prior to the 2023 ASMFC benchmark stock assessment, a South Carolina State Wildlife Grant (SC-T-F18AF00965) was obtained to improve understanding of American eel populations in the state (SCDNR SWG 2020). The research recommendations put forth by the previous 2017 stock assessment were the driving force in securing this grant. The overall goal was to leverage an existing collection of histological and otolith samples to address critical data gaps identified in 2017. Eel datasets were used to assess life history parameters such as age structure, sex ratio, size-at-maturity, and age-at-maturity of American eels in South Carolina. Other objectives included the evaluation of infection by the swimbladder nematode *Anguillicola crassus*, as well as a comparison of otolith processing methods to assess the precision of age determinations for eels. This last objective was pursued as the outcome of an in-person workshop hosted by SCDNR and conducted by the ASMFC in 2018 including representatives from 11 Atlantic and Gulf coast states, 4 of which regularly age American eel. Analysis of the two predominant aging methods (whole otoliths versus thin sectioned otoliths) showed that the methods were not statistically comparable to each other, and that South Carolina’s method of thin sectioned otolith aging produced less biased and more precise data. Recommendations were then made at the federal level for all states to use the thin sectioned method for aging American eel in the future.

As mentioned previously, following the acceptance of the 2023 stock assessment, there were 2 addenda proposed to the IFMP; one to modify the coastwide yellow eel harvest cap, and the other to address the quota for Maine’s glass eel fishery. Both these addenda were approved, which represents a significant effort to help the rangewide depleted stock status of American eels.

CONSERVATION RECOMMENDATIONS

- Conduct statewide eel distribution and population surveys to make prioritized decisions for restoration and passage.
- Inventory sources of American eel mortality and formulate remedies where practical.
- Determine contaminant levels in eel tissues and relate those to mortality and reproductive success.
- Investigate impacts of logging in swamp forests on water quality and habitat. Work with municipalities and landowners to direct forestry activities away from floodplain areas.
- Determine impacts to American eel populations of dewatering freshwater streams.
- Determine size, sex, and age structures for each sub-population of American eels.
- Determine potential presence and distribution of the Asian swimbladder nematode (*Anguillicola crassus*).
- Determine potential impacts to American eels from competition and predation by non-native species and, to the extent possible, control and prevent further distribution of non-native blue and flathead catfish populations.
- Determine the scope and impact of American eel harvest on sub-populations, and revise South Carolina eel regulations to limit harvest of any eel life stage or sub-population.
- Conduct genetics studies to document sub-populations by region or river basin.
- Investigate opportunities to provide passage at dams and other obstructions that are not under FERC authority, and to develop more cost-effective and efficient techniques for providing both upstream and downstream passage of American eels at migration barriers. Partner with NMFS, USFWS, United States Army Corps of Engineers (USACE) and non-governmental organizations (NGOs) to promote the inclusion of fish passage designs, wherever prescribed, that can successfully provide two-way passage of American eels.
- Build partnerships with NGOs, permitting authorities and county and local governments to improve and implement the use of Best Management Practices (BMPs) in agriculture and urban development activities to reduce siltation and contaminant input.
- Partner with the Department of Health and Environmental Control to develop or improve water removal guidelines for agricultural, civil, or industrial purposes that protect American eels.
- Work with the USACE to identify dredging protocols that consider the timing of eel migration.
- Form an alliance with other state and federal agencies as well as NGOs to implement range-wide conservation and management of the American eel as described in the ASMFC IFMP.
- Partner with the South Atlantic Fishery Management Council (SAFMC) to promote implementation of the Fishery Management Plan for Pelagic Sargassum Habitat of the South Atlantic Region.
- Promote changes in water release protocols for dams that will restore or approximate natural flow regimens and increase minimum flows.
- Institute permitting protocols for aquaculture and pet fish industries that require certification of the absence of diseases and parasites for all *Anguilla* species.
- Participate in interstate research examining the effects of oceanic changes on distribution of larval American eel and how these changes may be related to global warming.

DESCRIPTION

Taxonomy and Basic Description

The Atlantic sturgeon, *Acipenser oxyrinchus oxyrinchus* (Mitchell 1815) belongs to the sturgeon family, Acipenseridae. Atlantic sturgeon are among the longest-lived fish, with a life span approaching 50 years or greater in the northern part of their range and 35 to 40 years in the southern part of their range. Sexual maturity is not obtained until 8 to 20 years old, with males maturing younger than females (ASMFC 1990; ASMFC 1998). The Atlantic sturgeon is also the largest fish inhabiting freshwaters on the Atlantic Coast, with females in South Carolina reaching about 2.5 m (8 feet) Total Length (TL). There is little sexual dimorphism, although females reach a larger size than males. Sexually mature female Atlantic sturgeon, often called "cows," may weigh several hundred kilograms or pounds. Mature male Atlantic sturgeons, or "bucks," are generally smaller than females, rarely exceeding 1.8 m (6 feet) TL and 45 kg (100 pounds).

Atlantic sturgeon, like other sturgeon, are shaped like sharks and have a deeply forked tail in which the upper lobe is longer than the lower. A single, small dorsal fin is located far back toward the tail and a single anal fin is directly beneath the underside. Paired pectoral and pelvic fins originate immediately rear of the bony operculum and vent, respectively. The head extends forward into a snout that is pointed in juveniles and blunt and rounded in adults. The ventral protrusible mouth is at the rear of the snout and is preceded by a row of four barbels similar to catfishes. The mouth, the width of which is about one half the distance between the eyes, does not bear teeth, but bony plates in the throat are used to crush food items if necessary (Vladykov and Greeley 1963; Gilbert 1989). The skeleton is partly cartilaginous, with the skull and leading edges of the pectoral fins among the boniest structures. Structural support and protection are provided by thick, tough skin with five rows of bony plates or scutes. Dermal ossifications are well developed on the skin between the dorsal and lateral row while the rest of the body surface appears naked but has patches of smaller denticles (Vladykov and Greeley 1963). The skin is generally rough, and gritty, not unlike that of a shark. Coloration is dark bronze to brownish above, lighter on the sides and white below (Gilbert 1989).

The shortnose sturgeon, *Acipenser brevirostrum* (Lesueur 1818) is also classified in the Acipenseridae family. Adults are much smaller than adult Atlantic sturgeon, with "cows" reaching 1.2 m (47 inches) TL and reaching a maximum weight of perhaps 18 kg (40 pounds). Mature "bucks" are generally smaller than females, rarely exceeding 0.8 m (32 inches) TL and 7 kg (15 pounds). The shortnose sturgeon is similar in shape and physical characteristics to the Atlantic sturgeon. The snout is pointed only in young juveniles, and is broad, blunt and rounded in adults. The ventral protrusible mouth is nearly as wide (70%) as is the distance between the eyes, and wider than for Atlantic sturgeon of similar size (Gilbert 1989).The body is also protected by five rows of scutes, but compared to those of Atlantic sturgeon, the bony plates collectively cover less surface area and denticles are small and sparse. The skin, though thick and tough, is less rigid than that of Atlantic sturgeon and is much smoother and often slimy or mucous-covered (J.W. McCord, SCDNR, pers. obs.). Coloration is generally brownish above with pinkish or salmon tones, lighter on the sides, and white below. Because of this coloration, commercial fishers often refer to this species as "salmon sturgeon." Shortnose sturgeon are also long-lived fish, reaching age 67 in the northern part of their range (e.g., Canada, Dadswell 1979), while southern populations likely have shorter lifespans. Shortnose sturgeon reach sexual maturity at an earlier age than Atlantic sturgeon and in southern rivers males may mature as soon as 2 years old and females at 6 years old (Dadswell et al. 1984).

As indicated by the ventral mouth, both species of sturgeon are benthic feeders that primarily prey on invertebrates. Aquatic insects such as mayfly and midge larvae and small crustaceans predominate the juvenile shortnose sturgeon diets (Dadswell et al. 1984; Carlson and Simpson 1987), whereas mayfly larvae, amphipods and earthworms are most frequently consumed by juvenile Atlantic sturgeon. Adults of both species consume mollusks, snails and amphipods (Van Den Avyle 1984; Dadswell et al. 1984; Haley 1998). Amphipods are particularly abundant in the lower Edisto River near the fresh-brackish interface (J.W. McCord, SCDNR, pers. obs.); preliminary evidence indicates amphipods and polychaetes as prevalent dietary items for sturgeons in similar habitat in the Savannah River (B. Post, SCDNR, pers. comm., 2005).

Status

Both the Atlantic and shortnose sturgeons are identified with rankings of G3 and S3 (NatureServe 2005), meaning that populations for both species are "vulnerable," both globally and in South Carolina. In general, populations of both species of sturgeon along the entire Atlantic Coast are reduced from historical levels for at least the past half-century (ASMFC 1990; ASMFC 1998; NMFS 1998). The Atlantic sturgeon was considered for listing under the Endangered Species Act (ESA) in 1998, but the National Marine Fisheries Service (NMFS) determined that listing was unwarranted. On October 6, 2009, NMFS received a petition from the Natural Resources Defense Council to list Atlantic sturgeon throughout its range as endangered under the Endangered Species Act. In January 2010, NMFS announced the petition had merit and it would formally consider whether to list the species under the Endangered

Species Act. In October 2010, NMFS proposed listing the species and sought public comment. NMFS received comments from 119 individuals or agencies, which were submitted in writing or during the six public meetings. In 2012, NMFS listed the New York Bight, Chesapeake Bay, Carolina, and South Atlantic distinct population segments of Atlantic sturgeon as endangered, while the Gulf of Maine population was listed as threatened. The ESA listing provides tools for greater protection and prohibits unauthorized "take" of the species. Additionally, it has been illegal to fish for, catch, or keep Atlantic sturgeon in South Carolina since the 1985 state moratorium. Furthermore, in 1998 the Atlantic States Marine Fisheries Commission implemented a long-term coast wide moratorium on all U.S. Atlantic sturgeon fisheries (Collins et al. 2000). However, the gulf sturgeon (*Acipenser oxyrinchus desotoi*), a subspecies of the Atlantic sturgeon restricted to rivers and adjacent waters of the Gulf of Mexico, remains on the candidate list and is currently listed as "threatened" under the ESA. The shortnose sturgeon has been listed as "endangered" under the ESA since 1967.

POPULATION DISTRIBUTION AND SIZE

Atlantic sturgeon historically ranged along the Atlantic coast from Labrador, Canada to the St. Lucie River, Florida (ASMFC 1990). The historical range of the shortnose sturgeon is very similar, from the St. John River, Canada to the St. Johns River, Florida (Vladykov and Greeley 1963). Currently, both species are thought to be either very rare or extirpated from the extreme southern portion of their ranges.

In South Carolina, Atlantic sturgeon and shortnose sturgeon both occur as relatively distinct populations by river system, as typical for anadromous fishes (Wirgin et al. 2000; Quattro et al. 2002). There are a minimum of four populations (presumably for both species) in South Carolina: the Pee Dee, Santee, Edisto, and Savannah River drainage basins. A dam locked population of shortnose sturgeon exists in the Santee Cooper Lake System (Collins et al. 2003). Since historical data relative to individual stock status are absent and current information is incomplete, the status of all stocks is still not well understood.

In general, shortnose sturgeon stocks are more genetically isolated and dissimilar than are Atlantic sturgeon stocks, presumably because shortnose sturgeon are freshwater amphidromous, (Kynard 1997; NMFS 1998; Wirgin et al. 2009) while Atlantic sturgeon are truly anadromous and different stocks regularly intermingle (Quattro et al. 2002; Kazyak et al. 2021; White et al. 2021a).

Historical data that relate directly to population size for South Carolina stocks are nonexistent, but historical distribution records and anecdotal information on abundance strongly indicate that all populations of sturgeons in South Carolina are reduced from early 20th century and previous levels (USFWS 2001). The current status and trends in stock status over the past 35 years for both sturgeons in South Carolina are based primarily on anecdotal information and short-term datasets. Collectively, stock status of Atlantic sturgeon throughout the state was considered in decline based on trends of commercial landings in the early 1980s (Smith et al. 1984).

Pee Dee Basin: The Pee Dee basin extends from the North Carolina border southeast to the Atlantic Ocean. It covers approximately 7,860 square miles and is the largest basin in the State. The main stem of the Great Pee Dee River is the dominant hydrologic feature of the basin. Major tributary streams include the Lynches, Little Pee Dee, Black, Sampit, and Waccamaw Rivers. The Lynches and Little Pee Dee Rivers drain into the Great Pee Dee River, while the Black, Sampit, Waccamaw, and Great Pee Dee Rivers drain into Winyah Bay (SCDNR 2013). Historically, South Carolina hosted a substantial sturgeon fishery with Winyah Bay supporting the primary fishing activity in the state. Laws and regulations concerning potential sturgeon overexploitation were created as early as 1906 (Smith et al. 1984) and led to full closure in 1985. Currently, this large basin provides sturgeon access to the vast majority of their historical range of spawning and early nursery habitat, which was identified by Mills (1826); low falls near the fall-line may have prevented further inland access except under high flows. Spawning of both Atlantic and shortnose sturgeon presently occurs over more than 200 km (100 mi) of river mainstem in suitable channel habitats.

Efforts to better understand the ecology and life history of sturgeons in this system, primarily in response to bycatch in the American shad fishery, began in 1994. Both species were collected in Winyah bay during the study (Collins and Smith 1996a). From 2002 to 2003, sampling was conducted to determine which of the several rivers in the system might support a population of shortnose sturgeon, identify spawning sites, and describe seasonal movements. A total of 26 shortnose sturgeon were captured and subsequent telemetry data revealed a spawning location in the Great Pee Dee River confirmed by the collection of fertilized eggs (Collins and Post 2003). From 2006 to 2009, sampling was conducted to monitor the movements and inter-basin transfer of shortnose sturgeon between the Santee River and Winyah Bay System. A total of 13 shortnose sturgeon and 10 Atlantic sturgeon were captured and transmitted. Telemetry data demonstrated that shortnose sturgeon residing in the Winyah Bay System have a larger range than previously published, with fish moving into the Black River, Sampit River, and inter-basin transfer between the Winyah Bay and the adjacent Santee River. Data also indicated that multiple spawning sites likely exist in the system (Gibbons and Post 2009).

The next period of sampling occurred from 2011 to 2013 as part of the National Marine Fisheries Service funded multistate study examining riverine movements of shortnose and Atlantic sturgeon in the Southeast. A total of 100 Atlantic sturgeon and 73 shortnose sturgeon were transmitted during the study. Telemetry data confirmed spawning runs occurred for both species (fall spawning run confirmed for Atlantic sturgeon) in the Great pee Dee River. Data also confirmed both species tagged in other systems inhabited tributaries of the Pee Dee River Basin for extended periods of time, confirming its importance as an aggregation area (Post et al. 2014). Around the same time, advancements in side scan sonar technology provided a new way to enumerate adult sturgeon and paddlefish that have been used to estimate abundance in several species (Thomas and Haas 2002; Hale et al. 2003; English et al. 2014). Researchers from North Carolina State University developed an approach to estimate numbers of spawning adult sturgeon using this technology (Flowers and Hightower 2013). Abundance estimates were determined during spawning runs using N-mixture and distance models for several rivers in South Carolina. The abundance estimate of riverine Atlantic Sturgeon >1 m TL in the Great Pee Dee River was 1,944 (95% CI: 1,036–3,646) (Flowers and Hightower 2015).

In 2015, FERC-relicensing was completed for Blewett Falls Dam on the Great Pee Dee River, as part of the Yadkin-Pee Dee River Hydroelectric Project. The Project Biological Opinion required long-term monitoring of adult shortnose and Atlantic sturgeon in the system. The first 10 years of monitoring (the Baseline) resulted in the capture of 72 shortnose sturgeon and 518 Atlantic sturgeon. Of those captures, 68 shortnose and 145 Atlantic sturgeon received internal acoustic transmitters. Movement data have shown spawning runs during the spring and fall annually for Atlantic sturgeon, and nearly annually for shortnose sturgeon. These data have also been used to evaluate environmental cues associated with spawning migration behavior in Atlantic sturgeon in both the spring and fall cohorts (Denison et al. 2021). In 2021, a range-wide analysis of population genetics for North American Atlantic sturgeon led to an updated and substantially improved genetic baseline (White et al. 2021). Results from this analysis confirmed the spring and fall spawning runs are genetically distinct in the Great Pee Dee River (also known as dual spawning). Future genetic analysis will potentially calculate additional genetic metrics such as estimate of effective population size and estimate of numbers of breeders.

In 2019 funding was received from NMFS to conduct a 3-year study to (1) estimate annual abundance for age 1 Atlantic sturgeon in the Winyah Bay System, and (2) develop, test, and implement side scan sonar techniques to estimate the annual abundance of spawning adult Atlantic sturgeon in the Winyah Bay System. For objective 1, over the course of the study period, sampling targeting juvenile sturgeon resulted in the capture of 1,253 sturgeon (1,247 Atlantic and six shortnose). Sturgeon were captured in the Black River, Sampit River, Waccamaw River, and Winyah Bay indicting wide ranging use of all system tributaries which was further validated through acoustic telemetry via 40 acoustically transmitted juvenile Atlantic sturgeon (Post and Waldrop 2024). Preliminary abundance estimates of juvenile Atlantic sturgeon (≤ 1,000 mm FL) were calculated using the Jolly-Seber POPAN Mark open population model in RMark. POPAN model comparisons based on AICc selected constant survival, constant capture probability, and variance in probability of re-entry as model parameters [Phi(~1)p(~1)pent(~time)N(~1)]. The POPAN model produced a comparable estimate of 3,060 individuals from 2021–2023 (1,997–5,001). For comparison to previous sturgeon population estimates, the Huggins closed capture model in RMark was also used. The Huggins model produced a superpopulation estimate of 3,001 individuals from 2021–2023 (95% CI = 2,013–6,583).

For objective 2, side-scan sonar surveys were conducted along a 70 km section of the Great PeeDee from RKM 52 to RKM 122. The entire study area was surveyed twice weekly over three sample days from March 1 – May 15, 2021 (spring run), and again from August 10 – November 7, 2021(fall run). Side-scan sonar imagery was reviewed in SonarWiz and only marks clearly identified as Atlantic Sturgeon were used in the analysis. N-mixture models were then used to estimate daily abundance of Atlantic Sturgeon and to identify environmental covariates associated with Atlantic Sturgeon abundance and detection in the study area. A total of 1,392 Atlantic Sturgeon were confidently identified from the sonar imagery. Over twice as many Atlantic Sturgeon were detected from the fall run (n = 966) as opposed to the spring run (n= 426). Estimated maximum weekly abundance of adult Atlantic Sturgeon in the study area was 587 (95% CI = 328–1085) and 875 (95% CI = 511–1607) individuals during the spring and fall spawning runs, respectively (Denison et al. submitted).

Santee Basin: The Santee Basin, originating in the Blue Ridge Mountains of North Carolina, is the second largest watershed on the East Coast (Hughes 1994), with the Santee River having the fourth largest average flow of any river on the Atlantic coast of the United States (SCDNR 2013). This large watershed has been impacted by damming to a greater extent than most basins on the Atlantic coast of North America. With the completion of the Santee Cooper Diversion Project in 1942, two large reservoirs (Lakes Moultrie and Marion), two dams (Santee and Pinopolis Dams), and a diversion canal linked the Cooper River to the Santee Basin, diverting approximately 88 percent of the Santee River's annual flow into the Cooper River (Kjerfve and Greer 1978). In 1985, to reduce shoaling downstream in Charleston Harbor, flows were re-diverted back into the Santee River near St. Stephen, South Carolina. This project created the "Rediversion Canal" between Lake Moultrie and the Santee River, and a new hydroelectric power generation facility (St. Stephen Dam) (NMFS 2019).

The Santee-Cooper Lakes: With the construction of the Santee-Cooper Lakes (Moultrie and Marion) in the 1940s, the majority of the Santee River was closed to migratory fishes. In the 1990s and early 2000s, several studies were conducted investigating the exchange of individuals between the Cooper River the reservoirs and any consequences of interactions with the dams. Results showed that the navigational lock at Pinopolis Dam is generally ineffective at passing shortnose sturgeon (Cooke et al. 2002; Collins et al. 2003; Timko et al. 2003). Since 2011, seven transmitted sturgeon (five shortnose and two Atlantic sturgeon) have passed though Pinopolis Lock into Lake Moultrie (E. Waldrop, SCDNR, pers. comm., 2024). Fish passed from the Santee River at St. Stephen Dam are recorded, and only six sturgeons have been passed at the St. Stephen Dam since 1985 (B. Post, SCDNR, pers. comm., 2011). During the approximately 80 years since the impoundment of the Santee River, average flows in the Santee River seaward of Santee Dam have been greatly reduced from historical levels (Kjerfve and Greer 1978). Stocks of both sturgeons may have been severely impacted over the decades of generally low flows. Surveys have recorded both adult shortnose sturgeon and juvenile Atlantic sturgeon in rather low numbers through 2023 (Collins and Smith 1996b; Cooke and Leach 2004a; Post et al. 2014; Post and Holbrook 2018; Post and Waldrop 2023).

A dam-locked population of shortnose sturgeon is present in the Santee-Cooper Lakes (primarily Lake Marion) with spawning occurring in the Congaree River below Columbia, SC (Collins et al. 2003; Post 2008). Fish passage observations indicate that this population may receive little genetic influx from either river (see above), although it is still unclear how frequently sturgeon are able to use the Pinopolis Lock. The sustainability of the population within the lakes is unknown, but the dam-locked shortnose sturgeon population tends to be in poorer conditions than the open river populations (Collins et al. 2003). More recent genetic analyses of shortnose sturgeon haplotype frequencies in the remnant Santee River population in Lake Marion did not differ significantly from those in the Cooper River. This suggests that the Cooper River harbors descendants of the Santee River population that are unable to access their historical spawning locales (Wirgin et al. 2010).

In 2020, Santee-Cooper Public Service Authority was issued a new FERC License including specific requirements for shortnose and Atlantic sturgeon monitoring and spawning habitat restoration. Potential passage of both sturgeon species into the Santee Cooper Lakes System at the Santee Dam on the Santee River and Pinopolis Dam on the Cooper River is also included in

the License (Santee Cooper Hydroelectric Project, FERC Project No. 199). Dedicated studies focusing on all life stages of shortnose sturgeon will begin in 2025.

The Santee River: In 1991 two significant fish kills occurred in the Rediversion Canal in the Santee River. Both were the result of low dissolved oxygen that developed following a shutdown of the St. Stephen Hydro Facility. A total of 20 shortnose sturgeon were collected and documented (White and Lamprecht 1991). No Atlantic sturgeon were collected. In general, there has been limited documentation of sturgeon in the Santee River by SCDNR personnel. Efforts during several of the previously mentioned studies resulted in few if any sturgeon collections (Collins and Smith 1996a; Collins and Smith 1996b; Collins et al. 2003; Gibbons and Post 2006). Sampling during the NMFS multistate study (2011 to 2013) only resulted in the capture of 18 sturgeon (2 shortnose and 16 Atlantic) and four were transmitted. Telemetry data showed no detectable patterns of movement and no spawning migrations in the Santee River (Post et al. 2014). As mentioned in Pee Dee Basin section, researchers from North Carolina State University developed an approach to estimate numbers of spawning adult sturgeon using side scan sonar technology (Flowers and Hightower 2013). Unfortunately, the researchers did not observe sturgeon in the surveyed portion of the Santee River, resulting in no population estimate (Flowers and Hightower 2015).

The most dedicated sampling in the Santee River to date took place from 2014 to 2018. In that time two shortnose and 84 Atlantic sturgeon were captured. Of those Atlantic sturgeon, ten were considered young of year (<350 mm FL) and all were captured in 2016. Unfortunately, no other young of year were captured and it is possible that these fish emigrated from the Winyah Bay via the Intracoastal Waterway during periods of high flow (Post and Holbrook 2018). Over the last decade, several shortnose sturgeon (originally transmitted in Lake Marion or the Cooper River) entered the Santee River via the Santee Dam or St. Stephen Dam. However, exchange between the three populations is considered rare (Post and Waldrop 2023).

In 2020, Santee-Cooper Public Service Authority was issued a new FERC License including specific requirements for shortnose and Atlantic sturgeon monitoring and spawning habitat restoration (Santee Cooper Hydroelectric Project, FERC Project No. 199). Dedicated studies focusing on all life stages of shortnose and Atlantic sturgeon began in 2024.

The Cooper River: As mentioned above, the Cooper River was heavily impacted by damming beginning in the 1940s. While historic data are lacking, prior to the construction sturgeon were not thought to inhabit the Cooper River since it was historically a small tidal river (ASMFC 2017). Shortnose sturgeon were first documented in the Cooper River in 1992 (Cooke and Leach 2004b). Since 1995, the SCDNR Diadromous Fishes Program has conducted sampling for adults below the Pinopolis Dam (rkm 77). Results have indicated that adult shortnose sturgeon still reside in the Cooper River, albeit it at low levels (approximately 230 annually over the last decade) (Post and Waldrop 2023). Fertilized eggs have been collected below Pinopolis Dam as recently as 2017 (Cooke and Leach 2002; Duncan et al. 2004; Post and Holbrook 2017). However, neither larvae nor juveniles have been collected and successful reproduction has not been confirmed (Cooke and Leach 2004b).

From 2015 to 2018, dedicated sampling occurred throughout the Cooper River. Adult shortnose sturgeon were collected, but no larvae, young of year, or juveniles. Juvenile Atlantic sturgeon were also collected. Sampling included netting below Pinopolis Dam in the fall months (which has continued) to target adult Atlantic sturgeon. Sampling resulted in the capture of 21 adults including 19 males and two females (Post and Waldrop 2023). Telemetry movement data from these fish, water temperature, seasonal capture, and physiological stage of maturity of captured fish all provide evidence of fall and potentially spring spawning behavior for Atlantic sturgeon in the Cooper River (see Balazik et al. 2012; Farrae et al. 2017), however further verification is required before final conclusions can be drawn. Overall, the status and viability of sturgeon populations in the Cooper River remains poorly understood, particularly for Atlantic sturgeon. Long-term studies will continue as part of the Santee-Cooper Public Service Authority license requirements listed above (Santee Cooper Hydroelectric Project, FERC Project No. 199).

Ashley River: The Ashley River is a small, coastal plain drainage. Several juvenile Atlantic sturgeon have been taken in the Ashley River during shrimp trawl surveys (Collins and Smith 1996b). Several transmitted Atlantic sturgeon and one shortnose sturgeon have been detected in the lower Ashley River over the last decade, but detections represent only brief visits. The status of both the Atlantic and shortnose sturgeon is not well known for this small river.

Edisto Basin : The Edisto River Basin is drained by four major streams: South Fork Edisto River, North Fork Edisto River, Edisto River, and Four Hole Swamp. The Edisto River is the longest and largest river system completely contained within the borders of South Carolina (SCDNR 2013). The rivers that make up this largely pristine basin remain unimpounded.

Prior to 1994, there were very few authenticated records of shortnose sturgeon in the Edisto Basin (Collins and Smith 1996b; McCord 2003). Shortnose sturgeon captures are still rare 30 years later and spawning has not been observed in the Edisto River, however several young of year have been captured (Post and Waldrop 2023). The current status of shortnose sturgeon stocks in the Edisto Basin is poorly understood, however a new study focused on confirming the existence of a native shortnose sturgeon population in the system should provide more information (Post and Waldrop 2023).

Atlantic sturgeon were commercially harvested in the Edisto River in the late 1970s and early 1980s (Smith et al. 1984). In 1994, a sampling program was initiated by SCDNR that was originally intended to tag American shad, (*Alosa sapidissima)*, in the Edisto River, but also captured juvenile Atlantic sturgeon (McCord et al. 2007). Since then, SCDNR has conducted a sturgeon mark and recapture study in a portion of the Edisto River, resulting in the longest continuing data set for Atlantic sturgeon in South Carolina (1994–present). The primary objectives of this study are to assist in the development and implementation of FMP activities through fishery independent sturgeon mark and recapture studies, and to focus on a series of special studies directed at critical fisheries where data collection needs to be concentrated in South Carolina. Annual results of this long-term study are used to produce abundance and recruitment data for ASMFC benchmark stock assessments (ASMFC 2017) and stock assessment updates (ASMFC 2024) and ASMFC compliance reports and that will assist in correctly assessing management needs of sturgeon in Edisto River. A 2022 analysis of these data (1994–2022) provided a current juvenile (≤1050 millimeters total length) abundance average of

837 individuals (range = 333–1,343, 95% CI = 677–997) based on the average of daily and monthly encounter history population estimates (Takacs et al. in prep.).

Atlantic sturgeon are confirmed to spawn in both the spring and fall in the Edisto River (dual spawning), (Collins et al. 1999; 2000; Post et al. 2014), with the two populations considered genetically distinct with little gene flow or admixture between them (Farrae et al. 2017; White et al. 2021). Genetic characterization also showed a moderate effective population size estimate compared to published estimates for other Atlantic sturgeon populations (Farrae et al. 2017). Sampling during the NMFS multistate study (2013 to 2013) resulted in the capture of 90 individual Atlantic sturgeon and 5 shortnose sturgeon. Telemetry data from transmitted fish highlighted the distinct seasonal spawning runs and the differences between them (maximum river kilometer and spawning run duration) (Post et al. 2014). As mentioned in sections above, researchers from North Carolina State University developed an approach to estimate numbers of spawning adult sturgeon using side scan sonar technology (Flowers and Hightower 2013). Abundance estimates were determined during spawning runs using N-mixture and distance models for several rivers in South Carolina. The abundance estimate of riverine Atlantic Sturgeon >1 m TL in the Edisto River was 343.5 (95% CI: 150–788) (Flowers and Hightower 2015).

Salkehatchie Basin: The Salkehatchie River basin is in the southern Coastal Plain region of the State, with an area of approximately 2,870 square miles. The major streams draining this mostly middle and lower Coastal Plain basin are the Salkehatchie River, Coosawhatchie River, and Ashepoo River. The Salkehatchie and Little Salkehatchie Rivers join to form the tidally influenced Combahee River. The Coosawhatchie River discharges into the Broad River, a tidal saltwater river that also receives drainage from surrounding marshlands. The coastal area of this basin contains the most extensive estuarine water bodies in the State. These coastal water bodies are dominated by St. Helena Sound and Port Royal Sound and include numerous, often interconnecting, tidal creeks and rivers (SCDNR 2013).

All rivers in this basin are small, coastal plain drainages. Atlantic sturgeon were harvested commercially in the Coosawhatchie and Combahee Rivers in the early 1980s (Smith et al. 1984). There are a few records of juvenile Atlantic sturgeon taken by shrimp trawls in lower Port Royal Sound. Prior to 1994, there were very few authenticated records of shortnose sturgeon in the basin and only one record in the lower Ashepoo River (Collins and Smith 1996b; McCord 2003). Starting in 1998, attempts were made to capture adult shortnose sturgeon for a telemetry study to identify movements and habitat use (Collins, unpubl. data), these were largely unsuccessful. Atlantic sturgeon may spawn in the Combahee Rivers (Collins et al. 1999; 2000), however no records exist for adult Atlantic sturgeon in Ashepoo River. During the NMFS multistate study (2010 to 2011), seven Atlantic sturgeon were captured in the Combahee River (Post et al. 2014). Additional Atlantic sturgeon tagged in other river systems were also detected in the Combahee River, as well as several shortnose sturgeon. In general, the status of both the Atlantic and shortnose sturgeon is not well known for these small rivers.

Savannah Basin: The Savannah basin is located in western South Carolina and extends 265 miles southeast from the North Carolina state line to the coast. It shares its western border with Georgia and is the second largest in the State, encompassing an area of approximately 4,900

square miles. The Savannah River is the major watercourse in the basin (SCDNR 2013) and the only tributary known to contain sturgeon.

According to historical distribution records much of the historically available spawning and nursery habitat for sturgeons in the Savannah River remains accessible (USFWS 2001; ASSRT 2007). SCDNR has conducted dedicated sturgeon monitoring studies in the Savannah River since the 1980s. Most research was directed toward shortnose sturgeon, but information on Atlantic sturgeon (especially juveniles) was also acquired (Collins et al. 2000). From 1985 through 1992, and 1997 to 2000, sturgeons were captured by directed sampling and acquired from the by-catch of a network of commercial American shad (*Alosa sapidissima*) gill-net fishermen (Hall et al. 1991; Smith et al. 1993, unpubl. data). Radio and acoustic telemetry studies were conducted on shortnose sturgeon during 1985 to 1991 (Hall et al. 1991; Collins and Smith 1993). Detection data helped to determine seasonal movements (including the identification of two probable spawning sites), spawning frequency, adult sex ratios, and preferred habitats for both life stages (e.g., a nursery area for juveniles and use of freshwater versus saltwater or brackish habitats) (Hall et al. 1991; Collins and Smith 1993). Some of these shortnose sturgeon were also used as brood fish as part of a pilot stock enhancement program in the Savannah River (Smith and Collins 1996). About 92,000 progeny of various ages were released into the river at several locations. In addition to the stock-enhancement work, cultured juveniles were used in other studies, such as delineation of environmental tolerances (salinity, temperature, and DO; Jenkins et al. 1993) and identification of optimal tagging techniques (Smith et al. 1990; Collins et al. 1994). Spawning and culture research on Savannah River strain shortnose sturgeon has been conducted since the mid-1980s at several locations, including U.S. Fish and Wildlife Service facilities (e.g., Orangeburg National Fish Hatchery, Bears Bluff National Fish Hatchery) and South Carolina Department of Natural Resources facilities (e.g., Marine Resources Research Institute, Waddell Mariculture Center) (Collins et al. 2000).

A collaborative study (including Nature Conservancy, NOAA National Marine Fisheries Service, Georgia Department of Natural Resources, Georgia Ports Authority, and the Southeastern Natural Sciences Academy), was conducted from 2007 to 2009. The study focused on shortnose sturgeon essential fish habitat and resulted in the capture of 115 shortnose and 180 Atlantic sturgeon (SCDNR unpubl. data). During the NMFS multistate study (2011 to 2013), 47 Atlantic sturgeon and 33 shortnose sturgeon were captured (Post et al. 2014). Telemetry data from transmitted fish highlighted the spawning behavior of shortnose sturgeon as well as potential dual spawning runs of Atlantic sturgeon (Post et al. 2014).

Beginning in 2013, SCDNR has conducted sturgeon telemetry studies for the U.S. Army Corps of Engineers (USACE)-Savannah District as part of the Savannah Harbor Expansion Project. The study is ongoing and includes acoustically transmitting adults and juveniles of both species while maintaining the acoustic receiver array established in the Post et al. (2014) study. Telemetry data have been used to improve the understanding of seasonal nursery and foraging habitats for both species and to monitor annual spawning migrations of both species. These data have also identified potentially separate spring- and fall-spawning runs for Atlantic sturgeon however further validation is needed (Vine et al. 2019a).

Telemetry data from 2013 to 2018 were also used in a study to identify environmental cues of spawning migration behavior for both species. Results showed that cues for the initiation of migration and upriver movement were species-specific, but water temperature was the primary predictor of sturgeon migrations, and discharge also played a significant secondary role (Vine et al. 2019a). Another study conducted in the fall of 2017 used side scan sonar surveys to estimate Atlantic Sturgeon spawning migration abundance in the Savanah River. Results from Bayesian N-mixture modeling estimated a maximum daily spawner abundance between 35 and 55 individuals (95% credible interval) (Vine et al. 2019b).

Since the Savannah River forms the east–west border separating the states of South Carolina and Georgia, the University of Georgia has also conducted sturgeon research in the Savannah River and has conducted multiple population estimates in recent years. A study conducted from 2013 to 2015 used Huggins closed capture models to estimate that the Savannah River contained 528 (95% CI = 402–726) age-1 juvenile Atlantic sturgeon in 2013, 589 (478–742) in 2014, and 597 (437–852) in 2015 (Bahr and Peterson 2016). During the same study (2013 to 2015), shortnose sturgeon were also collect. Analyses estimated that the Savannah River contained 81 (95% CI = 27–264) age-1 juvenile shortnose sturgeon in 2013, 270 (162–468) in 2014, and 245 (104–691) in 2015. Huggins closed-capture models also estimated the river to contain 486 (198–1,273) age-2+ juveniles in 2013, 123 (69–235) in 2014, and 187 (81–526) in 2015. Similarly, the adult population was estimated to be 1,865 (784–4,694) individuals in 2013, 1,564 (1,005–2,513) in 2014, and 940 (535–1,753) in 2015. These data suggest that the Savannah River may contain the second largest population of Shortnose Sturgeon in the southeast (Bahr and Peterson 2017). An updated analysis of the Atlantic sturgeon data set to include the 2 subsequent years indicate greater numbers of age-1 Atlantic sturgeon (973 [95% CI = 786–1233], fish in 2016 and 639 [449–953] fish in 2017), implying abundance of age-1 recruits may be increasing in the Savannah River, however more data are needed to confirm this trend (Fox et al. 2023).

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

Because of the highly migratory nature of sturgeons, particularly the Atlantic sturgeon, these fishes require access to an expansive variety of high quality freshwater and marine habitats. Within state waters, adult Atlantic sturgeon migrate through nearshore Atlantic shelf waters and enter coastal sounds, bays and inlets to access the river basins in which they spawn. Shortnose sturgeon move primarily from tidal estuarine or brackish channels into freshwater reaches to spawn, however use of nearshore Atlantic shelf waters does occur (Post et al. 2014). Both species spawn in freshwater channel habitats from tidal river reaches to at least as far inland as the fall line in large, unobstructed river basins. Eggs of both species are adhesive and successful spawning is dependent upon the availability of relatively clean, hard substrates within river channels for egg adhesion and development. Both spawning and egg survival to hatching are dependent upon habitats with low to moderate flows and limited sedimentation. Shortnose sturgeon and, presumably, Atlantic sturgeon generally spawn where flow rate is 0.2 to 1.8 meters per second (0.7 to 6.0 feet per second) (Kynard 1997). Nursery and foraging habitats for both sturgeons (including adults within rivers) include all channel and adjacent out-of channel submerged habitats from a few kilometers seaward to estuarine sounds and bays of river basin deltas. During the fall and winter, sturgeon move seaward into brackish and estuarine channels. The Atlantic sturgeon over winters in deep channels and holes within coastal sounds and bays. It

is during such seaward migrations that Atlantic sturgeon may transfer into other river basins by traversing coastal Atlantic continental shelf waters (McCord 2003). Atlantic sturgeon tagged in South Carolina have been found as far south as northern Florida and as far north as New York.

CHALLENGES

Dams prevent upstream migration of sturgeons and other species (ASMFC 1990; NMFS 1998; USFWS 2001). Atlantic streams from Maine to Florida have undergone a restriction or loss of access for migratory fishes to about 84 percent of stream habitat within historic ranges from dams alone (Busch et al. 1998). Obstructed access to a diversity of habitats may limit basin-specific populations of both Atlantic and shortnose sturgeon. The Pee Dee, Santee, and Savannah basins in South Carolina are impacted by dams that restrict migrations of sturgeons into historical habitats (USFWS 2001). Dams can block spawning migrations and severely restrict the availability of spawning and nursery habitat, particularly in large river systems when dams are near the coast (ASMFC 1990), as in the Santee and Cooper Rivers. Dams and other impediments to migration have eliminated sturgeons from many historical habitats in South Carolina (USFWS 2001); the result being a general reduction in sturgeon populations in even currently accessible river reaches.

The Santee Basin has the second largest drainage area and total discharge (only the Susquehanna is larger) of all river systems on the east coast of the U.S. (Hughes 1994). However, this large watershed has been impacted by damming to a greater extent that most basins on the Atlantic Coast of North America, with nearly 45 dams in the South Carolina portions of the basin alone (USFWS 2001). The original Santee-Cooper diversion project, completed in 1942, shifted approximately 88 percent of the historical Santee River flow into the Cooper River, changing the average Cooper River flow rate from 2 cms (cubic meters per second) or 7 cfs (cubic feet per second) to 442 cms (1560 cfs) (Kjerfve 1976). Prior to rediversion in 1985, water releases at Pinopolis Dam on the Cooper River were generally continuous. A weekly average flow of 122 cms (430 cfs) has been maintained in the Cooper River since rediversion to protect water supplies (Orlando et al. 1994), but generation time has been restricted to as little as 10 hours per day. The original diversion of Santee River historical flows into the Cooper River caused average freshwater flow in the Santee River seaward of Wilson Dam to drop from 525 to 74 cms (1850 to 260 cfs) and allowed saltwater intrusion (Kjerfve and Greer 1978). The Santee-Cooper Rediversion Project returned about 70 percent of the Cooper River flow to the Santee, increasing average flow to approximately 367 cms (1,290 cfs) and reducing salinity in the lower Santee (Orlando et al. 1994). However, there is no minimum flow requirement at St. Stephen Dam on the Rediversion Canal (D. Cooke, SCDNR, per. comm., 2005) and the average daily flow from Wilson Dam is only 18 cms (63 cfs) higher (Orlando et al. 1994). During periods of low inflow into the Santee-Cooper Lakes, water releases can be discontinued at St. Stephen Dam (D. Cooke, SCDNR, per. comm., 2005). In contrast, the average daily discharge from Wilson Dam can approximate 500 cms (1,760 cfs) higher during flood-control releases (Orlando et al. 1994). The net result of flow regimens in both the Cooper and Santee Rivers is flows that are typically in highs and lows with more abrupt changes in flows from peaked power generation and flood releases than are characteristic of more gradual river flow changes that occur in open rivers where waters expand into, and withdraw from, floodplains. Dams, and particularly hydropower dams, often produce flow regimens that are not reflective of natural seasonal flows. Dams may

reduce minimum flows, thereby potentially dewatering otherwise productive habitats and increasing water temperature (NMFS 1998; USFWS 2001). Pulse flows used for peaking hydropower production can disrupt natural productivity and prey availability for larval and early juvenile fishes (Crecco and Savoy 1987; Limburg 1996), can displace eggs and/or larvae from otherwise highly productive habitats (USFWS 2001), and can disrupt both upstream and downstream migration patterns for adult and juvenile anadromous fishes (ASMFC 1985; ASMFC 1999; Limburg 1996; USFWS 2001). As part of dam relicensing through the Federal Energy Regulatory Commission (FERC), prescribed flows through the Santee Dam and St. Stephen Dam will be changed and increased to benefit sturgeon in the coming years (Santee Cooper Hydroelectric Project, FERC Project No. 199).

Atlantic sturgeon prefer moderate water temperatures, 12 to 24°C (54 to 75°F); body weight is negatively impacted at higher temperatures (McCord 2003). Reduced flows caused by dams can reduce dissolved oxygen (DO) to levels unsuitable for sturgeon (Secor and Niklitschek 2001). For example, DO within the Santee River Rediversion Canal can reach less than 3.0 mg/L (milligrams per liter) and more frequently reaches less than 4.0 mg/L during summer periods with low or no flows from St. Stephen Dam (Cooke and Leach 2004a). At least 20 adult shortnose sturgeon were killed in the Rediversion Canal following a DO crash related to decaying submerged vegetation that had been trapped on trash racks associated with turbines in St. Stephen Dam (Cooke and Leach 2004a). However, dissolved oxygen sensors have since been installed downstream and upstream of that dam and sensors are regularly monitored regularly. If the dissolved oxygen drops below a certain level, water is released from the dam. Water releases from deep reservoirs may be poorly oxygenated and/or of below normal seasonal water temperature, thereby causing loss of suitable spawning or nursery habitat in otherwise suitable river reaches. Deepwater releases in late winter through early spring (season of spawning) are often below the required temperatures: 13.3 to 17.8ºC for Atlantic (Borodin 1925), 8.0 to 15.0ºC for shortnose (Dadswell et al. 1984; Buckley and Kynard 1985).

Dredging and bridge construction may negatively impact sturgeons in several ways (ASMFC 1990). Deepened channels can allow saltwater to intrude further inland, and changes in salinity regimens can dramatically impact prey distribution (ASMFC 1990). Prey availability can also be reduced by the removal of benthic invertebrates within sediments (ASMFC 1990). Dredging can also negatively affect fish populations by producing suspended sediments (Reine et al. 1998). Sediment resuspension from dredging can cause increased turbidity and localized depletion of dissolved oxygen, as well as increased bioavailability of any contaminants that may be bound to the sediments (Clarke and Wilber 2000). High concentrations of suspended sediments, as well as relatively low concentrations sustained for several days, have been shown to cause direct mortality, impaired hatching success, reduced larval feeding, and diminished larval growth in several species of estuarine and anadromous fishes (Clarke and Wilber 2000). Suspended sediments have been linked to a variety of lethal and sublethal responses in juvenile and adult fishes that are consistent with oxygen deprivation due to gill clogging (Sherk et al. 1975; Sherk et al. 1974). Behaviorally, chronic turbidity from frequent or prolonged dredging can affect fish migration, spawning, conspecific interactions, and foraging (Coen 1995). Some fishes avoid waters of high sediment load, even during spawning migrations (ASMFC 1985; Reine et al. 1998). Water quality impacts and/or the reduction or elimination of prey may also disturb sturgeon concentration areas near the freshwater-brackish interface. Dredges, primarily hydraulic

or hopper dredges may damage or kill sturgeons by entrainment or impingement in drag-arms or impellers (ASMFC 1990; NMFS 1998).

Siltation from dredging and from agricultural, silvicultural, and other land use practices can also reduce spawning success by causing mortality of eggs or by coating substrates needed for attachment of adhesive eggs (NMFS 1998). Pollution, runoff and siltation input contaminants and pollutants into sturgeon habitat that can cause lowered pH or lowered DO, which can reduce survival of eggs, larvae, or juveniles (Rogers and Weber 1995; NMFS 1998; USFWS 1998). Bioaccumulation of contaminants, such as dioxin in parts of Winyah Bay, may reduce productivity or increase susceptibility to diseases or stress (Cooper 1989; Varanasi 1992; Sindermann 1994; NMFS 1998).

Erosion from agriculture and silviculture (logging) can significantly lower water quality and cause drastic adverse reactions in aquatic life (Butler 1968). Runoff carries silt, chemicals and nutrients into wetlands that, acting alone or in combination, can be lethal to aquatic life, and particularly to larval forms (Matthews et al. 1980; Aust et al. 1997). Runoff can cause sedimentation and nutrients can encourage algal blooms, both leading to eutrophication and possible dissolved oxygen (DO) depletion (Matthews et al. 1980; Lockaby et al. 1997). Siltation can also cause increased water temperature (Aust and Lea 1991; Perison et al. 1993). Further, siltation results in reduced productivity beginning at lower levels of food-chain relationships upon which juvenile sturgeons are dependent and disturbance of food-web relationships in adjacent and downstream waterways (Batzer et al. 2005). Forestry BMPs for bottomland forests are recommendations to landowners in order to conserve site productivity, primarily for silviculture, and are voluntary (South Carolina Forestry Commission 1998). When BMPs are not used, braided streams may be obstructed by plant material and disturbed soils, excessive ruts may channel eroded sediments into streams, partially stagnated waters may become nutrient-rich and promote algal growth that can die under extended periods of cloud-cover (J.W. McCord, SCDNR, pers. comm.). These factors contribute to increased water temperature and reduced DO.

Siltation, from erosion due to land use practices or from dredging, physically covers and kills some aquatic life, including submerged aquatic vegetation and thereby increases BOD (biological oxygen demand) (Funderburk et al. 1991; Valdes-Murtha and Price 1998). Submerged aquatic vegetation provides important ecological functions in freshwater habitats. Submerged aquatic vegetation improves water quality (Rybicki and Hammerschlag) and provides habitat for predator avoidance, foraging and nursery development for many macro-invertebrates and resident and migratory fishes (Maldeis 1970; Killgore et al. 1989; Monk 1988). Submerged aquatic vegetation is adversely affected by suspended sediments greater than 15 mg/l (Funderburk et al. 1991) and by deposition of excessive sediments (Valdes-Murtha and Price 1998).

Dewatering of freshwater streams from irrigation and other water removal projects decreases habitat availability and contributes to reduced water quality by concentrating non-point source pollution and increasing water temperature (ASMFC 1985). Density dependent impacts such as predation and competition may also increase. Sturgeons of various sizes can become impinged or entrained by intakes for power plants or by municipal, industrial or agricultural water intakes (Hoff and Klauda 1979; NMFS 1998).

Sturgeon also have been affected by commercial and recreational fishing operations. By-catch from gill nets, trawls, or trotlines may cause excessive mortality on adult shortnose sturgeon and on adult and juvenile Atlantic sturgeon (NMFS 1998). By-catch mortality for Atlantic sturgeon occurs in fisheries within the Exclusive Economic Zone (EEZ) (the Atlantic Ocean from 3 to 200 miles offshore). There is currently no management plan for sturgeon in the EEZ. (ASMFC 1998; Kahnle et al. 1998). Evidence of impingement in crab traps has been observed for juvenile Atlantic sturgeon (J.W. McCord, SCDNR, pers. comm.) and abandoned or lost traps may be problematic as potential sources of injury or mortality for both species of sturgeon. Illegal harvest of both species is likely, particularly for animals captured incidentally in American shad and shrimp trawl fisheries, but also from directed effort (NMFS 1998). Allowable take of sturgeons, as permitted under the ESA, may allow excessive mortality, particularly for adults in small populations (NMFS 1998). However, in 2010, NMFS required the state of South Carolina to account for and reduce by-catch of both species of sturgeon in fisheries. In response, SCDNR has made several changes to their shad fisheries and sent required documentation to NMFS.

Predation and competition between sturgeon and non-native species, such as flathead catfish (*Pylodictis olivaris*) and blue catfish (*Ictalurus furcatus*), may be additive to "more natural" sources of mortality. Both of these non-native catfishes are presumed to be problematic to sturgeons as both competitors and predators (NMFS 1998).

CONSERVATION ACCOMPLISHMENTS

The shortnose sturgeon was listed as an endangered species in 1967, the Atlantic sturgeon in 2012. In addition, both Atlantic and shortnose sturgeon received a high level of protection with the closure of the directed Atlantic sturgeon gill-net fishery in 1985, which made the possession of any sturgeon illegal in the South Carolina.

Both sturgeon species were incidentally caught in the ocean shad fishery (J.W. McCord, SCDNR, pers. comm.). The ASMFC's Amendment 1 to the Interstate Fisheries Management Plan (IFMP) for shad and river herring mandated closure by 2005, preceded by an effort phase-out period. Any reduction in shad fishery effort reduces the potential for by-catch and associated mortality. Participation in South Carolina's American shad gill-net fishery has gradually declined over at least the past 30 years.

An IFMP was developed for the Atlantic sturgeon under the auspices of the Atlantic States Marine Fisheries Commission (ASMFC 1990; 1998). In addition to numerous management recommendations, the sturgeon amendment also includes requirements for states to monitor by-catch in all fisheries and to control levels of by-catch if necessary. More importantly, the 1998 amendment required all states to implement a moratorium on sturgeon harvest for 20 to 40 years. Despite the earlier closure of directed Atlantic sturgeon fisheries in South Carolina, the coast wide moratorium is important for management of populations in South Carolina because of the migratory behavior of Atlantic sturgeon.

Additional protection from bycatch mortality was afforded to both Atlantic and shortnose sturgeon with the initiation of bycatch reduction devices (BRDs) and turtle excluder devices

(TEDs) in shrimp trawl nets, as required by the NMFS. In 1990, TEDs were required and BRDs were required in 1996. According to commercial shrimp trawler captains interviewed by the author in 1995, sturgeon bycatch has been substantially reduced by these devices.

The Santee-Cooper Rediversion Project completed in 1985 also enhanced year-around flows and average late winter and spring water levels in the Santee River, primarily seaward of the Rediversion Canal. These improved flow regimens have presumably produced increases in the quantity and quality of spawning and nursery habitat for both sturgeons seaward of St. Stephen Dam and the Rediversion Canal. Accordingly, both Atlantic and shortnose sturgeon may have been positively influenced.

CONSERVATION RECOMMENDATIONS

- Conduct statewide surveys of Atlantic and shortnose sturgeon populations, particularly for small rivers where stock status is poor or unknown, to determine abundance (or presence/absence), age structure, and recruitment indices of juveniles into spawning populations. Develop standardized sampling protocols for inventorying life stages for both species.
- Expand sturgeon tagging programs to other South Carolina rivers to gather additional information on movements of both species within and between river basins.
- Validate aging techniques for South Carolina sturgeons by analyzing archived hardened fin-rays collected from sturgeons and comparing growth rings with seasonal growth (in length) of recaptured sturgeon.
- Explore the application of alternative ageing approaches and techniques for South Carolina sturgeons such as chemical marking (e.g., calcein or alizarin red S), DNA methylation, Near-infrared spectroscopy, and scanning electron microscopes.
- Compare the genetic relationship of shortnose sturgeon between all South Carolina Rivers.
- Determine genetic relationships for spring and fall spawning Atlantic sturgeon within all individual drainage basins.
- Prioritize the genetic assignment of tagged fish, including the processing of archived samples, to improve the estimates of Z at the DPS-level.
- Develop standardized methods that can be used to create reliable indices of abundance
- for adults and young juveniles (age 0–1) to reflect the status of individual DPSs.
- Determine the minimum viable populations for both Atlantic and shortnose sturgeon, below which stocking should be considered.
- Develop breeding and stocking protocols for both species of sturgeon that protect the genetic integrity of unique populations.
- Document seasonal distribution of both sturgeons throughout the state to identify and map essential habitat.
- Inventory existing sources of mortality for sturgeons and formulate remedies where practical.
- Improve quality and scope of coverage for sturgeon by-catch records received from mandatory catch and effort records collected from shad and herring fisheries and expand the program to include non-gamefish gill-nets. Additionally, create a survey to collect

sturgeon by-catch information from gill-net fisheries and to determine the reliability of mandatory reports. Require sturgeon by-catch reporting for all trawl fisheries.

- Investigate impacts of logging in swamp forests on water quality and habitat, especially as related to sturgeon spawning and nursery habitat.
- Determine impacts of dewatering of freshwater streams from irrigation and other water supply withdrawal projects. Determine the relation of river discharge rates to sturgeon spawning success.
- Characterize the degree to which vessel strikes in specific rivers and estuaries may be impacting populations which spawn in other locations.
- Evaluate strategies to reduce or mitigate mortalities from ship strikes. Improve understanding of how dredging may concentrate Atlantic sturgeon within high-traffic shipping channels and elevate risk of adverse interactions.
- Investigate potential need for fish passage at various dams by evaluating upstream spawning and nursery habitat.
- Investigate the potential for improving spawning success of both species by deployment of rock to supplement natural spawning substrate or to create new spawning habitat.
- Conduct an interview survey of past sturgeon fishery participants for the purpose of gathering invaluable information on productive fishing techniques and gear, on most productive sites, and on seasonality of sturgeon spawning runs.
- Determine potential impacts of predation and competition from non-native species on sturgeons and, to the extent possible, control and prevent further distribution of non-native blue and flathead catfish populations.
- Evaluate state water quality standards and BMPs that may impact wetlands to ensure that these practices adequately protect sturgeon habitat.
- Determine minimum flows below dams that are necessary to maintain appropriate dissolved oxygen levels for sturgeons and the response of sturgeons to low dissolved oxygen, particularly within preferred habitats.
- Determine impacts of pollution, contaminants, and siltation on all life history stages of sturgeons.
- Evaluate utilization and effectiveness of existing fish passage structures and protocols for Atlantic and shortnose sturgeon.
- Determine impacts of biotic and abiotic factors on egg, larval, and juvenile survival and development and how such factors relate to spawning stock recruitment.
- Assess the impacts of dredging, open water disposal of sediments, and blasting on sturgeons and on their habitat and prey base.
- Determine food habits by habitat type and life stage for both species of sturgeon and the relationships of food habits to availability and density of potential prey.
- Determine contaminant loads in sediments of areas frequented by either sturgeon species, determine contaminant loads in sturgeon tissues, and determine the impacts of contaminants on sturgeon health.
- Participate in FERC-relicensing exercises and partner with USFWS, NMFS and NGOs (non-governmental organizations) to ensure that cost-effective and efficient designs for providing both upstream and downstream passage of sturgeons are installed in dams that are currently blocking access to suitable spawning and nursery habitats.

- Partner with NMFS, USFWS, USACE, NGOs, and local governments to improve access to a full diversity of habitats by including fish passage designs wherever appropriate and by removing, breeching, or bypassing impediments to migration such as nonfunctional dams, dikes, or causeways.
- Build partnerships with NGOs, permitting authorities, and county and local governments to improve and/or implement the use of Best Management Practices (BMPs) in agriculture, silviculture, and urban development activities to reduce siltation and contaminant input.
- Partner with the South Carolina Department of Environmental Services to develop water removal guidelines for agricultural, civil or industrial purposes that include considerations for the needs of migratory fishes.
- Continue and expand partnerships with UGA and GADNR to study and manage sturgeon populations in the Savannah River.
- Continue and expand partnerships with UNCW and North Carolina natural resource agencies to study and manage Atlantic and shortnose sturgeon populations in the Pee Dee Basin.
- Continue and expand partnerships with NMFS and regional universities (Clemson University, University of Georgia, University of North Carolina Wilmington, and Coastal Carolina University) to study sturgeon populations throughout the southeast.
- Partner with GADNR, USACE, USFWS, NMFS, and local governments to provide sturgeon passage at New Savannah Bluff Lock and Dam and at dams inland of this point, should passage be deemed appropriate at other barriers.
- Partner with NGOs state and federal agencies, and industry to discourage deforestation of river floodplains and swamp forests.
- Partner with appropriate permitting authorities, including the USACE, to design dredging protocols that consider the timing of sturgeon migration and that protect freshwater-brackish interface zones.
- Partner with other coastal states, possibly through the ASMFC, to promote protection of the Atlantic sturgeon in the EEZ.
- Form an alliance with other state and federal agencies as well as NGOs to implement range wide conservation and management of sturgeons as described in the ASMFC IFMP for Atlantic sturgeon and the NMFS FRP for shortnose sturgeon.
- Partner with NGOs and other state and/or federal agencies to promote changes in water release protocols for dams that will restore or approximate natural flow regimens, increase minimum flows and improve water quality below dams.
- Partner with South Carolina Department of Environmental Services, federal agencies and NGOs to develop or revise river basin plans to identify habitats areas of particular concern (HAPCs), to identify degraded or threatened habitats and to identify preventative or mitigation actions.
- Partner with South Carolina Department of Environmental Services to designate critical coastal areas, such as freshwater-brackish interface zones.
- Partner with other state agencies to regionally review and manage projects and planning activities that protect sturgeon habitat.

- Partner with the NMFS, USFWS, and other groups to confine allowable take of sturgeons by water intake facilities to levels that do not limit population growth, particularly for small stocks.
- Critical habitats and migration patterns for Atlantic and shortnose sturgeon should be included in Coastal Zone Management Plans, in BMPs for non-point source pollution, and in State Pollution Discharge Elimination Systems permits. Develop education and outreach programs that distribute information to governments, civic groups, educational systems and NGOs regarding critical habitat needs, threats and potential conservation actions for sturgeons.
- Improve understanding of offshore habitat use, particularly in areas where offshore energy development and mineral removal may be planned.
- Leverage species distribution models and acoustic telemetry data to identify key areas of occupancy along the coast throughout the year (for the species overall, and specific to each spawning population and DPS).
- Develop education programs to specifically address by-catch of sturgeons in American shad and other gill-net fisheries, trawl fisheries and various trap and trot-line fisheries.

MEASURES OF SUCCESS

By improving aquatic ecosystem health and access to and from suitable spawning and nursery habitats, and by monitoring population responses to conservation actions as suggested above, SCDNR will be able to promote and document rebounding populations of both Atlantic and shortnose sturgeons.

“Atlantic” Highfin Carpsucker

Carpiodes velifer

DESCRIPTION

Taxonomy and Basic Description

The “Atlantic” Highfin Carpsucker (*Carpiodes* sp. cf. *velifer*) is a member of the sucker family (Catostomidae), which is represented by 78 described species in North America (Page et al. 2023). Suckers comprise about 8% of the continent’s freshwater ichthyofauna, behind only minnows (Leuciscidae) and perches and darters (Percidae) in number of species (Warren and Burr 2014). There are currently three described species of *Carpiodes* suckers (Page et al. 2023), which are primitive, deep bodied, silver-colored fishes with a long dorsal fin (Jenkins and Burkhead 1994). The form of the Highfin Carpsucker on the Atlantic slope has long been recognized as distinct from populations in the Mississippi and eastern Gulf drainages (Lee et al. 1980; Rohde et al. 2009; Tracy et al. 2024) but awaits full description.

This family is characterized by soft-rayed fins, a mouth located on the underside of the head, thick, fleshy, distensible lips, and paired fins attached low on the body (Rohde et al. 1994). “Atlantic” Highfin Carpsuckers can reach lengths of 50 cm (19.7 in.; Rohde et al. 1994). In South Carolina, the “Atlantic” Highfin Carpsucker most closely resembles the “Carolina” Quillback (*Carpiodes* sp. cf. *cyprinus)*, but the former has a steeper forehead and shorter snout, a nipplelike projection on the lower lip, and usually has fewer lateral scales and dorsal fin rays.

Status

The “Atlantic” Highfin Carpsucker is currently listed globally as apparently secure (G4) to secure (G5) (NatureServe 2024). It is listed as vulnerable (S3) in South Carolina and is considered imperiled to vulnerable (S2S3) in Georgia. This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The “Atlantic” Highfin Carpsucker occurs on the Atlantic Slope from the Cape Fear River in North Carolina to the Altamaha River in Georgia (Rohde et al. 2009). In South Carolina, the Highfin Carpsucker occurs in the Santee basin (known from the Tyger, Broad and Congaree Rivers and Lake Marion) and the Savannah River. SCDNR staff collected this species in lower

Twelvemile Creek, a tributary of Lake Hartwell in the upper Savannah River basin, in 2012 and subsequent years, representing a population there. Despite being known from relatively few, now decades-old records in the North Carolina section of the Great Pee Dee River below Blewett Falls Dam (Tracy et al. 2024), there are no records from the South Carolina portion of the river (Rohde et al. 2009).

In South Carolina, this species was observed in 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023. There appear to be healthy populations with recruitment in the Broad River, Congaree River, and Savannah River, although it is still relatively uncommon compared with most other catostomids in these rivers. Based on recent work in North Carolina, the "Atlantic" Highfin Carpsucker is presumed to have been extirpated from the Great Pee Dee River (or exists at nearly undetectable levels and is extremely close to extirpation) (Tracy et al. 2020; B. Jones, NCWRC, pers. comm. 2024). Extensive sampling for suckers in the section of the Great Pee Dee River downstream of Blewett Falls Dam in recent years has failed to yield this species (B. Jones, NCWRC, pers. comm. 2024). In the Cape Fear River, North Carolina, this species was last recorded in the mid-1990s despite targeted sampling in recent decades; it is also presumed to be extirpated from this river (B. Jones, NCWRC, pers. comm. 2024). Preservation of populations in the Santee and Savannah River basins is extremely important to the global preservation of the species given its likely extirpation from the Cape Fear and Pee Dee rivers.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The "Atlantic" Highfin Carpsucker inhabits small to large rivers in areas with moderate or swift current over firm sand and gravel substrate (Robison and Buchanan 1988; Etnier and Starnes 1993; Pflieger 1997; Rohde et al. 2009). In standardized sampling covering streams to small rivers of South Carolina, this species exhibited its highest frequency of occurrence (5.6%) and highest average relative abundance (0.03%) in upland small rivers (watershed area 300 – 2,000 km^2) of the Santee River basin, and it is also found in larger rivers (for which standardized data was not available). *Carpiodes* suckers spawn in slow current and pools, with eggs deposited on firm gravel (Warren and Burr 2014 and sources therein).

CHALLENGES

This species is susceptible to the same pervasive types of anthropogenic habitat alteration and fragmentation affecting other large riverine catostomids (Cooke et al. 2005), including the construction and operation of dams and impoundments, sedimentation of important foraging and spawning habitats, alteration of hydrologic regimes, and introduction of non-native species. Among the *Carpiodes* suckers, the Highfin Carpsucker has been regarded as the most sensitive to anthropogenic alteration and impoundment of riverine habitats (Robison and Buchanan 1988; Etnier and Starnes 1993; Pflieger 1997; Marcy et al. 2005), with associated effects implicated in its decline in portions of the range (Smith 2002; Boschung and Mayden 2004). During unsuccessful searches for "Atlantic" Highfin Carpsuckers in the Cape Fear River, North Carolina, abundant non-native Flathead Catfish and Blue Catfish were documented in the habitats being targeted for this carpsucker (B. Jones, NCWRC, pers. comm. 2024).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

    - Mruzek, J.L., L.M. Bower, M.C. Scott, K. Kubach, and B.K. Peoples. *In review* 2024. Relative influence of flow regime, natural and anthropogenic environment on dimensions of local fish diversity. Hydrobiologia.

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna.

CONSERVATION RECOMMENDATIONS

- Complete work on genetic relationships of existing wild populations of the Highfin Carpsucker.
- Identify and protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this and other species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Banded Killifish is a member of the topminnow family (Fundulidae) and one of 38 described species of the genus *Fundulus* (Page et al. 2023), many of which occur predominantly in brackish or estuarine waters. As of 2024, genetic investigations are in progress and suggest the form occurring in the Waccamaw River in South Carolina may be distinct from other populations along the Atlantic drainages and other portions of its range (F. Rohde, pers. comm. 2024). It is closely related to and probably evolved from the Waccamaw Killifish (*F. waccamensis*), endemic to Lake Waccamaw in southeastern North Carolina (Rohde et al. 2009).

The Banded Killifish reaches a length of 130 mm (5.1 in.). The fundulids are commonly used as bait (Jenkins and Burkhead 1994) and are important for mosquito control (Rosen 1973). Hobbyists also keep many members of the family in aquaria. The Banded Killifish is distinguished from others in the genus by a more elongate body, longer and more flattened snout, small scales and numerous narrow bars. Bars are darker than the background color in females and silvery in males (Rohde et al. 1994).

Status

The Banded Killifish is considered secure or apparently secure (G5) throughout most of its global range (NatureServe 2024). In locations on the fringes of its range, it is classified as critically imperiled (S1) in South Carolina and South Dakota, and imperiled (S2) in Iowa and Manitoba (NatureServe 2024). The Banded Killifish is considered apparently secure (S4) in North Carolina.

POPULATION SIZE AND DISTRIBUTION

Broadly, the Banded Killifish is widely distributed along the Atlantic Slope from the Waccamaw River in South Carolina to the Canadian Maritime Provinces and Newfoundland; St. Lawrence, Great Lakes, and Mississippi River Basins from Quebec to Manitoba; and south to southern Pennsylvania, northern Illinois, and northeastern Nebraska (Page and Burr 1991). However, the subspecies *F. d. diaphanus* dominates in Atlantic slope drainages and *F. d. menona* in the remainder of its range, with the exception of the St. Lawrence and Lake Erie drainages where the

two subspecies integrate. In South Carolina, the Banded Killifish occurs only in the Waccamaw and Sampit Rivers (Rohde et al. 2009). This species is common to abundant throughout much of its range; however, on the southern fringe of its global range in the Waccamaw River drainage, it is by all indications relatively uncommon. This species was not observed in any SCDNR standardized stream and river sampling over the past 20 years, and four individuals collected in the Waccamaw River by a Coastal Carolina University ichthyology class (D. Crane, Coastal Carolina University, pers. comm.) represent the only known recent observations of this species in its native range in the state.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Banded Killifish can survive in a wide range of salinities, from fresh water to estuaries with salinity as high as 20 ppt but reside almost exclusively in fresh water (Warren and Burr 2020). It inhabits quiet waters of lakes, ponds, and sluggish streams, usually over a sand, gravel, or detritus-covered bottom where there are patches of submerged aquatic plants. Schools of these fish tend to stay in shallows in the summer (NatureServe 2024).

CHALLENGES

Challenges to this species are similar to those for other aquatic fauna and include alterations in channel morphology and flow, point and nonpoint source pollution and sedimentation. Based on the indications that the Waccamaw River form of this species may be genetically distinct from other populations, this form represents an endemic and highly unique component of the state's aquatic biodiversity. Its apparently low abundance and elusiveness represent a fundamental challenge in establishing a baseline for evaluating abundance and monitoring trends. The restricted range in a coastal river furthermore places this species in an area of rapid development and habitat alteration. For example, flow control measures are commonly employed to facilitate development along coastal river corridors, which can alter the natural flow regime of littoral habitats, both reducing habitat availability/suitability as well as the fitness of inhabitant species (Farly et al. 2021).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and

restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

    - Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Identify lotic and lentic habitats with healthy populations and intact critical habitat in the Waccamaw and Sampit River systems. Protect these areas, once identified.

- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) as well as protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators on the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Banded Sunfish

Enneacanthus obesus

Contributors (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

Photo: NCFishes.com

DESCRIPTION

Taxonomy and Basic Description

The Banded Sunfish is a member of the sunfish family (Centrarchidae), which is currently represented by 41 described North American species including many popular sport fishes (Page et al. 2023). *Enneacanthus* sunfishes, all three of which are found in South Carolina, are small, laterally compressed sunfishes collectively distributed on the Atlantic and Gulf coastal plains from New Hampshire to Mississippi (Sweeney 1972; Darden 2008). Among the *Enneacanthus* species, the Banded Sunfish is most closely related to the Bluespotted Sunfish (*E. gloriosus*) and studies have shown evidence of a relatively recent divergence from *E. gloriosus* (Darden 2008; Kie 2011).

Adult Banded Sunfishes are small and stocky, ranging in total length from 50 to 95 mm (2.0 to 3.8 in.) (Rohde et al. 2009). The body is olive-brown to olive-green, with 5 to 8 dark vertical bars on the side and many small, irregularly-placed iridescent spots on the side and fins. Typically, there is a continuous iridescent bluish crescent under the eye and a large black spot (larger than the pupil) on the operculum (Rohde et al. 2009).

Status

The Banded Sunfish is considered secure (G5) on a global scale and is currently ranked vulnerable (S3) in South Carolina (NatureServe 2024). This species is considered vulnerable (S3) or more highly imperiled (S2 or S1) in all states within its range except Georgia (S4), Maryland (S3S4), Massachusetts (S4) and New Jersey (S4) (NatureServe 2024). It is considered State Significantly Rare in North Carolina (Tracy et al. 2020) and was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Banded Sunfish is found on the Atlantic Coastal Plain from southern New Hampshire to north-central Florida and along the Gulf Slope to eastern Alabama (Rohde et al. 2009). It is found across all of South Carolina's Coastal Plain drainages, occurring most widely in the mid to outer (lower-elevation) coastal plain (compared with Blackbanded Sunfish, which associates primarily with the inner coastal plain) (Rohde et al. 2009; Marion et al. 2015; SCDNR data). This species is relatively uncommon (Rohde et al. 2009); based on standardized sampling in

South Carolina, frequency of occurrence and relative abundance of Banded Sunfish are both almost five times lower than those of its congener on the outer coastal plain, the Bluespotted Sunfish (*E. gloriosus*). In South Carolina, this species was observed in 3.8% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

Banded Sunfish occur primarily in sluggish Coastal Plain streams and swamps as well as vegetated backwaters of lakes and ponds, often over silt or sand (Rohde et al. 2009). It is most strongly associated with streams exhibiting low current velocity (Marion et al. 2015) and, like the other *Enneacanthus*, is most often found near aquatic vegetation (Ciccotto 2011). This species has also been collected in tidally-influenced coastal rivers (SCDNR data). Natural watershed forest and wetland cover is important in maintaining the dependent water chemistry required by this species, which is characterized by low pH and high dissolved organic carbon (Ciccotto 2011). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (13.7%) and average relative abundance (0.8%) in small streams (watershed area 0-15 km^2) of the outer coastal plain.

CHALLENGES

Although it appears to have a wide range across the Coastal Plain of South Carolina, the Banded Sunfish generally occurs in low abundance where it is found. Anthropogenic alteration of natural landscapes for development or agriculture, siltation, and hydrologic alterations such as channelization and construction of impoundments threaten this species. The conversion of native forest and wetland cover in the watershed and riparian zone for development or poorly planned agriculture reduces in numerous ways the suitability of low-gradient coastal plain habitats for this species and its ecological associates. The physicochemical habitat template for which this species and other lowland coastal plain specialists are evolved is dependent on intact forested watersheds with functional wetlands (Ciccotto 2011). Mature forest and riparian vegetation are important sources of large woody debris in Coastal Plain streams, which provides critical habitat for many endemic southern Atlantic coastal plain species including the Banded Sunfish (Marion 2008). Alteration of naturally sluggish lowland swamps and streams into channelized, shallow drainage ditches with unnaturally high current velocities greatly reduces the suitability of habitat this species and other “non-fluvial” specialists (Marion et al. 2015). Furthermore, the introduction of contaminants from agricultural runoff (exacerbated by removal of riparian vegetation) can disrupt physiological function in such settings and biological assemblages (Breitmeyer et al. 2022).

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) as well as protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Bannerfin Shiner belongs to the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). The Bannerfin Shiner is one of eight described plus one undescribed (as of 2024) species of *Cyprinella* in South Carolina.

Members of the genus *Cyprinella* are distinguished from other leuciscids by their diamond-shaped scales and black pigmentation in the dorsal fin membranes (Rohde et al. 1994). Bannerfin Shiner can be distinguished from other *Cyprinella* by the position of the black blotch, which occurs on the anterior portion of the dorsal fin. Bannerfin Shiners are deep-bodied, slender fish with a flattened underside and long, rounded snout. The back is olive-tan with a dark middorsal stripe; the belly is white and the flanks are silvery gray (with a purplish iridescence in breeding males). Bannerfin Shiners reach lengths of 100 mm (3.9 in.; Rohde et al. 1994).

Status

The Bannerfin Shiner is considered apparently secure (G4) globally but is considered vulnerable (S3) in South Carolina (NatureServe 2024). Bannerfin Shiner populations appear to be stable (Warren et al. 2000; NatureServe 2024), although it is uncommon and sometimes rare (Page and Burr 1991; NatureServe 2024). Collections have been made at numerous sites throughout its limited range. The Bannerfin Shiner is considered vulnerable (S3) in Georgia and Florida.

POPULATION SIZE AND DISTRIBUTION

The Bannerfin Shiner occurs in Atlantic slope drainages from the Edisto River, South Carolina to the Altamaha River, Georgia (NatureServe 2024). It also occurs in the gulf slope drainages of the Ochlockonee and Suwanee Rivers in Georgia and Florida (Marcy et al. 2005). In South Carolina, the species is restricted to the coastal plain ecoregion in the Edisto and Savannah River drainages

(Rohde et al. 2009). This species was observed in 0.3% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Bannerfin Shiner inhabits channels of medium- to large-sized, sand-bottomed, coastal plain rivers. Schools often gather in eddies behind woody debris or other structure. They rarely enter tributary streams farther upstream than the modern floodplain (Marcy et al. 2005). As with other non-barbeled *Cyprinella* species, the Bannerfin Shiner is a crevice spawner, depositing eggs in crevices of logs and rocks in a territory defended by the male over an extended spring-summer breeding period (Gale and Buynak 1978; Rohde et al 1994; Rohde et al. 2009). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (15.4%) and average relative abundance (0.1%) in small coastal plain rivers (watershed area 300-2000 km^2) of Sand Hills (fluvial) character.

CHALLENGES

The Bannerfin Shiner, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. The breeding behavior of the non-barbeled *Cyprinella* makes this group particularly vulnerable to impacts from both suspended and deposited sediment. Because the breeding process is dependent on visual cues (extended display and territorial defense period) as well as clean crevices for egg deposition and larval development, suspended sediment (increased turbidity) and deposited sediment has been shown to delay or inhibit spawning success in fishes of this genus (Hubbs and Echelle 1972; Burkhead and Jelks 2001; Warren and Burr 2014).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use

and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Identify streams and rivers with healthy Bannerfin Shiner populations and intact critical habitat in the Savannah River drainage below the Fall Line, the Edisto River System, and the ACE basin. Protect these areas, once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices as well as protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.

- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Educate aquarists as to the adverse impacts of removing fish from the wild.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

“Bartram’s” Bass

Micropterus sp. cf. *coosae*

Photo: NCFishes.com

Contributor (2005): Dan Rankin and Jason Bettinger [SCDNR]
Reviewed and Edited (2013): Jean Leitner and Mark Scott [SCDNR]
Reviewed and Edited (2024): Mark Scott, Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, and Andrew Peel [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

Bartram’s Bass is a member of the family Centrarchidae. Bartram’s Bass represents one of only 3 native black basses in South Carolina; both Smallmouth and Alabama Bass (*Micropterus dolomieu* and *M. henshalli*, respectively) are introduced in this state. The closest relative of the Bartram’s Bass is the Redeye Bass (*M. coosae*), which is endemic to the Mobile River system (Lee et al. 1980). Historically, Bartram’s Bass was considered as another population of Redeye Bass and was referred to under that name, until taxonomic revisions of this complex recognized new species across the Mobile River basin and the Chattahoochee drainage, from what was part of the original *M. coosae* range (Baker et al. 2013). The Savannah River basin represents a distinct genetic lineage as well, indicating separate species status with the suggested common name of “Bartram’s Bass” (Freeman et al. 2015). Further, Oswald et al. (2015) found significant genetic diversity within the Savannah and identified multiple management units. The species has yet to be formally described, but final work is now being performed to describe South Carolina populations as “Bartram’s” Bass.

Bartram’s Bass are similar in structural features and more closely related to Alabama Bass than to Smallmouth Bass. However, Bartram’s Bass are known to hybridize with both species (Turner and Bulow 1989; Pierce and Van Den Avyle 1997; Philipp et al. 2002). In native stream habitat, Bartram’s Bass range in length from 144 to 381 mm (5.6 to 15 in.; Rohde et al. 2009); however, where found in the Savannah River impoundments, Bartram’s Bass often exceed this size range. Bartram’s Bass are typically olivaceous to bronze dorsally with black blotching or mottling. The jaw extends even with the back of the eye. Laterally, Bartram’s Bass have black vertical bars or blotches, which are not connected. Bartram’s Bass typically have eleven or fewer lateral bars or blotches, whereas Alabama Bass generally have a more or less continuous lateral stripe, or it is broken up into more than eleven bars or blotches. Bartram’s Bass have ventro-lateral streaks that are typically darker and more irregular than those in Spotted or Alabama Basses. A white margin on the upper and lower tips of the caudal fin and often along the margin of the anal fin is a key characteristic. This margin may be less obvious in older specimens. The anal fin typically has dark pigmentation. About 60% of Bartram’s Bass from the upper Savannah River basin possess a tooth patch on the tongue (SCDNR unpublished data).

Status

The Bartram's Bass was listed as stable in Warren et al. (2000), before the risk of introgressive hybridization was recognized, and is currently globally unranked (GNR; NatureServe 2024). The Bartram's Bass is ranked critically imperiled (S1) in South Carolina (NatureServe 2024); studies have shown that South Carolina populations are imperiled due to introgressive hybridization with nonnative black bass species, primarily Alabama bass (Bangs et al. 2018, Peoples et al. 2021). Hybrids have also been collected from stream and river populations throughout the upper and middle Savannah Basin though their impact is not yet fully understood (Leitner et al. 2015, Peoples et al. 2021). In Georgia, Bartram's Bass are considered vulnerable (S3) while in North Carolina they are considered critically imperiled (S1), largely due to their limited range (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

The native range of the originally described Redeye Bass includes the Mobile Basin above the Fall Line and the upper Chattahoochee, Altamaha and Savannah drainages (Etnier 1993; Rohde et al. 2009; Lee et al. 1980), although—as noted above—populations outside of the Mobile including the Savannah system have been shown to be distinct. The Bartram's Bass is native to the Savannah River basin of Georgia, South Carolina and a small portion of North Carolina. It is primarily found in the uplands, or the upper half of the Savannah River basin, but is also present at and just below the Fall Line in the main stem Savannah River (Rohde et al. 2009). The Chattooga River, once being a tributary to the Chattahoochee system (Ross 1970), likely explains the presence of Bartram's Bass in the Savannah drainage. Ramsey (1973) considered all populations outside this range to be a result of stocking. Redeye Bass have also been introduced in Tennessee, Kentucky, California and Puerto Rico (Lee et al. 1980; Etnier and Starnes 1993).

The Bartram's Bass occurs in the Santee drainage in South Carolina as well. In the Saluda River it is found primarily in the river's mainstem and tributaries below the Saluda Dam, with records dating to the 1960s (SCDNR unpublished data). One report of Bartram's Bass from a tributary upstream of Saluda Dam is documented in the Clemson University's museum collection. The species also occurs in the Broad River, including the Enoree and Pacolet Rivers. Their patchy distribution and apparently recent spread would tend to support taxonomists' opinions that Bartram's Bass are not native to the Santee River system, but this is debatable and currently under study.

Bartram's Bass are sensitive to habitat alterations in their native flowing-water systems, and this is exacerbated by presence of nonnative bass (Peoples et al. 2021). Bartram's Bass can be locally common in their upper Savannah range (Peoples et al. 2021; SCDNR unpublished data) but concern remains over unknown dynamics of nonnative invasion and hybridization throughout the system. The research over the last decade has included a National Fish & Wildlife Foundation (NFWF) grant through the Southeast Aquatic Resources Partnership and a Competitive State Wildlife Grant (with GADNR and Clemson University as partners). Results from 2017-2018

collections documented an expansion of the Alabama Bass genome widely into lotic habitats across the upper Savannah range, with 45% of sites where bass were collected being occupied by Alabama Bass or their hybrids, and the discovery of hybrid nesting and progeny production *in situ* (Judson et al. 2021, Peoples et al. 2021).

Even in some tributaries where non-native bass are not yet known, the persistence of Bartram's Bass may be uncertain. In several drainages in which historical records of Bartram's Bass exist, recent sampling efforts in what seem outwardly suitable habitats have not been successful in relocating any individuals. For example, in the upper Stevens Creek/Turkey Creek system in which numerous collection localities date to the 1970s, recent sampling efforts have failed to yield Bartram's Bass in this portion of the drainage. Similarly, in the Little River system (South Carolina) draining to Lake Thurmond, sampling of the lone historic collection locality were unproductive; numerous samples throughout the system over the past 18 years have also been unsuccessful in confirming its persistence. Searches of the best remaining large shoal habitats in many tributaries have not been successful in locating the species. It remains to be determined whether the lack of detection in such cases reflects actual extirpation or very low densities. Nevertheless, numerous populations of pure or nearly pure Bartram's Bass continue to persist in largely disjunct tributaries across the basin, with nearly 60% of sites sampled in 2017-2018 harboring pure Bartram's (Peoples et al. 2021).

Although Redeye Bass reportedly perform poorly in impoundments within their native range, Bartram's Bass thrived in the large oligotrophic and mesotrophic reservoirs of the upper Savannah River system prior to the introduction of Alabama Bass (Barwick and Moore 1983; Barwick et al. 2006; Oswald et al. 2015). However, recent studies show the Bartram's Bass has since likely been eliminated from Lakes Keowee and Russell via introgressive hybridization. The species also declined by more than 60% in Lakes Jocassee and Hartwell over the 6-year period from 2004 –2010 (Bangs et al. 2018). Recent collections in 2021-22 have failed to document presence of genetically pure Bartram's Bass in Lakes Hartwell and Jocassee (SCDNR unpublished data).

Current work continues to focus on what effects introduced black bass will have on Bartram's Bass in their native running-water habitats – mainstem Savannah and tributary streams. Many of the tributaries to the lakes do have barriers to upstream fish movement, which may protect stream populations of Bartram's Bass from invasion of Alabama Bass or their hybrids to some extent, although angler-assisted movement of nonnative bass remains a serious issue. Tagging and telemetry work on Eastatoee Creek showed limited movement upstream by Alabama Bass and their hybrids from their Lake Keowee source population, with refugia for pure Bartram's Bass in the upper reaches of the creek (Zumwalt 2023). The dynamics of this situation in terms of active invasion versus segregation remains to be seen. This species was observed in 3.9% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

Bartram's Bass occur in a variety of habitats in South Carolina from fast flowing, high-gradient streams of the Blue Ridge and Upper Piedmont Ecoregions to lower-gradient streams and the Savannah River just below the Fall Line. It is found in mid-sized streams to large rivers and

reservoirs; the Savannah River mainstem below Stevens Creek Dam to Augusta Shoals may be one of the strongest populations extant, and robust populations also occur in the Chattooga and Chauga Rivers. This species exhibits its highest densities in large, high-gradient shoal habitats characterized by bedrock and boulders producing heterogeneous pockets and pools. Outside of rocky shoals, in lower-gradient reaches, woody debris is particularly important in creating habitat heterogeneity and providing cover for this species. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (45.5%) in upland large streams (watershed area 100-300 km²) and highest average relative abundance (1.5%) in upland small rivers (watershed area 300-2000 km²) of the Savannah River basin.

CHALLENGES

Bartram's Bass is primarily threatened by the introduction and spread of nonnative Alabama Bass (and to a lesser extent Smallmouth Bass) as well as habitat alteration. Recent results suggest that persistence of Bartram's Bass is at serious risk, with populations in most river systems being affected by hybridization and others being potentially on the verge of colonization by nonnative species. Hybridization between endemic Bartram's Bass and invasive Alabama Bass is widespread throughout the upper Savannah basin with models indicating that prevalence of hybridization is related to habitat disturbance and distance from the reservoirs which serve as source pools for Alabama Bass (Bangs et al. 2018; Peoples et al. 2021). Evidence suggests that maintaining natural land cover (forest, in this context) at both the watershed and local scales will be important for maintaining integrity of Bartram's Bass populations, as model results suggest occurrence of pure Bartram's Bass is sensitive to even low levels of local development (Peoples et al. 2021). As such, working with local authorities and stakeholders (e.g. counties, municipalities, and landowners) to preserve and restore natural riparian land cover in developing regions may help maintain existing populations of pure Bartram's Bass. In addition, it will be important to work with resource managers, land trusts, mitigation banks, and other nongovernmental organizations to preserve and enhance natural land cover across the landscape regardless of proximity to reservoirs.

CONSERVATION ACCOMPLISHMENTS

Since the 2015 SWAP the Bartram's Bass has been the subject of some of the most intensive research and conservation efforts of any freshwater fish in SC, save perhaps the Robust Redhorse. The filling of information gaps with regard to the extent of hybridization in the Savannah Basin allows the informed use of resources to further the conservation of this species. Funding from NFWF and the U.S. Fish & Wildlife Service has been secured to formally describe the species, establish more in-depth baseline genetic, distributional, and habitat data on tributaries in the upper Savannah, to identify genetically pure populations, characterize movement, and assess protections provided headwater populations by in-place barriers. Results will guide prioritization of sub-watersheds for further conservation actions.

A microsatellite panel to determine genetic integrity of Bartram's Bass was developed by the SCDNR Population Genetics Laboratory in Ft. Johnson that utilizes a Beckman Coulter CEQ Genetic Analysis System at 16 loci (*Msaf27, Msaf05, Msaf08, Msaf22, Msaf32, Msaf17, Msaf24, Msaf09, Msaf13, Msaf25, Msaf31, Msaf06, Msaf10, Msaf29, Msaf12, Msaf28*). All tissue

samples are genetically analyzed for species identification and degree of hybridization following a standardized protocol for the clustering program STRUCTURE. This protocol involves comparing unknown sample genotypes to the genotypes of known black bass species referred to as a reference set. Reference set samples were identified and provided by Florida FWC, except for Bartram's Redeye Bass samples which were provided and verified by SCDNR Freshwater Fisheries staff during protocol optimization in the SCDNR Population Genetics Laboratory. Detailed information on this procedure and the reference set are included in Judson et al. (2021). A thorough population genetic health analysis from tissues across the range is scheduled to be completed in 2024, which will give information on genetic structure and indicate sub-population diversity which must be managed for.

Efforts to establish methods to culture Bartram's Bass were initiated in 2020, when wild broodstock were collected from Stevens Creek (n=23). Genetic analysis indicated that all fish were genetically pure, but that the population suffered from inbreeding due to its location between downstream and upstream dams on the creek which severely limited geneflow beyond that reach. The individuals had good survival and growth over two years but no successful reproduction ensued. In 2022 there was a total mortality event in which an external predator is suspected of accessing the holding area. Plans are to secure additional wild broodstock from a healthy population and continue with developing culture methods prior to consideration of potential conservation stocking strategies.

Outreach and education efforts have included media engagement in the Augusta-Central Savannah River Area local news (Hale 2021) and through partnership with Clemson University (Bradley 2018) to highlight the existence and conservation challenges facing this species. Numerous angling-centered postings on social media and the Internet have cropped up since the last SWAP, indicating that awareness of this endemic fish is on the rise.

Bartram's Bass habitat is primarily protected by land ownership patterns in some key habitats including the Chattooga River, Chauga River, Eastatoee River, and Stevens Creek. However, the amount of unprotected habitat for this species far exceeds protected habitat.

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

In addition to the targeted collections for Bartram's Bass, following and building upon the dataset amassed from the South Carolina Stream Assessment SWG study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating

future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- Formal description of Bartram's Bass is expected to be published in 2024 or 2025.
- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use available data to populate decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity
- Assess spatial and temporal patterns of introgression of nonnative genes in lotic populations.
- Identify genetically pure tributary populations of Bartram's bass.
- Consider identified management units and strive to protect the full complement of genetic diversity among Bartram's Bass populations within the Savannah Basin.
- Describe life history and habitat requirements of Bartram's Bass.
- Inventory and monitor water quality and habitat in Bartram's Bass streams to identify water quality threats as well as habitat needs and deficiencies.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Monitor the success of Bartram's Bass habitat protection and advocate for additional protection through the environmental permit review process.
- Conduct an education and outreach campaign to raise awareness of the impacts of illegal introductions of nonnative species.
- Promote Bartram's Bass as a sport fishery in larger streams to raise awareness of the species.

MEASURES OF SUCCESS

Formal description of the species will significantly enhance the awareness of the existence and conservation challenges facing Bartram's Bass. Identification of genetically pure populations that can benefit from conservation measures will be a key component in the protection of this species. Establishing refugia for pure Bartram's Bass populations above barriers that may deter immigration of nonnative black basses would be a benefit. Determining the distribution, life history, habitat needs, and population structure and trends would represent a measure of success for this species. Methods that protect water quality and aquatic habitats, such as maintenance and restoration of native forest cover, are also protective of this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the

effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Blackbanded Sunfish is a member of the sunfish family (Centrarchidae), which is currently represented by 41 described North American species including many popular sport fishes (Page et al. 2023). *Enneacanthus* sunfishes, all three of which are found in South Carolina, are small, laterally compressed sunfishes collectively distributed on the Atlantic and Gulf coastal plains from New Hampshire to Mississippi (Sweeney 1972; Darden 2008).

This species is a small, deep-bodied, extremely compressed fish with a small mouth and 6 black bars on a silvery body. The caudal fin is rounded. The anterior edges of the pelvic fins are pink to red (Rohde et al. 1994, 2009). It reaches an adult size of 50 to 82 mm (2 to 3.2 inches) (Rohde et al. 1994).

Status

The Blackbanded Sunfish is considered apparently secure to vulnerable (G3G4) globally. It is ranked imperiled to vulnerable (S2S3) in South Carolina but is considered critically imperiled (S1) or imperiled (S2) in the majority of other jurisdictions (NatureServe 2024). This species is presumed extirpated (SX) from Pennsylvania and is considered critically imperiled (S1) in Georgia, Virginia and Maryland (NatureServe 2024), where only one known, isolated population remains in the entire Chesapeake basin (Cessna et al. 2023). It is a State Significantly Rare species in North Carolina (Tracy et al. 2020). Additionally, the Blackbanded Sunfish was considered vulnerable in a recent assessment of North American freshwater fishes (Jelks et al. 2008) and was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern. The imperilment of this species represents documented decline rather than a naturally disjunct and isolated distribution (Kilian et al. 2009; Cessna et al. 2023). In many areas such as Maryland, it has declined to a level warranting the development of captive propagation efforts to support reintroduction or augmentation strategies (Cessna et al. 2023; Murray et al. 2023).

POPULATION SIZE AND DISTRIBUTION

The Blackbanded Sunfish has a relatively wide but patchy distribution along the Atlantic coastal plain from New Jersey to Florida, as well as some Gulf slope drainages in Georgia and Florida (Lee et al. 1980; Darden 2008; Rohde et al. 2009). Its range is unusually fragmented; the species is often missing from areas where appropriate habitat is seemingly present (Rohde et al. 1994).

In South Carolina, the Blackbanded Sunfish is found predominantly in the inner coastal plain (especially the Sand Hills) across all of the state's river basins (Rohde et al. 2009). Interestingly, despite being found in the South Carolina portion of the Savannah River basin, at this time it is not known to occur on the Georgia side of the basin or elsewhere in the Sand Hills ecoregion of Georgia. By comparison with its status in most other states, the Blackbanded Sunfish appears to be relatively secure in South Carolina in appropriate habitat. Results from environmental DNA (eDNA) sample concentrations and traditional sampling catch per unit effort indicated that Blackbanded Sunfish populations in South Carolina were both more widespread and abundant where present than those in Georgia (Darden et al. 2019). This species was observed in 1.0% of over 900 standardized statewide stream and river assessment samples across South Carolina between 2006 and 2023; however, these studies did not include swamps, backwaters and beaver impoundments, which represent primary habitats for this species.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Blackbanded Sunfish is found in quiet, densely vegetated margins of tannin-stained swamps, sloughs, backwaters, streams and rivers with sand or mud bottoms (Shute et al. 1981; Jenkins and Burkhead 1994; Rohde et al. 2009). It is often abundant in artificial mill ponds in the Sand Hills with dense aquatic vegetation. Blackbanded Sunfish habitats in South Carolina are typically very acidic, often exhibiting pH values below 5.0 and sometimes below 4.0 (Darden et al. 2019). This species associates with areas of low current velocity and high aquatic vegetation coverage (Cessna et al. 2022); in a recent study in South Carolina, sites in which Blackbanded Sunfish was present had higher mean percent coverage of floating/emergent (5.9%) and submerged (45.2%) aquatic vegetation than those in which the species was not detected (3.7% and 27.3%, respectively) (Darden et al. 2019). Although most abundant in swamps and backwater areas in association with dense aquatic vegetation, it has been found in low numbers near filamentous root matter and similar cover along the banks of streams and rivers. In the lotic systems of the Middle Savannah River Basin, adults seasonally migrate into beaver ponds to spawn (Marcy et al. 2005); these habitats are also important nursery areas (Snodgrass and Meffe 1999). The estimated lifespan is 3-4 years (Rohde et al. 2009; Cessna et al. 2024). In standardized sampling covering streams to small rivers of South Carolina, this species exhibited its highest frequency of occurrence (7.1%) in medium streams (watershed area 15-100 km^2) of the Sand Hills and highest average relative abundance (0.1%) in large streams (watershed area 100-300 km^2) of the Sand Hills.

CHALLENGES

By comparison with its status in most other parts of its range, the Blackbanded Sunfish in South Carolina appears to be relatively widespread in appropriate habitat and, in certain places, abundant. However, the range-wide trend of decline and imperilment for this species is concerning and signals risk for the integrity of its populations in the state. In the adjacent and

ecologically similar coastal plain of North Carolina, the Blackbanded Sunfish is considered State Significantly Rare (Tracy et al. 2020).

The conversion of native forest and wetland cover in the watershed and riparian zone for development or poorly planned agriculture reduces in numerous ways the suitability of inner coastal plain habitats for this species and its ecological associates. Its narrow habitat requirements make it susceptible to physical and chemical changes in habitat resulting from the alteration of natural land cover. The presence of sensitive *Enneacanthus* sunfishes has been shown to be related to high amounts of forest and wetland cover in the watershed (Ciccotto 2011). This species is adversely affected by the practice of draining swamps as well as by pesticide contamination (Burkhead and Jenkins 1991).

Decline, fragmentation and isolation of Blackbanded Sunfish populations has contributed to low population genetic diversity and associated complications such as inbreeding (Kercher 2005; Darden et al. 2019; Cessna et al. 2022). The relatively low genetic diversity exhibited by South Carolina populations (Darden et al. 2019), which by all indications represent a stronghold for the species compared with most other states, suggests that fragmentation may already be occurring. This species inherently exhibits low movement and dispersal with resulting low population genetic diversity (Darden et al. 2019), placing it at heightened risk for crossing the threshold of genetic decline due to fragmentation by physical barriers as well as habitat degradation. Additionally, the potential for this species to be collected for the aquaria trade could result in adverse impacts to isolated populations (Burkhead and Jenkins 1991).

The elusiveness of this species and resulting data deficiency represent a fundamental challenge in its conservation. As illustrated in Georgia (Darden et al. 2019), especially where Blackbanded Sunfish densities are low, the species can be extremely difficult to detect using traditional sampling methods, confounding efforts to identify and protect critical areas.

CONSERVATION ACCOMPLISHMENTS

The development and implementation of an environmental (eDNA) tool (Darden et al. 2019) has enabled more effective detection and conservation of Blackbanded Sunfish. This tool is useful for detecting previously unknown populations, confirming the persistence of populations difficult to detect using traditional sampling methods, and evaluating habitat factors important in supporting Blackbanded Sunfish. For example, in Georgia, where only three localized populations were known as of 2015, this eDNA tool led to the discovery of Blackbanded Sunfish at four new sites and confirmed the existence of another population that was thought to have been extirpated. In South Carolina, the eDNA tool was used to provide a survey of Blackbanded Sunfish status across its range in the state and evaluate habitat and landscape factors influencing its presence, thereby enhancing our understanding of its distribution and abundance to serve as a baseline for future monitoring (given its nearly universal decline elsewhere). Environmental DNA is also being used to identify and monitor Blackbanded Sunfish populations in Virginia (K. Chestnut-Faull and J. Hallacher, pers. comm. 2025).

Results of the State Wildlife Grants collaborative study with Georgia (Darden et al. 2019) were presented at local, regional, and national scientific meetings – including meetings of the

Southern Division of the American Fisheries Society, Southeastern Fishes Council, South Carolina Chapter of the American Fisheries Society, and SC DNR Marine Resources Research Conference. A total of 13 presentations have been shared to date by the project team. Additionally, a project press release was developed and released through both the SCDNR and GADNR media centers. Although we have not published the results from the project yet, we have three manuscripts in preparation including 1) eDNA tool development and optimization, 2) Distribution of *E. chaetodon* in Georgia and South Carolina using both eDNA and traditional survey methods, and 3) Genetic population characterization of *E. chaetodon* in the southeastern US.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.

- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

Our project team recommends the following general measures to protect *E. chaetodon* populations:

- Management for native aquatic plant communities by preventing the spread of invasive plant species (e.g., http://stopaquatichitchhikers.org/), preventing run-off of fertilizers that can lead to eutrophication and algae blooms, and avoiding the use of aquatic herbicides in *E. chaetodon* habitat.
- Protection and restoration of water quality through general watershed protection measures, including protection of wetland habitats and riparian buffers and best management practices for forestry and agriculture.
- Protection of water quantity and natural hydrology through water conservation efforts, protection of instream flows, and maintenance of aquatic connectivity. Factors that could negatively affect aquatic connectivity include dams and poorly designed culverts that impede dispersal of aquatic species as well development (i.e., roadways, housing, etc.) that interferes with the inundation of floodplain habitats and wetlands.
- Management for native fish communities by protecting water quality and habitat (see previous three bullets) and preventing the spread of non-native species. Although native sport fishes often co-occur with *E. chaetodon*, we do not recommend stocking sport fishes in the few known populations. Fishing with live fishes or crayfishes as bait should be avoided or carried out using legally harvested native bait species from the local watershed.
- Protection of habitats with yet unknown but potential populations of *E. chaetodon*. Our eDNA tool can be utilized to assess areas with potential populations of *E. chaetodon* as part of the environmental review of projects that could negatively impact habitat, such as large developments and road construction projects.

Conservation recommendations have been provided to State managers in both Georgia and South Carolina. We have also developed an online species profile to share these management recommendations with the general public through the Georgia Biodiversity Portal. The website (link) also includes photographs, a range map, and other biological information. We have also created an online conservation status map (link) that categorizes all occurrences of *E. chaetodon* in South Carolina and Georgia by date of last observation at different spatial scales such as watersheds or stream reaches. This tool also allows users with a password access to fine scale data that is not available to the general public. Additionally, we have created a conservation and management brochure for private landowners near *E. chaetodon* project sites to help promote the awareness of the species and its biology, our project results, and incorporation of the recommendations above into their land management practices (Appendix C). Due to differences in land ownership near project and known locations of *E. chaetodon* between Georgia and South Carolina, we focused the brochure to target South Carolina private landowners. With the reduced number of known *E. chaetodon* locations in Georgia, all landowners are known, and the most significant one is USFWS (OSNWR) who is already managing the swamp for natural ecosystems. The project team has been in direct contact with all private Georgia landowners who have been informed in person about the project and the online data portal.

In addition to the *E. chaetodon*-specific recommendations above, the following general recommendations are beneficial to conservation of aquatic resources.

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop other educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Educate aquarists as to the adverse impacts of removing fish from the wild.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs

are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Bluebarred Pygmy Sunfish is a member of the small, secretive family Elassomatidae, of which all 7 known species are placed in the genus *Elassoma* (Page et al. 2023). Four species of elassomatids occur in South Carolina. This species and its close relative, the Carolina Pygmy Sunfish (*E. boehlkei*), were not described until 1987 (Rohde and Arndt 1987). Bluebarred Pygmy Sunfish range in length from 24 to 35 mm (0.9 to 1.4 in.). As with other members of the genus *Elassoma,* the Bluebarred Pygmy Sunfish lacks a lateral line, has a relatively large eye, an upturned mouth and a rounded caudal fin. This colorful fish is very similar and closely related to the Carolina Pygmy Sunfish (Sandel et al. 2014), with an alternating series of bright blue and black bars, but the black bars of the Bluebarred Pygmy Sunfish are about three times wider than the blue bars (Rohde et al. 1994), and black bars number 8 to 14 (mode 11) (Rohde et al. 2009). The taxonomic placement of the *Elassoma* remains somewhat uncertain, with some studies suggesting they belong in Centrarchidae rather than a separate family (Near et al. 2012).

Status

Globally, it is considered imperiled (G2) to vulnerable (G3) (NatureServe 2024). While this small sunfish is considered vulnerable to imperilment throughout its range (Warren et al. 2000), it is considered critically imperiled in Georgia (S1) and is critically imperiled to imperiled (S1S2) in South Carolina (NatureServe 2024). In a recent assessment of North American freshwater fishes, the Bluebarred Pygmy Sunfish was considered vulnerable to imperilment (Jelks et al. 2008). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

Bluebarred Pygmy Sunfish are restricted to the lower Savannah River drainage in Georgia and South Carolina and the lower Combahee and Edisto Rivers in South Carolina. The populations within South Carolina are restricted to the coastal plain, occurring most frequently in the Middle

Atlantic Coastal Plain ecoregion. Quattro et al. (2001) observed genetic differences between the Edisto basin populations and those in the New and Savannah basins (Rohde et al. 2009).

Bluebarred Pygmy Sunfish populations are generally uncommon and localized in South Carolina but can be abundant in favorable settings (Page and Burr 1991). Locally, populations experience frequent fluctuations with hydrologic conditions (see HABITAT OR NATURAL COMMUNITY REQUIREMENTS). In spite of this, these populations overall are currently considered stable. Owing to its patchy distribution and preference for other habitat types, this species was only observed in 0.1% of over 900 standardized statewide stream and river assessment samples throughout South Carolina between 2006 and 2023. The species co-occurs in a few watersheds with the Everglades Pygmy Sunfish, but individuals do not tend to share space in close proximity (Sandel & Harris 2007, Rohde et al. 2009). The Bluebarred Pygmy Sunfish has no known coexistence with its closest relative, the Carolina Pygmy Sunfish, in South Carolina (Sandel & Harris 2007, Rohde et al. 2009).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Bluebarred Pygmy Sunfish inhabits shallow backwaters of streams and rivers, as well as other watercourses with appropriate habitat. It is found in shallow water with abundant submerged and/or emergent vegetation that is rooted in soft, detritus-rich substrate (Rohde and Arndt 1987) and can apparently tolerate certain altered habitats such as drainage ditches and backwaters adjacent to boat landings (Rohde and Arndt 1987). This species is very short-lived, spawning at age one and dying shortly thereafter (Snelson 1989). Bluebarred Pygmy Sunfish populations fluctuate widely with predominant hydrologic conditions and stability of water levels (Rohde and Arndt 1987; Snelson 1989; Sandel & Harris 2007), proliferating during wet periods supporting sufficient aquatic vegetation and becoming locally extirpated during droughts. Direct observations of the spawning behavior for these elusive fish and its relatives are sparse; some accounts exist for the relatives from captivity among aquarists (Bohlen & Nolte 2012). As such, survey efforts may yield drastically different successive catch rates at a given site, with the species being undetectable or extirpated one year and abundant the next (Snelson 1989). Hydrologic pulses appear to be beneficial to the Bluebarred Pygmy Sunfish, with Lee et al. (2016) noting that it was caught in the Savannah River floodplains only in years with flood events connecting the floodplains to the river channels. In standardized sampling covering streams to small rivers across South Carolina, this species exhibited its highest frequency of occurrence (7.7%) and average relative abundance (0.1%) in small rivers (watershed area 300-2000 km^2) of the coastal plain.

CHALLENGES

Primary threats to the Bluebarred Pygmy Sunfish include loss of natural/forested land cover and especially the removal of riparian cover along coastal plain streams. Fish assemblage integrity of coastal plain streams increases with natural land cover, whereas integrity decreases as the amount of agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in Coastal Plain streams, which provides critical habitat for many endemic Southern Atlantic Coastal Plain species including the Bluebarred Pygmy

Sunfish (Marion et al. 2015). Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species.

Although Bluebarred Pygmy Sunfish can occur in anthropogenically altered environments such as drainage ditches, the high variability of populations and low dispersal capability render this species susceptible to acute disturbances and habitat fragmentation (Snelson 1989). Furthermore, the extreme variability in abundance and corresponding detection difficulties confound efforts to monitor its distribution and overall population trends (Cannister & Bechler 2019).

CONSERVATION ACCOMPLISHMENTS

Riverbanks Zoo currently has a propagation and maintenance program of representative populations of Bluebarred Pygmy Sunfish.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.

- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.

CONSERVATION RECOMMENDATIONS

- Identify critical habitats and areas with healthy populations for the Bluebarred Pygmy Sunfish.
- Describe life history and habitat requirements for the Bluebarred Pygmy Sunfish.
- Conduct genetic assessments to determine appropriate taxonomy for the Bluebarred Pygmy Sunfish.
- Protect critical habitats for the Bluebarred Pygmy Sunfish from future development and further habitat degradation by following Best Management Practices (BMPs) as well as protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Bluebarred Pygmy Sunfish.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate off-road motor vehicle operators on the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

“Brassy” Jumprock

Moxostoma sp.

Contributors (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

Photo: NCFishes.com

DESCRIPTION

Taxonomy and Basic Description

The “Brassy” Jumprock is an undescribed member of the sucker family (Catostomidae), which is represented by 78 described species in North America (Page et al. 2023). Suckers comprise about 8% of the continent’s freshwater ichthyofauna, behind only minnows (Leuciscidae) and perches and darters (Percidae) in number of species (Warren and Burr 2014). The genus *Moxostoma* includes 23 described species (Page et al. 2023), about one third of which are considered imperiled at some level (Jelks et al. 2008; Warren and Burr 2014).

Due to being mis-assigned by Robins and Raney (1956) as what is now known as *Moxostoma robustum* (Robust Redhorse), this species did not receive further taxonomic investigation until the error was discovered by Robert E. Jenkins in 1992 (Rohde et al. 2009; Tracy et al. 2020), and a full description has yet to be completed. Among suckers found in South Carolina, the “Brassy” Jumprock is most closely related to the Striped Jumprock (*Moxostoma rupiscartes*).

The Brassy Jumprock grows to moderately large size, with adults reaching 240 to 456 mm total length and having an elongate yet stout and slightly laterally compressed body (Rohde et al. 2009). Overall coloration ranges from tan to olive, with increasing brassy coloration in larger and mature individuals. Fins are typically dusky (dorsal and caudal) or pale orange (paired ventral fins). Younger individuals usually have alternating longitudinal light and dark stripes; below the lateral line, the light stripes are wider than or equal to the width of the dark stripes (conversely for the Striped Jumprock) (Rohde et al. 2009; Tracy et al. 2024). Dorsal fin rays usually total 12-13 (sometimes 11). The lower lip is plicate, lacks or has few transverse grooves, and has a relatively straight posterior margin (i.e., not deeply notched) (Tracy et al. 2024).

Status

The “Brassy” Jumprock is currently considered to be apparently secure globally (G4; NatureServe; accessed 2024) but is listed as vulnerable (S3) in South Carolina. This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern. Although it can be relatively abundant in optimal habitat of larger streams and rivers, it is also patchy and uncommon in certain river basins and many of its native habitats have been highly altered by the construction of large reservoirs and numerous dams as well as land uses contributing to sedimentation of shoals.

POPULATION SIZE AND DISTRIBUTION

The “Brassy” Jumprock occurs on the Atlantic Slope from the Cape Fear River basin in North Carolina to the Altamaha River basin in Georgia. In South Carolina, the species is predominantly found above the fall line. This species was observed in 7.8% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023. It is particularly abundant in the Broad River, where population measures indicated relatively stable status (Bettinger and Crane 2011).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The “Brassy” Jumprock primarily inhabits rocky shoals, runs and pools with sandy to rocky substrate in moderate to large streams and rivers, where it feeds on benthic invertebrates (Rohde et al. 2009). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (100.0%) in upland small rivers (watershed area 300-2000 km²) of the Savannah River basin and highest average relative abundance (1.2%) in upland small rivers (watershed area 300-2000 km²) of the Santee/Pee Dee River basins.

CHALLENGES

Although the “Brassy” Jumprock appears relatively wide-ranging across the uplands of South Carolina and was found to be apparently stable in the Broad River in the early 2000s (Bettinger and Crane 2011), its habitat requirements for larger streams and rivers place it within some of the most altered aquatic habitats in the state. Much of its range, such as the upper Savannah River basin, has been impounded by the construction of numerous large reservoirs, and many similar reservoirs exist across the Saluda, Broad and Catawba-Wateree basins. Furthermore, many additional dams limit movement throughout river networks and alter hydrologic and temperature regimes to which this species has adapted. Both the frequency of occurrence and mean relative abundance of this species were several times higher in rivers (watershed area > 300 km²) than smaller streams (SCDNR 2023); because larger rivers make up a proportionally small amount of aquatic habitat by length, its core populations are more vulnerable to the effects of cumulative and acute disturbances in these locations. This species is susceptible to the same pervasive types of anthropogenic habitat alteration and fragmentation affecting other large riverine catostomids (Cooke et al. 2005), including the construction and operation of dams and impoundments, sedimentation of important foraging and spawning habitats, alteration of hydrologic regimes, and introduction of non-native species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion and “ecobasin” (ecoregion x river basin). These estimates for the first time provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the "Brassy" Jumprock.
- Identify critical habitats and areas with healthy populations of "Brassy" Jumprock, and protect these areas once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. If more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling

applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Bridle Shiner

Notropis bifrenatus

Photo: NCFishes.com

Contributor (2005): Jason Bettinger (SCDNR)
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Bridle Shiner belongs to the minnow family (Leuciscidae) and remained classified within *Notropis* based on a recent investigation of shiner taxonomy (Stout et al. 2022; Page et al. 2023), joining Comely Shiner (*N. amoenus*), Taillight Shiner (*N. maculatus*) and Sandbar Shiner (*N. scepticus*) as the only *Notropis* minnows in South Carolina following this taxonomic revision. Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023).

Bridle Shiners are relatively small, reaching a maximum total length of 48-66 mm (1.9-2.6 in.) (Rohde et al. 2009). A prominent black lateral stripe extends from the tip of the snout to the tail fin. The back is straw-colored and the sides of the fish are silver with blue-green iridescence. Breeding males develop light yellow to bright yellow-gold color on the lower sides of their bodies and faint yellow fins (Jenkins and Burkhead 1994).

Status

Globally, the Bridle Shiner is considered vulnerable (G3) (NatureServe 2024). In South Carolina, the Bridle shiner is currently considered possibly extinct (SH), and critically imperiled (S1) in North Carolina (NatureServe 2024). Widely regarded as at-risk across the majority of jurisdictions (Margolis 2003), the Bridle Shiner is listed as critically imperiled (S1), imperiled (S2), or possibly extinct (SH) in 11 of the 15 states that comprise its historic range (NatureServe 2024). In a recent assessment of North American fishes, the Bridle Shiner was identified as a species vulnerable to imperilment (Jelks et al. 2008). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Bridle Shiner has a widespread but patchy distribution in eastern North America, occurring in Atlantic basins from western Lake Ontario-St. Lawrence drainages east to Maine and south to South Carolina. Bridle Shiner populations are highly disjunct, with gaps in excess of 200 km

(124 mi) between known localities. Furthermore, populations are declining throughout the range (NatureServe 2024). Once common in Pennsylvania (Cooper 1983), it has been reduced to a single known extant population in one small drainage (Criswell 1998; Finger 2001; Leckvarcik 2005; Hanson 2013). The Bridle Shiner is rare or declining in Maine, Vermont (Shervinskie 1998), Massachusetts (Chandler et al. 1998), Rhode Island, Connecticut, New York, Delaware, Virginia (Starnes et al. 2025), North Carolina, and South Carolina. In Virginia, the Bridle Shiner is extant in the James River basin but is likely extirpated from most other basins in which it was known or believed to have occurred (Jenkins and Burkhead 1994; Starnes et al. 2025). Recognition of its possible extirpation from North Carolina began in the 1960s, but it was rediscovered in 2000 and subsequent decades from a few localities (Tracy et al. 2020; Tracy et al. 2024).

Within South Carolina, the only known collection sites are in Lakes Marion (1954) and Moultrie (1981) (Jenkins and Burkhead 1994; Rohde et al. 2009). Targeted searches in and around the known collection localities in recent decades have been unsuccessful (W. Starnes, North Carolina State Museum [retired], pers. comm. 2024) yet also inconsistent. Despite the South Carolina records being from large reservoirs and approximately 330 km (204 mi) from the nearest known populations (lower Neuse River, NC), they are not believed to be the result of introduction by humans (Rohde et al. 2009). The determination of its persistence in South Carolina is confounded by its probable elusiveness and specific habitat and sampling requirements (Jensen 2012; Jensen and Vokoun 2013; Pregler et al. 2015; Pregler et al. 2019).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

Due to nearly universal decline across its large range, the Bridle Shiner has received a relatively high amount of research attention in recent years. The Bridle Shiner inhabits the quiet areas of warmwater streams (slower-flowing sections), swamps, and lakes with clear water and is usually associated with abundant aquatic vegetation (Finger 2001; Henning 2012; Jensen and Vokoun 2013; Hanson 2013; Starnes et al. 2025), as these areas are used for feeding and breeding. This species is generally found over sand, mud (Henning 2012; Hanson 2013), or gravel substrates and broadcasts eggs over submerged aquatic vegetation (Harrington 1947). The Bridle Shiner can be found in tidal and slightly brackish water in the southern portion of its range (Burkhead and Jenkins 1991). In South Carolina, it has only been found in the shallow lacustrine areas of Lakes Marion and Moultrie (Rohde et al. 2009). This species has been shown to benefit from floodplain connectivity and natural flooding regimes (Farly et al. 2021).

CHALLENGES

With only two known localities and a span of over 40 years since the last observation of this species in South Carolina, its persistence in the state is very uncertain. The apparently universal decline of this species across a wide range of ecological settings and types of habitat alteration suggest it is sensitive to a spectrum of anthropogenic factors (Finger 2001; Leckvarcik 2001; Hanson 2013). Its susceptibility to cumulative degradation is exemplified by its remaining distribution in Connecticut, which was positively associated with high levels of forest cover and low amounts of impervious land cover (Pregler et al. 2019). This species is particularly sensitive to increased turbidity, which can both directly affect its feeding efficiency and behavior (Gray et

al. 2014) and physiological function (Gray et al. 2016) as well as indirectly affect this fish by altering the growth of submerged aquatic vegetation on which the species is dependent ecologically (Jenkins and Burkhead 1994; Henning 2012). Agricultural runoff may also negatively impact its habitat (Burkhead and Jenkins 1991), which could be particularly problematic since its only known localities in South Carolina lie in a region of widespread agriculture. Species with disjunct or isolated populations are typically at greater risk of detrimental effects from low genetic diversity. Northeastern disjunct populations of Bridle Shiners were found to exhibit low within-population genetic diversity, which can lead to additional problems associated with inbreeding depression (Geneva et al. 2018).

The apparent elusiveness of this species and resulting data deficiency represent a fundamental challenge in its conservation. In South Carolina, the physicochemical template that supports this species may represent a moving target in an expansive and anthropogenically changing landscape. However, the perceived absence or possible extirpation are difficult to interpret due to the recognized challenges associated with its apparent elusiveness coupled with the lack of dedicated sampling efforts using appropriate species- and habitat-specific methods (Jensen and Vokoun 2013; Pregler et al. 2015; Pregler et al. 2019; Katz 2023; Starnes et al. 2025). If the Bridle Shiner is still extant in South Carolina, a specialized and standardized sampling approach will be necessary to quantify the probability of its persistence in the state and enable informed conservation efforts (Jensen and Vokoun 2013; Pregler et al. 2015; Pregler et al. 2019; Katz 2023; Starnes et al. 2025). For example, employing multiple and/or targeted methods led to the rediscovery of multiple Bridle Shiner populations in Connecticut (Pregler et al. 2019) and Maine (Katz 2023).

CONSERVATION ACCOMPLISHMENTS

Bridle Shiner populations are currently protected as part of the Santee Wildlife Refuge.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by

numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Describe the life history and habitat requirements for Bridle Shiner.
- Determine the statewide distribution and population status for Bridle Shiner with targeted surveys.
- Survey Lake Marion and its tributary streams to identify the presence of additional Bridle Shiner populations and verify its existence in Lake Marion.
- Conduct genetic assessments to determine the appropriate taxonomy for Bridle Shiners.
- Explore reasons for the decline of Bridle Shiners in South Carolina.
- Protect critical habitats for Bridle Shiner from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.

- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for Bridle Shiner.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate off-road motor vehicle operators on the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The “Broadtail” Madtom is an undescribed member of the family Ictaluridae (bullhead catfishes), the most diverse family of freshwater fishes indigenous entirely to North America (Warren et el. 2020; Page et al. 2023). The genus *Noturus*, which includes small catfishes known as madtoms, includes 29 described species and is the most diverse genus in the family (Rohde et al. 1994; Page et al. 2023). The “Broadtail” Madtom was first documented in the 1960s and 1970s in most of the river basins in which it is known to occur (Tracy et al. 2020); Jenkins and Palmer (1978) published the first recognition of the new species. More recently, investigations continue into the taxonomy of this group and indicate distinctiveness by river basins; among described species, the “Broadtail” Madtoms are most closely related to the Margined Madtom (*N. insignis*) (Bennetts et al. 1999; Hardman and Hardman 2008; Burr et al. 2020; F. Rohde, pers. comm. 2024). Tracy et al. (2020; 2024) recognize three forms in North Carolina—the “Cape Fear,” “Lake Waccamaw” and “Pee Dee” (the latter also occurring in South Carolina); the Edisto River form may also be distinct.

Madtoms are small and can be distinguished from other catfish by their long adipose fin, which is continuous with the caudal fin. The “Broadtail” Madtom is a slender-bodied fish with fine black speckling on an otherwise pale body and a dark blotch at the base of its caudal fin (Rohde et al. 2009). It has a “banjo-shaped” body when viewed from above (Rohde et al. 2009). Although there is not much known about this fish, it probably reaches lengths similar to the Speckled Madtom (*N. leptacanthus*), which has a maximum total length of 94 mm (3.7 in.) (Rohde et al. 1994).

Status

The “Broadtail” Madtom has received legal status and is listed as State Threatened in South Carolina. In North Carolina, the only other state in which it occurs, it is of Special Concern and is considered critically imperiled (S1). Tracy et al. (2020) noted that the range of the “Cape Fear Broadtail” Madtom has contracted in recent decades, and it may be extirpated from that basin. This species is critically imperiled (S1) in South Carolina (NatureServe 2024) and is considered

vulnerable to imperilment throughout its range (Warren et al. 2000). The "Broadtail" Madtom is globally considered to be imperiled (G2) (NatureServe 2024). It was also considered vulnerable in a recent assessment of North American freshwater fishes (Jelks et al. 2008). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

The "Broadtail" Madtom is only known from coastal plain rivers in the Carolinas, including the Cape Fear, Lumber, Little Pee Dee, Waccamaw (including Lake Waccamaw), Lynches and Edisto rivers (Rohde et al. 2009; Tracy et al. 2020). Within South Carolina, it is known from the South Fork Edisto, Lynches, and Little Pee Dee Rivers (Rohde et al. 2009). The "Pee Dee Broadtail" Madtom is known from the Waccamaw River in North Carolina and within close proximity to South Carolina (Tracy et al. 2020; Tracy et al. 2024); it may therefore occur in the South Carolina portion of the Waccamaw River, although this has not been documented. Due to its elusiveness and apparent habitat preference for deep portions of coastal plain rivers, very little is known about its population sizes, but it is most likely more widely distributed along these rivers than collection records indicate (Rohde et al. 2009). Monitoring by the North Carolina Wildlife Resources Commission from 2019 to 2024 has confirmed the presence of the "Broadtail" Madtom in multiple tributaries of the Lumber River just upstream of South Carolina (Omerberg and Jones 2025).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The "Broadtail" Madtom generally occupies the middle of narrow and deep coastal plain rivers with sand and gravel substrates (Page and Burr 1991; Rohde et al. 2009). However, the recent detection of this species by the North Carolina Wildlife Resources Commission (Omerberg and Jones 2025) in small artificial habitat structures deployed in moderate depths suggests habitat use may not be restricted to the deepest areas. The specific habitats of this fish are poorly known, but "Broadtail" Madtoms are often associated with woody debris (F. Rohde, pers. comm.). Spawning apparently takes place from May to June (Rohde et al. 2009).

CHALLENGES

The "Broadtail" Madtom is susceptible to the many forms of anthropogenic habitat alteration reducing the integrity of coastal plain rivers. Clearing of watershed and riparian forest and natural land cover for poorly planned agriculture or development can cause an array of impacts to streams and rivers, including runoff and non-point source pollution, disruption of natural hydrologic and sediment regimes, reduction in habitat heterogeneity including the input of wood to stream systems, and habitat fragmentation. The apparent dependence of this species on habitat structure in deep coastal plain channels makes it particularly vulnerable to alterations reducing the amount of wood and organic matter entering rivers (i.e., deforestation and poor riparian management). Furthermore, the "Broadtail" Madtom, like other small ictalurids, is adversely affected by the nonnative Flathead Catfish (*Pylodictis olivaris*) and Blue Catfish (*Ictalurus furcatus*), both of which are known to be expanding in coastal plain rivers and occupy similar

deeper sections of rivers. These large catfish are voracious predators that have decimated ictalurid and other native fish populations throughout the southeastern United States (Guire et al. 1984; Jenkins and Burkhead 1994; Bart et al. 1994). The apparent decline and possible extirpation of the “Cape Fear Broadtail” Madtom (Tracy et al. 2020) suggest the “Broadtail” Madtoms are sensitive to a range of disturbances.

CONSERVATION ACCOMPLISHMENTS

Efforts by the North Carolina Wildlife Resources Commission to document “Broadtail” Madtoms using small, deployed artificial habitat structures known as “madtom motels” have been successful (Omerberg and Jones 2025), representing a promising method for detecting this species in South Carolina. These structures are inexpensive and function as a passive method for attracting the fish, affording a relatively low-effort technique to increase sampling coverage and efficiency.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Continue to determine statewide distribution and population status for the "Broadtail" Madtom through assessment surveys as well as targeted sampling using methods such as the deployment of "madtom motels" (Omerberg and Jones 2025).
- Describe life history and habitat requirements for the "Broadtail" Madtom.
- Identify critical habitats and areas with healthy populations for the "Broadtail" Madtom.
- Conduct genetic assessments to determine appropriate taxonomy for the "Broadtail" Madtom.
- Formally describe the "Broadtail" Madtom and examine morphological and genetic differences among the populations in the Edisto, Pee Dee, Lynches, and Lumber Rivers.
- Protect critical habitats for the "Broadtail" Madtom from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the "Broadtail" Madtom.
- Encourage responsible land use planning.
- Consider species needs when participating in the environmental permit review process.
- Continue development of educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.

- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect most of this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Carolina Darter

Etheostoma collis

DESCRIPTION

Taxonomy and Basic Description

The Carolina Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). The Carolina Darter, along with the Swamp Darter (*E. fusiforme*) and Sawcheek Darter (*E. serrifer*) in South Carolina, is placed in the darter subgenus *Hololepis* (Rohde et al. 1994). This species was originally described by Hubbs and Cannon (1935) as *Hololepis collis* along with another species, the Saluda Darter (*Hololepis saludae*); the species were distinguished by differences in the number of anal spines and interorbital pores (Page 1983; Kuehne and Barbour 1983; Rohde et al. 2009). The distinctiveness of these species, which both occur in the Santee River basin, was eventually investigated further (Collette 1962; Jenkins and Burkhead 1994) and genetic results indicated that they were not sufficiently distinct to warrant separate species; thus, these species were synonymized as *Etheostoma collis* (Jenkins and Burkhead 1994; Rohde et al. 2009; Oswald et al. 2009).

Carolina Darters reach a length of 60 mm (2.4 in.) (Rohde et al. 1994). The fish has a small head and mouth with a highly arched, incomplete lateral line characteristic of the subgenus *Hololepis* (Kuehne and Barbour 1983). The brown-spotted sides are marked with a median dark stripe that breaks into blotches on the peduncle (Eddy and Underhill 1979). A primary basicaudal spot has two spots of lesser intensity above and below (Rohde et al. 1994). Breeding males do not develop bright colors but may have breeding tubercles on the pelvic fin spine and rays as well as on all anal fin rays (Kuehne and Barbour 1983).

Status

The Carolina Darter is considered vulnerable (G3) globally (NatureServe 2024). The species is considered vulnerable (S3) in North Carolina (State Special Concern), imperiled (S2) in Virginia, and vulnerable (S3) in South Carolina (NatureServe 2024). The Carolina Darter was identified as a species vulnerable to imperilment in recent assessments of the southeastern (Warren et al.

2000) and North American (Jelks et al. 2008) freshwater fish faunas. This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Carolina Darter occurs in the Piedmont ecoregion from the Roanoke River basin of south-central Virginia to the Saluda (Santee) River basin of South Carolina (Rohde et al. 2009). In South Carolina, it is found predominantly in the Carolina Slate Belt and outer Piedmont ecoregions in the lower Saluda and Broad basins (i.e., the range of *E. saludae* before it was synonymized with *E. collis*) as well as the mid to upper Broad and Catawba/Wateree basins (Rohde et al. 2009). This species is most abundant in the Carolina Slate Belt and far outer Piedmont portions of the lower Saluda and Broad River basins. The Carolina Darter was observed in 6.3% of over 900 standardized statewide stream and river assessment samples across South Carolina between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Carolina Darter inhabits small to large streams in areas of low to moderately low current velocity and a wide range of substrate types (Collette 1962; Kuehne and Barbour 1983; Rohde et al. 2009). In the core area of its distribution in South Carolina—the Carolina Slate Belt streams of the lower Saluda and Broad River basins—the species is closely associated with streams exhibiting long, sluggish reaches interspersed with short riffles of bedrock, rubble and gravel. In this regard, the Carolina Darter appears to share a close ecological association with the Highfin Shiner (*Hudsonius altipinnis*) where their ranges overlap. During periods of seasonal or extended drought, these streams often reduce to long, stagnant, nearly broken to broken pools; Carolina Darters have been collected in abundance during such conditions and appear somewhat tolerant of this high variability in water level and temperature, provided they are not stressed by additional anthropogenic habitat alteration. Outside of this region, in more typical Piedmont streams, it is often found in slower areas with sand and gravel. Interestingly, it has been deemed somewhat tolerant of fine sediment (Kuehne and Barbour 1983; Rohde et al. 1994). In standardized sampling covering streams to small rivers of South Carolina, this species exhibited its highest frequency of occurrence (21.0%) in upland medium streams (15-100 km^2) of the Santee River basin and highest average relative abundance (1.5%) in upland small streams (watershed area 0-15 km^2) of the Santee River basin. Spawning occurs in March to April, and the lifespan appears to be 2 years (Kuehne and Barbour 1983; Rohde et al. 2009).

CHALLENGES

Geographic isolation of the Carolina Darter makes it extremely vulnerable to development, pollution and habitat alterations. Although *E. saludae* was synonymized with *E. collis*, sufficient genetic variation across its range still exists (Oswald et al. 2009) and may represent local adaptations at the level of individual sub-basins. Fragmentation and isolation of populations has already occurred over a large portion of the core range of this species in South Carolina due to the creation of large reservoirs in the lower Saluda River basin in the 1920s and 1930s; tributary populations have been isolated to gene flow, potentially impacting the genetic fitness of these

populations and reducing their resistance and resilience to disturbance. Additional fragmentation and or barriers to movement within these localized drainages could furthermore disturb its natural ability to handle acute disturbances including the high seasonal variability in flow and connectivity characteristic of the outer Piedmont and Carolina Slate Belt ecoregions. Conservation efforts within South Carolina are critical to the global conservation of this species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.

- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species and others. Methods that protect water

quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Carolina Fantail Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). It is placed in the subgenus *Catonotus* (Near et al. 2011). The Carolina Fantail Darter was recently elevated as a species (Blanton and Schuster 2008) from its previous status as a subspecies of the Fantail Darter, *E. flabellare.*

The adult Carolina Fantail Darter ranges from 45 to 95 mm (1.8 to 3.7 in.) in total length (Jenkins and Burkhead 1994). As is typical of other members of the subgenus *Catonotus*, the Carolina Fantail Darter has a deep caudal peduncle, frenum, closely set pelvic fins, and broadly joined gill membranes. Additionally, this fish is characterized by a spiny dorsal fin comprised of 7 short spines with enlarged golden knobs on both males and females, a characteristic of the *Richiella* clade (Near et al. 2011). The Carolina Fantail Darter usually has 7 dark bars on the side set against a light body coloration (Page and Burr 1991; Rohde et al. 1994).

Status

The Carolina Fantail Darter is globally considered apparently secure (G4) but imperiled (S2) in South Carolina (NatureServe 2024). Warren et al. (2000) listed the global status of Carolina Fantail Darter as currently stable within its range. The Carolina Fantail Darter is considered apparently secure (S4) in North Carolina and critically imperiled (S1) in Virginia. This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

Broadly, the Carolina Fantail Darter occurs in the Savannah, Santee and Pee Dee River basins of North and South Carolina (Blanton and Schuster 2008; Tracy et al. 2020). Although the Carolina

Fantail Darter occurs over a relatively wide range spanning multiple river basins, its distribution in South Carolina is oddly disjunct, with apparently isolated populations scattered across a range of elevations (Rohde et al. 2009). In the Santee River basin in South Carolina, it occurs in several streams and rivers of the upper Saluda and upper Broad drainages as well as one tributary of the Wateree River near the fall line. It is only known from one stream system in the far upper Savannah River basin. In the Pee Dee River basin of South Carolina, it is only known from one tributary of the Great Pee Dee River near the fall line. Interestingly, the streams in which it occurs in the Wateree and Pee Dee basins in South Carolina are apparently separated by considerable river network distance from the nearest respective populations in these basins in North Carolina (Tracy et al. 2020; Tracy et al. 2024). The Carolina Fantail Darter was observed in 1.5% of over 900 standardized statewide stream and river assessment samples in South Carolina between 2006 and 2023. In high-gradient streams and rivers with continuous suitable habitat it can be moderately abundant, but due to the siltation of many Piedmont streams and the localized nature of appropriate coarse riffles in lower-gradient Piedmont streams, it is often limited in abundance.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Carolina Fantail Darter inhabits gravel or rubble riffles in creeks and small to medium rivers where stronger currents exist (Rohde et al. 2009). Rocky substrates are important to its benthic feeding habits and spawning behavior, in which nests are excavated and guarded under rocks (Jenkins and Burkhead 1994; Rohde et al. 2009). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (14.3%) and highest average relative abundance (0.3%) in upland large streams (watershed area 100-300 km^2) of the Santee River basin.

CHALLENGES

The limited and extremely patchy distribution of this species within South Carolina makes it vulnerable to extirpation. Several of its populations in South Carolina are restricted to one stream within a given river basin, representing a very high risk of basin-level extirpation within the state. The Carolina Fantail Darter, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. The lithophilic requirements of this species make it particularly susceptible to impacts from both suspended and deposited sediment.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will

serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Describe life history and habitat requirements for Carolina Fantail Darters.
- Identify and protect areas with healthy populations and intact critical habitat for the Carolina Fantail Darter.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Consider this species' needs when participating in the environmental permit review process.
- Encourage responsible land use planning.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. Genetic resolution of the status of this species will allow for more specific management protocols. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast

Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

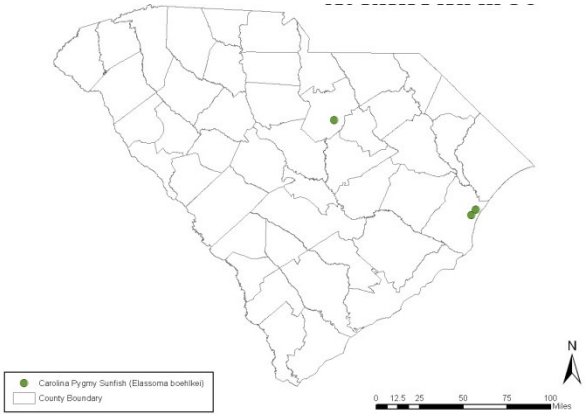
DESCRIPTION



Taxonomy and Basic Description

The Carolina Pygmy Sunfish is a member of the family Elassomatidae; this family of small secretive fishes contains 7 known species, all of which are placed in the genus *Elassoma* (Page et al. 2023). Four species of elassomatids occur in South Carolina. This species and its close relative, the Bluebarred Pygmy Sunfish (*E. okatie*), were not described until 1987 (Rohde and Arndt 1987). The elassomatids are found only in the southeastern United States (Rohde et al. 1994). Carolina Pygmy Sunfish range in length from 20 to 32 mm (0.8 to 1.3 in.) (Tracy et al. 2024). As with other members of the genus *Elassoma,* the Carolina Pygmy Sunfish lacks a lateral line, has a relatively large eye, an upturned mouth, and a rounded caudal fin. This species is identifiable by the series of 10 to 16 dark bars along its side (Rohde et al. 2009); males of the species display alternating blue and black bars along their sides, with the bars on the females alternate between dark brown and light brown (Rohde et al. 1994). The Carolina Pygmy Sunfish is most closely related to the Bluebarred Pygmy Sunfish (Sandel et al. 2014). The taxonomic placement of the *Elassoma* remains somewhat uncertain, with some studies suggesting they belong in Centrarchidae rather than a separate family (Near et al. 2012; Tracy et al. 2024).

Status

The Carolina Pygmy Sunfish is listed as State Threatened in both South Carolina and North Carolina, the only two states in which it occurs and recommended as a threatened status in Threatened fishes of the world (Sandel & Harris 2007). It is listed as imperiled on the global scale (G2), critically imperiled (S1) in South Carolina and imperiled (S2) in North Carolina (NatureServe 2024, Tracy et al. 2024). The species was identified as vulnerable to imperilment in a recent assessment of southeastern freshwater fishes (Warren et al. 2000). The Carolina Pygmy Sunfish was considered threatened in a recent assessment of North American freshwater fishes (Jelks et al. 2008). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

The Carolina Pygmy Sunfish is only known from the Waccamaw River drainage (Pee Dee basin) and Wateree/Congaree drainages (Santee basin) of North and South Carolina. In South Carolina, it is known from about 11 localities, three of which were recently discovered in 2013 and 2018 whereas two or three others may no longer support the species (Jones and Ewing 2019). Populations are known from scattered sites in the upper (Horry County) and lower (Georgetown County) Waccamaw River drainage near the confluence with the Great Pee Dee River. In addition, and rather disjunct from the Waccamaw River system, populations occur in several tributaries of the Wateree and Congaree Rivers in the central Santee River basin. These Santee basin populations were determined to be genetically distinct from those of the Waccamaw basin (Quattro et al. 2001).

Overall, especially in the North Carolina portion of the Waccamaw River drainage, this species is considered relatively stable, and it is likely that additional populations await discovery (F. Rohde, pers. comm.; Jones and Ewing 2019). Although its populations can fluctuate dramatically due to the variable hydrology characteristic of its habitats, in more stable habitats or under prolonged favorable wet periods, it can be very abundant (Jones and Ewing 2019). Owing to its patchy distribution and preference for other habitat types, this species was not collected during any SCDNR standardized stream and river assessment sampling from 2006 through 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Carolina Pygmy Sunfish inhabits slow-moving acidic waters with dense cover in swamps, streams, river backwaters and ditches in the coastal plain (Rohde and Arndt 1987). This species is generally associated with abundant aquatic vegetation and often occurs in the shallow (<15 cm) margins of these habitats (Rohde et al. 1994; Rohde et al. 2009). Spawning occurs mainly from February to May, and this short-lived species is mature at and rarely persists beyond one year; the maximum known age in the wild is 22 months (Rohde et al. 2009). The geographic range of the Carolina Pygmy Sunfish overlaps with that of the Banded Pygmy Sunfish (*E. zonatum*) and probably the Everglades Pygmy Sunfish (*E. evergladei*), but there is no known coexistence of this species with its closest relative, the Bluebarred Pygmy Sunfish (*E. okatie*) (Rohde et al. 2009).

CHALLENGES

Although the Carolina Pygmy Sunfish is often locally abundant and believed to be currently stable, its limited distribution is cause for concern. The isolation of this species makes it extremely vulnerable to development, pollution, and habitat alterations. Primary threats to the Carolina Pygmy Sunfish include loss of natural/forested land cover and especially the removal of riparian cover along coastal plain streams. Fish assemblage integrity of coastal plain streams increases with natural land cover, whereas integrity decreases as the amount of agricultural land

increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in Coastal Plain streams, which provides critical habitat for many endemic Southern Atlantic Coastal Plain species including the Carolina Pygmy Sunfish (Marion et al. 2015). Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of naturally stagnant lowland swamps and streams into channelized, shallow drainage ditches with consistently high current velocities represents a principal threat to Carolina Pygmy Sunfish habitat. In contrast to many of the North Carolina populations, those in South Carolina predominantly occur on private (unprotected) lands and in relatively close proximity to rapidly developing areas (Jones and Ewing 2019). The Waccamaw drainage in South Carolina is squarely within the coastal development corridor encroaching from cities including Conway, Myrtle Beach and North Myrtle Beach; a legitimate possibility exists for populations to be extirpated before they are discovered. Similarly, the central Santee basin populations are located within the growing footprints of Columbia, Camden and Sumter, which represent principal sources of habitat alteration. The high variability of populations and low dispersal capability render pygmy sunfishes susceptible to acute disturbances and habitat fragmentation (Snelson 1989). Furthermore, the extreme variability in abundance and corresponding detection difficulties confound efforts to monitor their distribution and overall population trends. Conservation efforts within South Carolina are critical to the global conservation of the species.

CONSERVATION ACCOMPLISHMENTS

Riverbanks Zoo currently has a propagation and maintenance program of representative populations of Carolina Pygmy Sunfish.

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use

and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

    - Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements for the Carolina Pygmy Sunfish.

- Conduct genetic assessments to determine appropriate taxonomy for the Carolina Pygmy Sunfish.
- Protect critical habitats for the Carolina Pygmy Sunfish from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Carolina Pygmy Sunfish.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of this species could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The "Carolina" Redhorse (*M.* sp. cf. *erythrurum*) is an undescribed member of the sucker family (Catostomidae), which is represented by 78 described species in North America (Page et al. 2023). Suckers comprise about 8% of the continent's freshwater ichthyofauna, behind only minnows (Leuciscidae) and perches and darters (Percidae) in number of species (Warren and Burr 2014). The genus *Moxostoma* includes 23 described species (Page et al. 2023), about one third of which are considered imperiled at some level (Jelks et al. 2008; Warren and Burr 2014).

Although vouchered specimens of this species date to the early 1960s, due to confusion and misidentification, the recognition of this undescribed species did not occur until 1995 (Rohde et al. 2009; Jenkins 2011). It is presumed to be most closely related to the Golden Redhorse, *M. erythrurum* (Rohde et al. 2009; Jenkins 2011).

This species is characterized by a stout body with an overall olive to gold coloration and one to three golden to brassy stripes of variable length on the flanks. The lips are deeply plicate, and the posterior margin of the lower lip is U-shaped (bottom of the U pointing anteriorly) and thinned at the corners. Fins are generally dusky to gray (caudal fin probably orange in young); the dorsal fin usually has 14-15 rays, and its distal margin is straight to slightly concave. Adults range from 390 to 560 mm total length (Rohde et al. 2009).

Status

The "Carolina" Redhorse is listed as threatened in North Carolina (NCWRC 2013). NatureServe (2024) lists the status as globally critically imperiled (G1Q) to imperiled (G2Q), though the taxonomy is currently questionable or uncertain. It is listed as critically imperiled (S1) in South Carolina and imperiled (S2) in North Carolina. This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

The “Carolina” Redhorse is currently only known from the Pee Dee River and Cape Fear River basins in North and South Carolina (Rohde et al. 2009; Jenkins 2011; Tracy et al. 2020). Jenkins (2011) proposed that this species may have also been native to the Santee River basin, possibly having been extirpated there as is presumed to have occurred with Robust Redhorse (*M. robustum*) (Tracy et al. 2020; Tracy et al. 2024). In South Carolina, this species has only been found in the Great Pee Dee River downstream to about 63 air km (40 miles) from the North Carolina state line (Rohde et al. 2009) and is probably recruiting from upstream sections of the river in North Carolina (W. Starnes, pers. comm.). Most recently in South Carolina, a specimen was collected and photographed on the Great Pee Dee River near Cheraw in October 2017 (S. Holbrook, pers. comm.). The “Carolina” Redhorse has likely declined considerably from its historic distribution based on the disjunct nature of currently known populations, which could represent remnants of a formerly broad range extending much higher into the Piedmont portions of the Pee Dee and Cape Fear basins (Jenkins 2011). However, it does seem to be locally stable in some isolated river reaches in the Pee Dee and Cape Fear drainages (W. Starnes, pers. comm.).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The elusiveness and only recent recognition of this species have confounded characterization of its habitat use and biology. It has been collected from cool to warm, moderate gradient streams (juveniles) to large rivers, small run-of-river reservoirs, and a large reservoir (Jenkins 2011). In rivers with moderate gradient, it prefers the deep pool areas along the shore that contain woody debris but moves into shoal areas to spawn in late April to May (W. Starnes, pers. comm.). Lackmann et al. (2023) reported a maximum age for the closely related Golden Redhorse (*M. erythrurum*) of 17 years, which exceeds previously published values and represents an expansion of knowledge regarding longevity of this species and its close relatives.

CHALLENGES

The population of “Carolina” Redhorse is limited to one short section of the Great Pee Dee River in South Carolina. Even small alterations to this river section or to the upstream reaches in North Carolina that probably serve as the primary population source could lead to the extirpation of the species from South Carolina. This species is susceptible to the same pervasive types of anthropogenic habitat alteration and fragmentation affecting other large riverine catostomids (Cooke et al. 2005), including the construction and operation of dams and impoundments, sedimentation of important foraging and spawning habitats, alteration of hydrologic regimes, and introduction of non-native species.

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and

developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Continue to define “Carolina” Redhorse habitat in the upper reaches of the Pee Dee River.
- Continue to advocate for responsible development and the adoption of Best Management Practices (BMPs) in timber and agricultural land use, especially in the upper Pee Dee system.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species’ needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina’s aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership’s 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Central Stoneroller

Campostoma anomalum

Photo: NCFishes.com

Contributor (2005): Dan Rankin and Jason Bettinger (SCDNR)
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Central Stoneroller is a member of the minnow family (Leuciscidae) and one of five to six recognized species of *Campostoma* (Warren and Burr 2014; Page et al. 2023). *C. anomalum* is widespread in central and eastern North America; variation across its range has long been known and several subspecies recognized (Rohde et al. 2009 and sources therein). Recent investigations indicate that the form occurring in southern Atlantic (including South Carolina) and adjacent drainages, currently considered *C. anomalum michauxi* (Fowler, 1945; Burr and Cashner 1983), is probably distinct at the species level (Blum et al. 2008). Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023).

Adult Central Stonerollers range in length from 122 to 239 mm (4.8 to 9.4 in.) (Rohde et al. 1994). The species is a round-bodied, chub-like minnow with a ventral mouth, hard ridge along the lower jaw, and a rounded snout. The back is brown to olive with a brassy sheen. The belly and fins are typically light colored (Jenkins and Burkhead 1994). Breeding males develop orange and black on the fins. Though primarily considered herbivores grazing on algae, the Central Stoneroller consumes considerable amounts of detritus and invertebrates and should instead be considered omnivorous (Evans-White et al. 2003).

Status

NatureServe (2024) lists the status as secure globally (G5). The Central Stoneroller is currently stable within its native range (Warren et al. 2000). Its current state ranking for South Carolina is vulnerable (S3) and is also listed as vulnerable in several states on the fringes of its native range, including North Dakota and New Mexico (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

Broadly (including all recognized subspecies), the Central Stoneroller is found throughout much of the Eastern and Central US in the Atlantic, Great Lakes, Mississippi River, and Hudson Bay (Red River) basins from New York and southern Ontario west to North Dakota and Wyoming, and south to South Carolina and Texas; Thames River system, Ontario; Gulf Slope drainages from Galveston Bay, Texas to Rio Grande, Mexico; and isolated populations in Southwestern Mississippi and Eastern Louisiana (Page and Burr 1991). Blum et al. (2008) found the southeastern form of *C. a. michauxi* to show sufficient distinctiveness to be classified as a unique species once the taxonomy of related forms is resolved; the range of this species would include the Savannah and Santee basins in addition to adjacent Atlantic drainages and portions of the Green and Tennessee basins. In South Carolina, the Central Stoneroller is found in the Blue Ridge and upper Piedmont ecoregions of the upper Savannah River, Saluda River, and Broad River drainages (SCDNR unpublished data). This species was observed in 1.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Central Stoneroller is found in small to medium rivers with cool, clear water, moderate or sometimes rapid current, and gravel or rubble substrates. It commonly occurs in pools with a current and in riffles of small rocky streams. Occasionally Central Stonerollers are found in slow-moving turbid water (NatureServe 2024). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (0.6%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin. It is particularly abundant in the Chattooga River.

CHALLENGES

The Central Stoneroller may be somewhat vulnerable in South Carolina due to its limited distribution that is apparently associated with unique zoogeographic events (Ross 1970). Primary threats to the Central Stoneroller include loss of forested land and especially the removal of riparian cover along upland streams. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. Although many of the Central Stoneroller populations in the upper Savannah and Saluda basins occur in protected, forested watersheds on federal and state lands, other populations in South Carolina and on the edge of the range of this species are vulnerable to development, such as those in certain portions of the Saluda and Broad basins. Further, regardless of land protection status, the limited range of this species in South Carolina in a limited elevational band places it at heightened risk from broader climatic change associated with human activity.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river

basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements for the Central Stoneroller.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop of educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. An increase in native Eastern Brook Trout populations within the State would also indicate that restoration and habitat protections were successful. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008

Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Christmas Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). Bailey and Richards (1963) recognized *E. hopkinsi* as polytypic and described two subspecies based primarily on differences in scale counts and coverage: *E. h. hopkinsi* in the Altamaha River basin and *E. h. binotatum* in the Savannah River basin. Subsequent authors have suggested (Kuehne and Barbour 1983) or published results supporting elevation to species level (Near et al. 2011) of *E. binotatum* in the Savannah basin, garnering the common name of Hanukkah Darter or sometimes Christmas Eve Darter. Although *E. binotatum* is not yet formally recognized by the American Fisheries Society (Page et al. 2023), the distinction of *E. binotatum* as the Savannah basin form and *E. hopkinsi* as the Altamaha form is widely acknowledged among the ichthyological community for conservation purposes. *E. binotatum* is most closely related to the sister species pair of *E. hopkinsi* and *E. fricksium* (Savannah Darter) (Near et al. 2011), the latter of which also occurs in South Carolina.

The colorful Christmas Darter ranges in length from 41 to 71 mm (1.6 to 2.8 in.). It has a small conical head, broad frenum, and two anal spines. Breeding males have a blue marginal and a red sub-marginal band on the spiny dorsal fin (Kuehne and Barbour 1983). This darter has 10 to 12 dark green bars on its side, separated by a red bar in a mature male and a yellow bar in the female. Its greenish back has eight dark saddles while its belly is light green.

Status

The Christmas Darter is considered stable within its range (Warren et al. 2000). NatureServe (2024) lists the status as secure to apparently secure both globally (G4G5) and in Georgia (S4S5). In South Carolina, the fish is considered to be imperiled (S2). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and

Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

The Christmas Darter (*E. binotatum* form) is restricted to the Savannah River basin at and above the fall line. It is generally absent from the higher elevations of the inner Piedmont and Blue Ridge and occurs mainly through the Southern Outer Piedmont and Carolina Slate Belt ecoregions. Its distribution within this range is patchy and it is not always present nor abundant in apparently suitable habitat. This species was observed in 5.0% of over 900 standardized statewide stream and river assessment samples in South Carolina between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Christmas Darter inhabits gravel or rubble riffles in cool water springs, creeks, and small- to medium-sized rivers with current and coarse substrate (Page 1983; Kuehne and Barbour 1983). It sometimes occurs in slower moving waters with submerged vegetation and in springs (Rohde et al. 1994, 2009). In high quality watersheds with intact habitat, this species is often found in association with Bartram's Bass (*Micropterus* sp. cf. *coosae*). In standardized sampling covering streams to small rivers across South Carolina, this species exhibited its highest frequency of occurrence (66.7%) and average relative abundance (2.0%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin. Gravid females and tuberculate males have been observed in March and April (Page 1983; Kuehne and Barbour 1983), and the lifespan is 2 years (Rohde et al. 2009).

CHALLENGES

The Savannah basin Christmas Darter (*E. binotatum*) appears to be fairly stable in suitable habitat; however, the disjunct distribution of intact habitats and robust populations warrants concern. Given its close ecological association with Bartram's Bass, it faces similar threats from habitat alteration and fragmentation throughout its core range. Much of its preferred larger, fluvial habitat in the upper Savannah River basin has already been lost to major reservoirs collectively spanning hundreds of thousands of acres. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. The patchy and limited distributions of remaining intact habitats and populations are vulnerable to development, deforestation, loss of riparian cover and siltation of suitable rocky habitats.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first

time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Christmas Darter.
- Conduct a genetic survey to determine the relationship between the Christmas and Savannah darters.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct an education and outreach campaign to raise awareness of the impacts of illegal introductions of non-native species.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best

accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Eastern Brook Trout is a member of the family Salmonidae and the genus *Salvelinus*, which includes five described species of chars (Page et al. 2023) and as many as 7-10 recognized forms (Behnke 1980; Cavendar 1980; Kendall and Behnke 1984). However, it has been suggested that this genus may contain as many as 16 species (Behnke 1990). The Eastern Brook Trout is the lone living member of the subgenus *Baione*, as its only other member, the Silver Char (*Salvelinus agassizi*), has become extinct (Jenkins and Burkhead 1994). Genetic variation of Brook Trout across its native range is consistent with geographic expansion from Mississippian, mid-Atlantic, and Acadian glacial refugia (Kazyak et al. 2021). Mississippian or southern Appalachian populations are typically found south of the New River in Virginia and are genetically distinct from northern populations at subspecific levels (Stoneking et al. 1981; McCracken et al. 1993; Danzmann et al. 1998; Guffey et al. 1999, Kazyak et al. 2021). In South Carolina, 12 of 18 patches (populations) of Brook Trout tested genetically were found to be of a pure or near-pure genotype and were highly differentiated across the two major river drainages with maximum pair-wise Fst=0.773 (Pregler et al 2018).

The brilliantly marked char range in adult length from 130 to 508 mm (5.1 to 10.0 in.) (Rohde et al. 1994); however, in the Southern Appalachians, Eastern Brook Trout rarely exceed 250 mm (9.8 in.) (Jenkins and Burkhead 1994). This char is identified by a white leading margin on a black sub-margin or streak on the ventral fins; yellow and olive pale spots and red spots with a pale blue halo on an olive background along the side; and a vermiculate (wormlike) back. The belly is brilliant orange-red bordered by black at the ventrolateral margin, especially in breeding males. Larger breeding males develop a distinct kype (hook) on the lower jaw.

Status

Eastern Brook Trout are considered currently stable by Warren et al. (2000) and globally secure (G5) (NatureServe 2024). NatureServe (2024) lists Eastern Brook Trout in South Carolina as critically imperiled to imperiled (S1S2). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The native range for Eastern Brook Trout extends from Canada south and east to Hudson Bay, and southward through the northern states from Eastern Minnesota and Northeastern Iowa eastward to Pennsylvania. The native range also includes the Appalachian uplands—particularly the Blue Ridge—south to Georgia. Drainage changes in the region, stream captures and piracies (Ross 1970) likely explain the occurrence of Eastern Brook Trout in Atlantic slope drainages of the Southern Appalachians, south of the New River, Virginia. These drainage changes in headwaters of the Savannah River drainage and Saluda River system in South Carolina, coupled with the occurrence of pure or near-pure native genotypes in both systems (Guffey 1995), are indicative of native heritage for South Carolina brook trout. The Eastern Brook Trout has been widely introduced outside its native range in North America and is established on all continents except Antarctica (Jenkins and Burkhead 1994).

The Eastern Brook Trout is widespread and seemingly stable across much of its range; however, a troubling decline in miles of stream occupied in the Southern Appalachians has occurred over the last century (Etnier and Starnes 1993). The range for Eastern Brook Trout in Great Smoky Mountains National Park (Moore et al. 1981) was estimated to have declined approximately 70 percent since monitoring efforts began. Factors resulting in this decline are deforestation (King 1937; Jenkins and Burkhead 1994) which causes excessive siltation and water warming, acidification, competition from non-native introductions, and global warming (Etnier and Starnes 1993; Larson and Moore 1985; Moore et al. 1986). A similar level of decline appears to have taken place in South Carolina and likely other regions of the southern Appalachians. The Brook Trout has been collected in 24 patches in SC including approximately 90 km of stream. SCDNR has expanded Brook Trout distribution through restoration and enhancement efforts in 12 streams including 30 km of additional stream.

Wild Brook Trout inhabit over 3,000 km (1,864 mi.) of streams across the Southern Appalachian region (Habera and Moore 2005). Mississippian or southern Appalachian Brook Trout populations are distributed from the New River drainage in Virginia southward into Tennessee, North Carolina, South Carolina and Georgia. The Southern Appalachian genotype (subspecies) comprises only about 17% of these streams. Most populations are located in the upper Tennessee River (Mississippi River) system; however, a few also occur in 3 Atlantic Coast and 2 Gulf Coast drainages. About 50% of Brook Trout streams in the Tennessee River system are the pure Southern genotype, while only about 5-10% of stream populations in the Atlantic Slope are pure. Of the 70% known Brook Trout resources in the Southern Appalachians, 88% occur on public lands (Habera and Moore 2005). This species was observed in 0.42% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Eastern Brook Trout inhabits rocky, often high-gradient, well-shaded, pristine coldwater mountain creeks (Rohde et al. 1994), generally above 600 m (1,969 ft.) in elevation but also occasionally down to 490 m (1,608 ft.) in streams with north-facing aspects (Etnier and Starnes 1993). Brook Trout require high dissolved oxygen levels and cannot tolerate temperatures

regularly above 20°C (68°F). Brook Trout are the most tolerant of the salmonids with regard to acidity, tolerating pHs from 4.5 to 9.5 (Jenkins and Burkhead 1994).

CHALLENGES

The Eastern Brook Trout is challenged by deforestation; specifically, the associated water temperature rises as shade trees are removed, and siltation from timber harvesting practices (King 1937; Jenkins and Burkhead 1994). Additionally, impoundments, acid deposition and displacement by non-native salmonids adversely affect this species (Etnier and Starnes 1993; Larson and Moore 1985; Moore et al. 1986). Climate change threatens the species in southern portions of its range (Meisner 1990). Contemporary genetics studies (Pregler et al. 2018) of Brook Trout in SC indicate the lowest local genetic diversity and highest genetic differentiation reported for the species to date. This creates great challenges for management, as is evidenced through occasional loss of populations.

CONSERVATION ACCOMPLISHMENTS

Many conservation practices have been accomplished for the Eastern Brook Trout. Range and population levels have been monitored across the species' range, and taxonomic characterization of the Eastern Brook Trout is well advanced. Further, water quality designations designed to protect the species have been implemented. The American Fisheries Society–Trout Committee's Position Paper (Habera and Moore 2005) is a valuable tool for management of the Southern Appalachian Brook Trout. This position paper is currently being updated to reflect new findings from contemporary genetics studies.

Additionally, the recent development of a state, federal and non-governmental organizations (NGOs) "Eastern Brook Trout Joint Venture" is focusing on protection and restoration of Eastern Brook Trout across its range in the US. To assist in this restoration, successful biological restoration techniques have been developed for this species. For the past 20 years, the South Carolina Department of Natural Resources has partnered with the USFWS, USFS, Trout Unlimited, and others to restore or enhance Eastern Brook Trout populations in 12 streams totaling approximately 30 km in South Carolina. SCDNR also completed a comprehensive assessment of in-stream habitat, water quality, and longitudinal fish distribution in several candidate streams for restoration. Recent successful restoration efforts include restoration of Brook Trout in Howard Creek (>2 miles) by removal of non-native rainbow trout and in-stream habitat enhancement. This project was funded through SARP Grant. SCDNR with partners also just completed restoration of Brook Trout in Pig Pen Branch (3.5 miles), including dam removal, non-native removal using Antimycin, and reintroduction of native strain Brook Trout.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Continue to monitor the distribution and population status with stream surveys for Eastern Brook Trout.
- Describe life history and habitat requirements for Eastern Brook Trout.
- Refine distribution information for Eastern Brook Trout, primarily on privately owned lands.
- Continue to assess water quality and habitat in Brook Trout streams to identify threats and deficiencies; establish long-term water quality and habitat monitoring programs in those streams.
- Protect critical habitats from future development and further habitat degradation by following best management practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Aggressively seek protection of Brook Trout habitat through land acquisition, conservation easements, agreements and other methods.
- Where feasible and appropriate, implement Brook Trout restoration in headwater streams.
- Conduct water quality monitoring and habitat enhancement in Brook Trout streams where habitat is determined to be impaired.

MEASURES OF SUCCESS

Monitoring the distribution, life history, and habitat needs would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies for this fish could assist in determining the effectiveness of those measures. An increase in native Brook Trout populations within the State would also indicate that restoration and habitat protections were successful. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Everglades Pygmy Sunfish is one of seven known species in the family Elassomatidae (Pygmy Sunfishes), all of which are placed in the genus *Elassoma and* are restricted entirely to the Southeastern United States (Rohde et al. 2009; Page et al. 2023). In addition to the Everglades Pygmy Sunfish, three other elassomatids occur in South Carolina: the Banded Pygmy Sunfish (*E. zonatum*), Bluebarred Pygmy Sunfish (*E. okatie*) and Carolina Pygmy Sunfish (*E. boehlkei*).

Everglades Pygmy Sunfish reach an adult size of only 0.9 to 1.3 in. total length (23 to 32 mm) (Rohde et al. 2009). They lack a lateral line and have a rounded caudal fin. Overall coloration varies and may be plain, mottled, or streaked with indistinct bars posteriorly and scattered blue flecks on the body and head. The breeding male is black with a bright blue spot behind and below the eye (Tracy et al. 2024). The Everglades Pygmy Sunfish and the Banded Pygmy Sunfish usually have four pores in the preopercular branch of the cephalic lateral-line canal (Snelson et al. 2009). Unlike the other three species of *Elassoma* in South Carolina, the Everglades Pygmy Sunfish has scales on the top of its head, which are often embedded (Rohde et al. 2009). Everglades Pygmy Sunfish is related to the Carolina and Bluebarred Pygmy Sunfishes, but not as closely as the latter are to each other (Sandel et al. 2014). The taxonomic placement of the *Elassoma* remains somewhat uncertain, with some studies suggesting they belong in Centrarchidae rather than a separate family (Near et al. 2012).

Status

The Everglades Pygmy Sunfish is considered secure (G5) on a global scale and is currently ranked as apparently secure in South Carolina (S4) (NatureServe 2024). It is currently stable according to Warren et al. (2000). In North Carolina and Alabama, the Everglades Pygmy Sunfish is considered vulnerable (S3), while in Georgia it is considered secure (S5) (NatureServe 2024, Tracy et al. 2024).

POPULATION SIZE AND DISTRIBUTION

The Everglades Pygmy Sunfish is distributed along the southern Atlantic Coastal Plain from the Cape Fear River Basin in North Carolina south to the Florida Everglades and west to Mobile Bay, Alabama (Rohde et al. 2009). It has been collected at scattered localities on the coastal plain across all of South Carolina's river drainages, although the highest concentration of records appears to be in the southern corner of the State (Rohde et al. 2009). This species was observed in only 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023; however, this likely reflects its preference for swamps and other densely vegetated backwaters, which were not among the habitat types targeted by these studies. In South Carolina, the ranges of this species and the Banded Pygmy Sunfish overlap across all river basins, and it also overlaps with the Bluebarred Pygmy Sunfish and Carolina Pygmy Sunfish in the smaller areas in which those species occur (Rohde et al. 2009).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Everglades Pygmy Sunfish prefers quiet backwaters of creeks, sloughs and swamps with abundant aquatic vegetation (Rohde et al. 2009, Bohlen & Nolte 2012). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (1.1%) and average relative abundance (0.03%) in small streams (watershed area 0-15 km^2) of the coastal plain. Individuals are most often found in or near dense vegetation. The species is more motile and active at night based upon capture in traps in the Florida Everglades region (Obaza et al. 2011). However, observed mating behavior indicates the male flashes its fins in a visual signal to females, which occurs during the day, as observed in captivity. Information on the life history aspects of this species is sparse, as direct observations are mostly of captive individuals documented by aquarium hobbyists (Bohlen & Nolte 2012).

CHALLENGES

Primary threats to the Everglades Pygmy Sunfish include loss of forested land and especially the removal of riparian cover along Coastal Plain streams. Mature forest and riparian vegetation are an important source of large woody debris in Coastal Plain streams, which provides critical habitat for many endemic southern Atlantic Coastal Plain species including the Everglades Pygmy Sunfish (Marion 2008). Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of naturally stagnant lowland swamps and streams into channelized, shallow drainage ditches with consistently high current velocities represents a principal threat to Everglades Pygmy Sunfish habitat. High variability of populations and low dispersal capability render pygmy sunfishes susceptible to acute disturbances and habitat fragmentation (Snelson 1989). The species is understudied, and the full extent of its distribution is unknown. Recent Georgia sampling efforts revealed new sites where the species is present, and a previously unknown site where the Everglades and Gulf Coast Pygmy Sunfishes coexist (Cannister & Bechler 2019).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's

freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Identify and protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of Everglades Pygmy Sunfish habitats would produce expected population densities comparable to or exceeding those observed in the South Carolina Stream Assessment (2006 – 2011) for given ecoregions, river basins and ecobasins. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Fieryblack Shiner belongs to the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). The Fieryblack Shiner is one of eight described plus one undescribed species of *Cyprinella* in South Carolina.

Members of the genus *Cyprinella* are distinguished from other leuciscids by their diamond-shaped scales and black pigmentation in the dorsal fin membranes (Rohde et al. 1994). Adult Fieryblack Shiners range in length from 47 to 110 mm (1.8 to 4.4 in.). This attractive species has a red snout, a black bar behind the opercle and a black margin on the caudal fin (Rohde et al. 1994). Breeding males display bright red and white bands on the caudal fin (Rohde et al. 1994).

Status

The Fieryblack Shiner is considered apparently secure globally (G4) (NatureServe 2024); however, there is some concern for their long-term status based on their limited distributions. The Fieryblack Shiner is considered vulnerable (S3) in South Carolina and apparently secure (S4) in North Carolina (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Fieryblack Shiner occurs in the Santee and Pee Dee River systems predominantly above the fall line in North Carolina and South Carolina. In South Carolina, it is most common and abundant in the moderate to higher elevations of the Saluda and Broad River drainages; it occurs less frequently and generally in lower abundance in the Pee Dee basin and areas in which it ranges into the inner coastal plain. Outside of certain high-quality watersheds supporting stronghold populations in the upper Saluda River drainage, the Fieryblack Shiner is usually

vastly outnumbered by its congeners the Whitefin Shiner (*C. nivea*) and Greenfin Shiner (*C. chloristia*) in most locations in the Piedmont and especially in disturbed watersheds. This species was observed in 3.5% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Fieryblack Shiner requires cool, clear water in creeks and small to moderate-sized rivers. The species is generally associated with rocky runs and pools below riffles (Page and Burr 1991; Rohde et al 1994). Where it occurs (in lower abundance) in the inner coastal plain, the streams are characterized by steady flow over sand and fine gravel (SCDNR data). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (33.3%) in upland small rivers (watershed area 300-2000 km^2) of the Santee River basin. As with other non-barbeled *Cyprinella* species, the Fieryblack Shiner is a crevice spawner, depositing eggs in crevices of logs and rocks in a territory defended by the male over an extended spring-summer breeding period (Gale and Buynak 1978; Rohde et al 1994; Rohde et al. 2009).

CHALLENGES

Although the distribution of the Fieryblack Shiner spans a relatively large portion of the South Carolina uplands, abundant populations are patchy and are typically restricted to undisturbed watersheds and habitats. Approximately half of the global distribution of the Fieryblack Shiner occurs in South Carolina. Therefore, conservation efforts within South Carolina are critical to the global preservation of this species. The Fieryblack Shiner, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. The breeding behavior of the non-barbeled *Cyprinella* makes this group particularly vulnerable to impacts from both suspended and deposited sediment. Because the breeding process is dependent on visual cues (extended display and territorial defense period) as well as clean crevices for egg deposition and larval development, suspended sediment (increased turbidity) and deposited sediment has been shown to delay or inhibit spawning success in fishes of this genus (Hubbs and Echelle 1972; Burkhead and Jelks 2001; Warren and Burr 2014). The rapidly developing Greenville-Spartanburg and Interstates 85 and 385 corridors are situated directly within the range of this species. Furthermore, the introduction and establishment of the highly invasive Red Shiner (*Cyprinella lutrensis*) in the North Carolina portion of the Pee Dee River basin (Poulos et al. 2012; Glotzbecker et al. 2016; Tracy et al. 2020; Tracy et al. 2024) represents a potential threat to native *Cyprinella*, including the Fieryblack Shiner. *C. lutrensis* has been shown to impact native *Cyprinella* through competition and hybridization (Walters et al. 2008; Ward et al. 2012), both of which can be exacerbated with additional stressors such as elevated turbidity resulting from alteration of natural land cover (Glotzbecker et al. 2015) and broader influences of climate change (Poulos and Chernoff 2014).

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.

- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Fieryblack Shiner.
- Identify critical habitats and areas with healthy populations of the Fieryblack Shiner.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the

Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Flat Bullhead is a member of the family Ictaluridae. The ictalurids, with approximately 51 species, represent the largest family of fishes indigenous to only North America (Warren et al. 2020; Page et al. 2023). The genus *Ameiurus* contains the moderately-sized (reaching only a few pounds) catfish collectively known as the "bullheads." Flat Bullheads have a large flat head, a relatively straight snout profile, a bi-colored maxillary barbel that has a white leading edge, short rounded anal fin (though usually several rays longer than that of the Snail Bullhead), emarginate tail, gold-yellow to dark brown colored back, dark mottling along the sides, and a cream-colored belly. In their natural habitats (rivers and streams), Flat Bullheads typically reach maximum adult sizes of 294 mm (11.4 in.) (Rohde et al. 1994). However, in impounded river reaches and reservoirs, they reach substantially greater sizes (443 mm, 17.6 in.) (SCDNR unpublished data).

Status

The Flat Bullhead is considered apparently secure (G4) globally (NatureServe 2024). However, in a recent assessment of North American fishes, this species was considered vulnerable to imperilment (Jelks et al. 2008). The Flat Bullhead is considered vulnerable to apparently secure (S3S4) in South Carolina and Virginia. In North Carolina this species is considered apparently secure (S4), while in Georgia it is considered apparently secure to secure (S4S5) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Flat Bullhead occurs in the Piedmont and coastal plain of the Atlantic slope from the Roanoke River basin in Virginia south to the Altamaha River basin in Georgia. In South Carolina, the Flat Bullhead is found in all river basins and ecoregions, although it is most widespread and abundant in the uplands. Flat Bullheads appear to be relatively stable in South Carolina streams; however, their fate in the larger rivers is uncertain due to the presence of the nonnative Flathead Catfish. Flat Bullheads are common to abundant in the upper Santee basin but decreasing trends have been noted in many coastal rivers like the Edisto River and lower

Savannah River following the introduction of Flathead Catfish (C. Thomason, SCDNR, pers. comm.). The largest populations of Flat Bullhead are probably located in the Broad River system; however, both the Flathead Catfish and Blue Catfish have been documented in the system in recent decades, and their impact has yet to be determined. This species was observed in 22.9% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Flat Bullhead is typically found in streams, rivers, and impoundments occupying areas with mud, sand, or rock bottoms, with slow-flowing water along the banks and in pool areas (Jenkins and Burkhead 1994; Rohde et al. 1994, 2009; NatureServe 2024). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (82.9%) and average relative abundance (1.0%) in upland large streams (watershed area 100-300 km²) of the Santee River basin.

CHALLENGES

The Flat Bullhead is adversely affected by the same myriad of challenges for all aquatic species, such as sedimentation, hydrologic modification, impoundments, non-point source pollution, and development. Other threats to the Flat Bullhead include loss of forested land and especially the removal of riparian cover along upland streams. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Additionally, this species is also threatened by the introduction of nonnative ictalurids like the Flathead Catfish and the Blue Catfish; both of these non-native species displace and prey on the smaller bullheads (Guire et al. 1984; Ashley and Buff 1986; Quinn 1988; Bart et al. 1994, Rohde et al. 2009).

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land-use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Develop a Non-Game Fishes of South Carolina poster and other educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Prevent the spread of Flathead Catfish and other non-indigenous aquatic species.
- Educate the public as to the discontents of stocking nonnative species.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Florida Gar

Lepisosteus platyrhincus

Contributor (2005): Jason Bettinger (SCDNR)
Reviewed and Edited (2013): Kevin Kubach and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Florida Gar is a member of the ancient family *Lepisosteidae*, which arose at least 100 million years ago (Warren and Burr 2014). Along with the Longnose Gar (*L. osseus*), it is one of two species of gars in South Carolina. *Lepisosteidae* is a small family with seven currently described species, five of which occur in eastern North America, one in Cuba and one in Central America (Warren and Burr 2014), though the Cuban Gar (*Atractosteus tristoechus*) is not currently recognized by the American fisheries society (Page et al. 2023).

Gars are distinctive, with a heavy armor of diamond-shaped scales and a long, beak-like mouth equipped with needle-sharp conical teeth. The Florida Gar can be distinguished from the Longnose gar by its broader and shorter snout, which has spots on top (absent in Longnose). The Florida Gar can attain lengths of 132 cm (52 in.) (Page and Burr 1991).

Status

The Florida Gar is considered globally secure and stable (G5) (Warren et al. 2000) but is listed as critically imperiled to imperiled (S1S2) in South Carolina (NatureServe 2024). In Georgia, this species is thought to be vulnerable (S3) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Florida Gar occurs from portions of the Savannah River Basin in South Carolina and Georgia into peninsular Florida and west to the Ochlockonee River drainage of Florida and Georgia (Rohde et al. 2009). In South Carolina, it was previously known only from the lower Savannah River near the mouth of Steel Creek and a handful of tributaries in Barnwell County near the Savannah River Site (Rohde et al. 2009). In 2020, SCDNR staff studying the state's small rivers collected the species in two additional localities: Boggy Branch, a tributary of the lower Savannah River in Hampton County, and the New River, a small coastal river just east of the Savannah River in Jasper County. The New River now represents the global easternmost known occurrence for the species. This species was observed in 0.3% of over 900 standardized statewide stream and river assessment samples throughout South Carolina between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Florida Gar inhabits sluggish pools of quiet streams, rivers, sloughs and oxbow lakes, usually near vegetation (Rohde et al. 2009). In standardized sampling covering streams to small rivers across the state, this species exhibited its highest frequency of occurrence (7.7%) and average relative abundance (0.3%) in small rivers (watershed area 300-2000 km^2) of the coastal plain.

CHALLENGES

Primary threats to the Florida Gar include anthropogenic habitat alteration near its limited range in the lower Savannah and New River basins. Although certain tributaries within its range in South Carolina are protected under management of the Savannah River Site (US Department of Energy), impacts to the Savannah River and its tributaries may affect habitat for the Florida Gar, including flow alterations and channelization of swamps and sluggish streams. Currently, the recently discovered population in Boggy Branch of the lower Savannah River basin in Hampton County is located in a watershed largely established as state-managed (SCDNR) Wildlife Management Area land and therefore maintained for the benefit of native species. However, the headwaters of this system should be monitored in order to reduce potential impacts on Florida Gar habitat for this potentially isolated population. The recently discovered Florida Gar population in the New River in Jasper County is at a relatively high risk of habitat alteration from development along the Interstate 95 and U.S. Highway 278 corridors and adjacent coastal communities experiencing rapid growth. Draining of floodplains for development and channelization of tributaries represent immediate threats on the global edge of the Florida Gar's range.

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online

tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

    - Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

Highback Chub

Hybopsis hypsinotus

Photo: NCFishes.com

Contributor (2005): Jason Bettinger (SCDNR)
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Highback Chub is a member of the minnow family (Leuciscidae) and is one of two species of *Hybopsis* in South Carolina, along with Rosyface Chub (*H. rubrifrons*). Minnows represent the most speciose family of freshwater fishes in North America, with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including six described species of *Hybopsis* (Warren and Burr 2014; Page et al. 2023).

This fish looks similar to numerous shiners but often has a small barbel in the corner of its inferior mouth, a long snout, and upward-looking eyes (Rohde et al. 1994). The Highback Chub has a strongly arched dark olive body with a black lateral stripe that extends onto the snout—it resembles a deeper-bodied version of its congener, the Rosyface Chub. During the breeding season, males display red fins. The adult size range is 43 to 84 mm (1.7 to 3.3 in) (Rohde et al. 2009).

Status

The Highback Chub is apparently secure globally (G4) (NatureServe 2024); however, there is some concern for their long-term status based on their limited distributions. The Highback Chub is considered vulnerable (S3) in South Carolina, apparently secure (S4) in North Carolina, and imperiled (S2) in Virginia (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Highback Chub is found in the Blue Ridge foothills and Piedmont ecoregions of the Santee and Pee Dee River drainages. Its core densities occur in the Broad River drainage of the Santee basin (Rohde et al. 2009). Although this species currently appears to be stable in South Carolina, it has a patchy distribution and is typically among the least abundant species in the fish assemblage where present, rarely exhibiting the levels of abundance often shown by the closely related Rosyface Chub (*H. rubrifrons*). This species was observed in 7.0% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Highback Chub is found in cool to warm water streams and small rivers, generally in riffles and runs with sand, gravel, and rock bottoms (Page and Burr 1991; Jenkins and Burkhead 1994). Lemly (1985) mentions finding them only in first-order streams in the Piedmont region of North Carolina. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (21.8%) and highest average relative abundance (0.9%) in upland small streams (watershed area 0-15 km²) of the Santee River basin. The Highback Chub spawns in May-June, using nests constructed by *Nocomis* chubs (Rohde et al. 2009).

CHALLENGES

The Highback Chub is currently stable with relatively large distributions throughout the State. They are of conservation concern because they are only found within a few major drainages. Approximately 50% of the global range of the Highback Chub occurs in South Carolina. Therefore, conservation efforts within South Carolina are critical to the global preservation of this species. Challenges to this species are similar to those faced by other aquatic fauna and include point and nonpoint source pollution, deforestation and loss of riparian corridors, impoundment development, siltation from poor land use practices, and unplanned or poorly planned urban and suburban development. Midway et al. (2014) modeled a positive occurrence response of Highback Chub with increasing forest land cover, indicating that preservation of natural land cover would be beneficial to the species. Introduction of non-native species is also a conservation concern; for example, Lemly (1985) only observed Highback Chubs in small first-order streams in which non-native Green Sunfish (*Lepomis cyanellus*) were absent.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Highback Chub.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Highfin Shiner belongs to the minnow family (Leuciscidae) and was recently moved to the genus *Hudsonius* from the polyphyletic *Notropis* (Stout et al. 2022 and sources therein), joining the Spottail Shiner (*H. hudsonius*) as the only current members of this genus in South Carolina and North America (Page et al. 2023). Minnows represent the most speciose family of freshwater fishes in North America, with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023).

Adult Highfin Shiners are small, ranging in total length from 36 to 63 mm (1.4 to 2.5 in.) (Rohde et al. 2009). This species has a diffuse, black lateral stripe extending from less than halfway onto the caudal fin to, and occasionally over, the eye and around the nostril. The lateral stripe does not extend below the lowest part of the lateral line, and it is bordered above by a light (mostly unpigmented) stripe. The scales on the back are outlined in black. The lateral line is often incomplete. The mouth is oblique and there is a U-shaped smudge of pigment between the nostrils when viewed from above. Little or no pigment is present along the anal fin base (Rohde et al. 2009). Highfin shiners have been found to be efficient larval hosts of the federally endangered Carolina Heelsplitter (*Lasmigona decorata*), a freshwater mussel found in North and South Carolina (Eads et al. 2010).

Status

The Highfin Shiner is considered secure (G5) on a global scale and is currently considered vulnerable to apparently secure in South Carolina (S3S4; NatureServe 2024). It is currently stable according to Warren et al. (2000). The Highfin Shiner is considered secure (S5) in North Carolina and vulnerable (S3) in Virginia (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Highfin Shiner occurs primarily in the Piedmont region of drainages from the Chowan River, Virginia to the Savannah River, Georgia/South Carolina (Rohde et al. 2009). It is found in all of South Carolina's river basins, predominantly in the outer Piedmont and especially the Carolina Slate Belt Ecoregion. This species was observed in 5.2% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Highfin Shiner occurs in pools and runs of small to large streams with substrata ranging from sand to rocks (Rohde et al. 2009). It is particularly abundant in relatively slow-flowing streams of the Carolina Slate Belt ecoregion exhibiting long, sluggish reaches interspersed with short riffles of bedrock, rubble and gravel. In this regard, the Highfin Shiner appears to share a close ecological association with the Carolina Darter (*Etheostoma collis*) where their ranges overlap. During periods of seasonal or extended drought, these streams often reduce to long, stagnant, nearly broken to broken pools; Highfin Shiners have been collected in abundance during such conditions and appear somewhat tolerant of this high variability in water level and temperature, provided they are not stressed by additional anthropogenic habitat alteration. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (22.9%) in large streams (watershed area 100-300 km^2) and highest average relative abundance (1.7%) in medium streams (watershed area 15-100 km^2) of the Outer Piedmont and Carolina Slate Belt of the Santee River basin.

CHALLENGES

Primary threats to the Highfin Shiner include loss of forested land and especially the removal of riparian cover along Piedmont and Carolina Slate Belt streams. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Highfin Shiner habitat. Fragmentation caused by road crossings or other anthropogenic barriers may be particularly detrimental in the Carolina Slate Belt ecoregion, reducing the ability of native species to locate suitable habitat during periods of drying and disconnection.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning

the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

Ironcolor Shiner

Alburnops chalybaeus

Photo: NCFishes.com

Contributors (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Ironcolor Shiner belongs to the minnow family (Leuciscidae) and was recently moved to the genus *Alburnops* from the polyphyletic *Notropis* (Stout et al. 2022 and sources therein), joining the reclassified Coastal Shiner (*A. petersoni*) as the only members of this genus in South Carolina (Page et al. 2023). Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and fusiform fishes including 18 recognized species of *Alburnops* (Warren and Burr 2014; Page et al. 2023).

Adult Ironcolor Shiners are relatively small, ranging in total length from 45 to 65 mm (1.8 to 2.6 in.) (Rohde et al. 2009). The sides and back are yellowish and there is a well-defined black lateral stripe extending from the caudal fin base to the snout with pigment present on the chin and lips. Its snout is shorter than the width of the eye and its mouth is small with a black roof. Breeding males have a bright orange stripe above the black lateral stripe and often have orange spots above and below the black caudal spot. The lateral line is usually incomplete (Rohde et al. 2009).

Status

The Ironcolor Shiner is considered apparently secure (G4) on a global scale and is currently considered vulnerable (S3) in South Carolina (NatureServe 2024). Although it occupies a relatively wide distribution, populations are disjunct (Lee et al. 1980) and it is considered rare or declining in many portions of its range. This species was regarded as vulnerable in a recent assessment of North American fishes due to present or threatened destruction and modification of its habitat (Jelks et al. 2008). Accordingly, it has received varying degrees of state conservation status as high as critically imperiled (S1) in Alabama, Delaware, Maryland, Michigan, Missouri, New York, Oklahoma, and Pennsylvania (NatureServe 2024). After being rediscovered in Pennsylvania, the species is confined to one stream system and its persistence there may depend on reintroduction and augmentation efforts (Leckvarcik 2005; Hanson 2013). In Georgia the Ironcolor Shiner is considered vulnerable (S3), while in North Carolina it is considered imperiled to vulnerable (S2S3) as its range there has apparently contracted over the past 30 years (Tracy et al. 2020). This species was selected as a Regional Species of Greatest

Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Ironcolor Shiner occupies a large but somewhat disconnected range that includes the coastal plain of the Atlantic and Gulf Slopes from Maine to Texas and northward in the Mississippi River Basin to Wisconsin (Rohde et al. 2009). Although it is found in all of South Carolina's river basins on the coastal plain, populations appear to be patchy based on standardized statewide assessment sampling. This species was observed in 4.3% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

In South Carolina, the Ironcolor Shiner generally inhabits low-velocity blackwater streams and swamps (Rohde et al. 2009), including a wide range of sizes from small streams to large swamp channels and blackwater rivers. In standardized sampling covering streams to small rivers across the state, this species exhibited its highest frequency of occurrence (38.5%) and average relative abundance (2.9%) in small rivers (watershed area 300-2000 km^2) of the outer coastal plain. It was particularly abundant in the streams of the Francis Marion National Forest as well as the Coosawhatchie River. In South Carolina, the Ironcolor Shiner is most often collected in habitats with a large amount of organic substrate (≥48% of channel substrate), consistent with the finding of swamps and blackwater streams being a primary habitat per Rohde et al. (2009) (SCDNR unpublished data). The Ironcolor Shiner is a broadcast spawner, releasing eggs into sand- and gravel-bottomed pools (Becker 1983; Rohde et al. 2009).

CHALLENGES

By comparison with its status in most other parts of its range, the Ironcolor Shiner in South Carolina appears to be relatively widespread and, in certain places, abundant. However, the range-wide trend of decline and imperilment for this species is concerning and signals risk for the integrity of its populations in the state. In the adjacent and ecologically similar coastal plain of North Carolina, the range of the Ironcolor Shiner has contracted over the past 30 years, and its frequency of occurrence and relative abundance also appeared to be lower in surveys of the southeastern basins in 2010-2016 than those observed in the same basins in the 1960s (Tracy et al. 2020). Its sensitivity to the spectrum of anthropogenic habitat alteration, which has been attributed to its decline elsewhere (Leckvarcik 2001), is notable. In South Carolina, much of the range of this species is in relatively rural or least-disturbed landscapes, but the high rate of human population growth outward from the state's major coastal plain cities and associated conversion of natural land to developed areas represents a principal threat. Fish assemblage integrity of coastal plain streams increases with natural land cover, whereas integrity decreases as the amount of agricultural land increases (SCDNR 2023).

Primary threats to the Ironcolor Shiner include loss of forested land and especially the removal of riparian cover along Coastal Plain streams. Mature forest and riparian vegetation are important sources of large woody debris in Coastal Plain streams which provides critical habitat for many

endemic southern Atlantic coastal plain species including Ironcolor Shiner (Marion 2008). Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of lowland swamps and streams into channelized, shallow drainage ditches with unnaturally high current velocities represents a principal threat to Ironcolor Shiner habitat.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.

- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Mirror Shiner belongs to the minnow family (Leuciscidae) and was recently moved to the resurrected genus *Paranotropis* from the polyphyletic *Notropis* (Stout et al. 2022 and sources therein), joining the reclassified Tennessee Shiner (*P. leuciodus*) as the only members of this genus in South Carolina (Page et al. 2023). Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including eight recognized species of *Paranotropis* (Warren and Burr 2014; Page et al. 2023).

This species is identified by its slender body, broad head, small subterminal mouth, and upward-directed eyes (Rohde et al. 1994). There is a prominent dark, triangular spot at the caudal fin base. During breeding season, males display red-orange fins with white margins. Adults range in length from 43 to 75 mm (1.7 to 3.0 in.) (Rohde et al. 1994).

Status

Globally, the Mirror Shiner is considered to be stable (Warren et al. 2000) and apparently secure (G4) (NatureServe 2024). It is considered vulnerable (S3) in South Carolina and Georgia (NatureServe 2024). In Virginia this species is considered imperiled (S2) and is considered apparently secure (S4) in both North Carolina and Tennessee (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Mirror Shiner mainly occurs in upland drainages in the upper Tennessee River basin of western Virginia, western North Carolina, eastern and southern Tennessee, and northern Georgia, along with small portions of the upper Savannah River basin and upper Broad River drainage (Santee basin) in North Carolina (Rohde et al. 2009). In South Carolina, it is only known from several locations in the upper Savannah River basin, with the bulk of its occurrences coming from the Chattooga River (Rohde et al. 2009). Its presence in the upper Savannah basin of the Atlantic slope is probably a result of stream capture with the Tennessee basin (Ramsey 1965; Ross 1970; Rohde et al. 2009), similar to other taxa in this volume with predominantly Mississippi drainage distributions. The Broad (Santee) population may have resulted from

human-mediated introduction (Tracy et al. 2020). It is considerably more abundant in the Chattooga River than its congener, the Tennessee Shiner (*P. leuciodus*). On a statewide scale, this species was observed in only 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Mirror Shiner inhabits clear, coolwater streams and rivers with moderate to high gradients (Jenkins and Burkhead 1994) and gravel and rubble substrates (Rohde et al. 2009). This species is generally found in the slower moving areas associated with pools, slow runs, and riffle margins (Rohde et al. 2009; Olson and Martin 2016). Spawning in western North Carolina occurred from April to July (Olson and Martin 2016). In standardized sampling covering streams to small rivers across South Carolina, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (0.6%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin.

CHALLENGES

While the Mirror Shiner is currently stable throughout the majority of its range, its limited distribution in South Carolina make it vulnerable to imperilment within the state. Although much of the Chattooga River drainage is officially designated as wilderness area and therefore protected from development, other anthropogenic actions such as the introduction of non-native species (both aquatic and terrestrial) or long-term environmental change represent potential threats to this species. For example, non-native organisms such as the hemlock woolly adelgid (*Adelges tsugae*) or other tree pathogens could cause widespread loss of major forest constituent tree species and therefore alter the natural thermal and other ecological regimes to which aquatic fauna have adapted. As with other freshwater fishes, anthropogenic landscape alteration can result in cumulative degradation of dependent aquatic ecosystems. The Mirror Shiner may be sensitive to changes in water quality as indicated by its failure to reestablish in a restored river section in which reintroductions of many other species were successful (Olson and Martin 2016).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and

restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- • Use South Carolina Stream Assessment decision-support GIS modeling tools to identify
- levels and spatial distributions of critical habitat factors to sustain the species in
- geographic areas of interest.

- • Use South Carolina Stream Assessment decision-support GIS modeling tools to identify
- priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Mirror Shiner.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Mottled Sculpin

Cottus bairdii

Photo: NCFishes.com

Contributor (2005): Mark Scott and Jason Bettinger [SCDNR]
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Mottled Sculpin is a member of the family Cottidae, which includes 36 species of predominantly freshwater fishes across North America (Page et al. 2023). Taxonomic relationships, geographic delimitations and species descriptions within this family have proven particularly challenging to resolve and have received considerable attention in recent decades (Page et al. 2023 and sources therein). Despite the recommendation of or use by some authors of *Cottopsis* and *Uranidea* in place of *Cottus* (Kinziger et al. 2005; e.g., Smith and Busby 2014; Robison and Buchanan 2020), the American Fisheries Society continues to recognize *Cottus* based on the confounding results of recent investigations (Page et al. 2023 and sources therein). *Cottus bairdii* in a broad sense occurs throughout eastern North America and on both sides of the western Continental Divide; variation across this large range has long been recognized (Robins 1954; Robins 1961; Jenkins and Burkhead 1994) and remains largely unresolved (Rohde et al. 2009; Tracy et al. 2020; Tracy et al. 2024). The form occurring in South Carolina and adjacent drainages, often referred to as the "Smoky Sculpin," probably represents a distinct species (Jenkins and Burkhead 1994; Warren et al. 2000; Rohde et al. 2009).

The adult Mottled Sculpin ranges in total length from 58 to 114 mm (2.3 to 4.5 in.). As is typical of other members of the genus *Cottus*, the Mottled Sculpin has a large head and mouth, 2 dorsal fins (the first is spiny and the second is soft-rayed) and three reduced preopercular spines. This sculpin has a complete lateral line—or nearly so—and well-developed palatine teeth. Red marginal and black basal bands in the spinous dorsal fin are found on males. Pigmentation is highly variable, with body background color ranging from coppery brown to slate gray, approaching black in nuptial males, with dark brown to black mottling on sides and back (Robins 1961; Page and Burr 1991; Jenkins and Burkhead 1994).

Status

Warren et al. (2000) listed the global status of the Mottled Sculpin as currently stable within its range, and it is considered secure (G5) by NatureServe (2024). The Mottled Sculpin is Considered imperiled to vulnerable (S2S3) in South Carolina (NatureServe 2024). In Georgia

this species is considered apparently secure (S4), while in North Carolina they are considered secure (S5). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The South Carolina form of the Mottled Sculpin is endemic to the southern portion of the Blue Ridge physiographic region (Warren et al. 2000). In South Carolina, it is found in the high elevations of the upper Savannah River drainage, primarily in the Blue Ridge ecoregion and in scattered locations of the Inner Piedmont (to as low as about 700 feet). The Savannah populations are thought to have colonized the basin due to stream capture of Tennessee drainages, similar to other taxa in this volume with predominantly Mississippi drainage distributions (Jenkins et al. 1971, Ramsey 1965; Ross 1970; Rohde et al. 2009); this may also explain its absence from the sufficiently high elevations of the upper Saluda River basin. Outside of South Carolina, the species occurs in the Blue Ridge portions of north Georgia and western North Carolina (Jenkins and Burkhead 1994).

This species can be abundant in high-elevation, high-gradient streams and rivers draining well-forested watersheds. It is extremely abundant in the upper Chattooga River, where its population appears stable based on annual fish population sampling (SCDNR unpublished data). Future population viability is likely in the high-elevation rivers draining protected lands of the Blue Ridge, particularly in light of the protected status afforded the Chattooga as a Wild and Scenic River. This species was observed in 1.0% of over 900 standardized statewide stream and river assessment samples across the state between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Mottled Sculpin inhabits clear, cold to cool headwaters, creeks, springs and small montane rivers of high to moderate gradient. Substrates are rubble and gravel, which are important to its benthic feeding habits and crevice spawning behavior. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (12.1%) and average relative abundance (1.1%) in upland small streams (watershed area 0-15 km^2) of the Savannah River basin.

CHALLENGES

The Mottled Sculpin is currently stable throughout its range. However, the limited distribution of this species within South Carolina makes it vulnerable to impacts from land development, deforestation, loss of riparian cover, siltation (McGinley et al. 2013), and hydrologic alterations (channelization and impoundment construction). Populations outside of the protected lands of the Blue Ridge escarpment, and especially those in relatively low elevations of the Inner Piedmont, are particularly susceptible to anthropogenic habitat alteration. Habitat alteration in the lower elevations of its range, where it is already closer to its thermal limits, is particularly detrimental. In addition, this species is among those in South Carolina most likely to be impacted by longer-term decline in habitat suitability associated with climate change.

CONSERVATION ACCOMPLISHMENTS

The core area of “Smoky” Sculpin abundance is protected by the Wild and Scenic Chattooga River.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements for the "Smoky" Sculpin.
- Conduct genetic studies of the "Smoky" Sculpin to resolve taxonomic questions regarding differentiation of Savannah populations.
- Identify and protect areas with healthy populations and intact critical habitat for the "Smoky" Sculpin.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Consider this species' needs when participating in the environmental permit review process.
- Encourage responsible land use planning.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. Genetic resolution of the status of the species will allow for more specific management protocols. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of

natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Piedmont Darter is a member of the family Percidae (perches and darters) and one of two species of *Percina* found in South Carolina, along with *P. westfalli* (Sooty-banded Darter) (Page et al. 2023). Percids represent the second-most diverse family of freshwater fishes in North America (behind Leuciscidae, minnows) with 224 currently recognized species and many forms awaiting full description (Page et al. 2023). The darters, predominantly small, bottom-dwelling fishes, comprise the vast majority of species in this family.

This is a moderate-sized darter ranging in adult length from 68 to 90 mm (2.7 to 3.5 in.) (Rohde et al. 1994, 2009). It is generally brown in color with 7 to 9 vertically elongated oval blotches joined by a mid-lateral band. A caudal spot is usually diffuse and vertically elongated (Kuehne and Barbour 1983). The Piedmont Darter has a black chin bar, black breast spot, and a large black teardrop below the eye. The first dorsal fin has a black edge, a tan band below, a yellow interior, and vertical black markings below the lower portion of each spine (Rohde et al. 1994). Chin, throat, and breast are lightly stippled in females and more heavily so in males.

Status

Globally, the Piedmont Darter is considered apparently secure (G4) (NatureServe 2024). Warren et al. (2000) classified the Piedmont Darter as currently stable. The Piedmont Darter is considered vulnerable (S3) in South Carolina (NatureServe 2024). In North Carolina it is considered apparently secure (S4) but is critically imperiled (S1) in Virginia (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Piedmont Darter occurs in the Santee, Pee Dee (a small portion of Virginia, through North Carolina and into South Carolina) and Cape Fear River basins of the Carolinas. In South

Carolina, it is most common and abundant in the Piedmont and foothills of the mountains, with additional populations occurring at generally lower densities on the inner coastal plain where topography supports flowing streams. This species was observed in 8.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Piedmont Darter is found in clean, moderate to large streams with a sand to cobble substrate. Though a riffle dweller, this darter does not seem to favor extremely strong currents (Kuehne and Barbour 1983; Rohde et al. 1994) and is often observed in moderately deeper and slower habitats adjacent to the main flow with woody debris. Where it occurs (in lower abundance) in the inner coastal plain, the streams are characterized by steady flow over sand and fine gravel, and wood plays an important role as cover and in creating habitat heterogeneity (SCDNR data). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (94.4%) and highest average relative abundance (1.4%) in upland small rivers (watershed area 300-2000 km^2) of the Santee River basin.

CHALLENGES

Although the Piedmont Darter is currently considered stable, conservation efforts within South Carolina are critical to its global conservation. Approximately one third of the global range of the Piedmont Darters occurs in South Carolina. Within the state, destruction of stream riffle habitat caused by land development, deforestation, loss of riparian cover, siltation, and hydrologic alterations like channelization and impoundments could jeopardize this species. Mature forest and riparian vegetation are important sources of large woody debris in coastal plain streams, which provides critical habitat for many endemic Southern Atlantic Coastal Plain species including the Piedmont Darter (Marion et al. 2015). Deforestation and clearing of riparian cover may be particularly detrimental to this species in the coastal plain portion of its range, where it is already near the limits of its thermal tolerance and in which wood may play a larger role as habitat in the absence of rock.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and

developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity. Describe life history and habitat requirements of Piedmont Darters.
- Identify streams with healthy Piedmont Darter populations and intact critical habitat in the upper Santee and Pee Dee drainages. Protect these areas, once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Pinewoods Darter

Etheostoma mariae

Photo: NCFishes.com

Contributor (2005): Scott Lamprecht and Jason Bettinger [SCDNR]
Reviewed and Edited (2013): Kevin Kubach, Mark Scott, Andrew R. Gelder, and M. Troy Cribb [SCDNR]
Contributors (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Pinewoods Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023).

The Pinewoods Darter is a member of the subgenus *Belophlox*, which can be separated from most other darters by the presence of a broad dark stripe on its side and a contrasting light lateral line (Rohde et al. 1994). The Pinewoods Darter has roughly 10 elongate dark blotches on its side and a red marginal or submarginal band in its first dorsal fin. Pinewoods Darters reach a maximum length of about 74 mm (2.9 in.) (Page and Burr 1991).

Status

The Pinewoods Darter has received recognition as State Endangered in South Carolina and of Special Concern in North Carolina, the only other state in which it occurs. It is considered imperiled (S2) in North Carolina and possibly extirpated (SH) in South Carolina while globally vulnerable (G3) (NatureServe 2024). The Pinewoods Darter was considered vulnerable in a recent assessment of North American freshwater fishes (Jelks et al. 2008) and was listed as a regional species of greatest conservation need (Rice et al. 2019), receiving a designation of high concern.

Although the Pinewoods Darter has not been confirmed in South Carolina since 1949 (Rohde et al. 2009), the isolated and complex habitats in which the species occurs coupled with comparatively few dedicated searches suggest it may still be extant in the state's waters. The discovery or rediscovery of several elusive fish species in North Carolina and Georgia in recent decades (Darden et al. 2019; Tracy et al. 2020; Tracy et al. 2024) illustrates the potential for this species to persist in South Carolina.

POPULATION SIZE AND DISTRIBUTION

The Pinewoods Darter is extremely restricted, occurring only in the Sand Hills ecoregion of the Lumber/Little Pee Dee River system in North and South Carolina. Although it is not extremely uncommon in appropriate habitat in its limited range within North Carolina, the species has not been documented in South Carolina since 1949 and is therefore considered possibly extirpated from the state (Rohde et al. 2009). The only records from South Carolina are from Panther and Beaverdam Creeks near the town of McColl, SC (Rohde et al. 2009).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Pinewoods Darter inhabits small, cool, flowing headwater streams with sand to gravel substrate and abundant aquatic vegetation (Rohde and Arndt 1991). Where their ranges overlap, the Pinewoods Darter shares a strong similarity in habitat requirements with the regionally endemic Sandhills Chub (*Semotilus lumbee*) (Rohde and Arndt 1991). Rooted aquatic vegetation is particularly important; Rohde and Arndt (1991) noted the highest abundances of this species in aquatic vegetation and rarely observed the species in streams lacking this habitat type. Young inhabit pools with vegetation and sand or silt substrates with little flow (NatureServe 2004).

CHALLENGES

Highly restricted in both range and habitat requirements, the Pinewoods Darter is extremely vulnerable to habitat alteration. Anthropogenic alterations within its range include agriculture and suburban development (primarily in North Carolina). Clearing of forest and riparian cover, channelization of streams for agricultural drainage, and improper or unregulated use of pesticides and fertilizers all disrupt the natural hydrology, water chemistry and habitat heterogeneity to which this species is adapted (Marion 2008). Further, both dam construction on streams to create ponds for golf courses and golf course irrigation has led to a direct loss of habitat and favor competitive and often highly predacious species like the Redbreast Sunfish, Bluegill, and Largemouth Bass (NatureServe 2004).

The elusiveness of the Pinewoods Darter in South Carolina and resulting data deficiency represent a fundamental challenge in its conservation. In South Carolina, the physicochemical template that supports this species may represent a moving target in a complex and dynamic landscape. Coastal plain streams are highly variable in space and time, often changing dramatically in physical characteristics on the scale of just kilometers due to both natural hydrologic variability as well as biotic factors such as beaver activity. The perceived absence or possible extirpation of this species are difficult to interpret due to the uncertainty in the amount and type of sampling effort required to yield a reasonable probability of detection. A specialized and standardized sampling approach will be necessary to quantify the probability of its persistence in the state and enable informed conservation efforts such as the strategies employed in the rediscovery of other elusive fishes including the Bridle Shiner (Jensen and Vokoun 2013; Pregler et al. 2015; Pregler et al. 2019; Katz 2023), Blackbanded Sunfish (Darden et al. 2019) and other darters (Bajo-Walker et al. 2024).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Determine the statewide distribution, population status, life history and habitat requirements for the Pinewoods Darter with statewide stream surveys.
- Survey streams in the Sandhills Ecoregion of the Little Pee Dee River system to determine the existence or extirpation of Pinewoods Darter. Previous positive locations in Panther Creek and Beaver Dam Creek should be re-surveyed. Protect any identified areas.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Educate aquarists as to the adverse impacts of removing fish from the wild.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of

greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The “Carolina” Quillback (*Carpiodes* sp. cf. *cyprinus*) is a member of the sucker family (Catostomidae), which is represented by at least 78 described species in North America (Page et al. 2023). Suckers comprise about 8% of the continent’s freshwater ichthyofauna, behind only minnows (Leuciscidae) and perches and darters (Percidae) in number of species (Warren and Burr 2014). There are currently three described species of *Carpiodes* suckers (Page et al. 2023), which are primitive, deep bodied, silver-colored fishes with a long dorsal fin (Jenkins and Burkhead 1994). Variation across the range of this species has long been recognized with multiple subspecies (Rohde et al. 2009); the form of the Quillback on the southern Atlantic slope is distinct from those to the north and west (Tracy et al. 2024) but awaits full species description.

This family is characterized by soft-rayed fins, a mouth located on the underside of the head, thick, fleshy, distensible lips, and paired fins attached low on the body (Rohde et al. 1994). Quillback are high bodied, laterally compressed fish that range in length up to 66 cm (26.0 in.) (Rohde et al. 2009). In South Carolina, the “Carolina” Quillback most closely resembles the “Atlantic” Highfin Carpsucker (*Carpiodes* sp. cf. *velifer)*, but the former has a shallower forehead and longer snout, lacks a nipplelike projection on the lower lip, and usually has more lateral scales and dorsal fin rays. Furthermore, the Quillback’s first long dorsal ray does not usually reach the full length of the dorsal fin base, while the first dorsal ray of the Highfin Carpsucker typically is as long as the fin (Rohde et al. 1994; Jenkins and Burkhead 1994).

Status

Quillback populations are considered to be stable by Warren et al. (2000) and common, widespread, and abundant by NatureServe (2024). It is currently considered secure globally (G5) and vulnerable to imperiled (S2S3) in South Carolina (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The “Carolina” Quillback occurs on the southern Atlantic Slope from the Pee Dee River basin in North Carolina to the Altamaha River basin in Georgia (Tracy et al. 2024). In South Carolina, it is found in the Savannah, Santee and Pee Dee River basins (Rohde et al. 2009). This species was not observed in any of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

The Quillback is commonly encountered during non-directed sampling efforts. Populations with abundant numbers are observed in the upper Santee and Savannah River drainages while Quillback are rare in the Pee Dee (SCDNR unpublished data). Population declines in the Pee Dee River may be related to introduced, non-native species like Buffalo.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Quillback is found in warm, low- to moderate-gradient reaches of most major rivers, including upper portions of associated reservoirs (Rohde et al. 1994; Jenkins and Burkhead 1994). It occurs over varied substrates in rivers, but seldom over mud. They tend to occupy calm water; however, Quillback may shift to swifter and deeper depths during times of low water. Quillback reportedly spawn in spring in riffles, calm stream reaches, and in floodplain bayous, laying eggs on gravel, sand, mud, and organic matter (Scott and Crossman 1973; Jenkins and Burkhead 1994). Quillback feed on insect larvae and other benthic organisms. Studies of Quillback (from outside the “Carolina” form range) have reported estimated ages of sexual maturity ranging from about 4 to 9 years (Parker 1987; Lackmann et al. 2022), with males generally maturing earlier than females, and maximum ages as high as 30 in Florida (Grabowski et al. 2012) to 44 years in Minnesota (Lackmann et al. 2022).

CHALLENGES

Quillback populations are likely stable throughout their range. However, habitat degradation from deforestation and urbanization remains as much a challenge to this native species as it does to most other riverine animal species. This species is susceptible to the same pervasive types of anthropogenic habitat alteration and fragmentation affecting other large riverine catostomids (Cooke et al. 2005), including the construction and operation of dams and impoundments, sedimentation of important foraging and spawning habitats, alteration of hydrologic regimes, and introduction of non-native species.

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Identify the distribution of Quillback throughout South Carolina.
- Resolve taxonomic relationships of Atlantic Slope, Interior Basin and Gulf Slope Quillback populations.
- Identify and protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Redlip Shiner is a member of the minnow family (Leuciscidae) and the genus *Hydrophlox*, which was recently elevated from within *Notropis* (Stout et al. 2022 and sources therein; Page et al. 2023). It is currently one of three described species of *Hydrophlox* in South Carolina along with the Yellowfin Shiner (*H. lutipinnis*) and Greenhead Shiner (*H. chlorocephalus*) (Page et al. 2023), but variation and intergradation in this group has long been recognized (Rohde et al. 2009 and sources therein) and additional forms have been treated as distinct in taxonomic keys (Tracy et al. 2024). Minnows represent the most speciose family of freshwater fishes in North America, with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including five currently recognized species of *Hydrophlox* (Warren and Burr 2014; Page et al. 2023).

This species is characterized by bright red lips with red coloration in the dorsal, anal, and caudal fins and black blotches on the sides (Rohde et al. 1994). The lateral line is complete (Jenkins and Burkhead 1994). Members of this genus are known to exhibit strong sexual dimorphism, in particular with breeding males developing bright red coloration over most of the body. Male Redlip Shiners attain a scarlet-red body and eye coloration with yellow fins (Rohde et al. 1994). Adults range in length from 38 to 72 mm (1.5 to 2.8 in.) (Rohde et al. 2009).

Status

The Redlip Shiner is considered apparently secure (G4) globally (NatureServe 2024). It is considered imperiled to vulnerable (S2S3) in South Carolina (NatureServe 2024). In North Carolina this species is considered apparently secure (S4), while it is considered vulnerable (S3) in Virginia (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Redlip Shiner is native to the Pee Dee River basin and the Dan River system of the Roanoke River basin in North Carolina and Virginia (Tracy et al. 2024). In South Carolina, the southern edge of its range, the Redlip Shiner is restricted to a small portion of the Pee Dee River drainage in the Carolina Slate Belt and Sand Hills ecoregions, with a population in the Thompson Creek

system and a couple collection localities in the Great Pee Dee River. This species was observed in 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Redlip Shiner occupies flowing pools of clear headwaters, creeks, and small rivers of the Piedmont and (outside of South Carolina) mountains; it prefers areas with sand-gravel to rubble substrate. Spawning takes place in May-June on gravel nests constructed by the Bluehead Chub (*Nocomis leptocephalus*), as is the case with other *Hydrophlox* minnows (Johnson 1991; Jenkins and Burkhead 1994; Rohde et al. 2009; NatureServe 2024). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (2.9%) and highest average relative abundance (0.4%) in upland large streams (watershed area 300-2000 km^2) of the Pee Dee River basin.

CHALLENGES

The occurrence of the Redlip Shiner in only one stream system in South Carolina, and on the southern fringe of its global range, makes it vulnerable to decline in the state. Cumulative or acute disturbances to Thompson Creek could cause extirpation of this species from South Carolina. Challenges to this species are similar to those of other aquatic fauna and include point and non-point source pollution, deforestation and loss of riparian corridors, impoundment development, channelization and siltation from poor land use practices, and unplanned or poorly planned urban and suburban development. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Because of its limited distribution, it is also vulnerable to habitat losses due to anthropogenic influences such as water withdrawals or environmental disturbances such as drought. Introduction of non-native species is also a conservation concern; for example, Lemly (1985) only observed Redlip Shiners in small first-order streams in which non-native Green Sunfish (*Lepomis cyanellus*) were absent.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a

rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Redlip Shiner.
- Survey Thompson Creek and surrounding areas in Chesterfield County to determine the status of the Redlip Shiner as this stream likely houses the strongest populations of this species and may have been severely impacted by the drought of 2002. Protect these areas, once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Robust Redhorse is a large, heavy-bodied sucker that can reach lengths greater than 70 cm (28 in.) and weights up to 8 kg (17.6 lbs.). The Robust Redhorse has large, molar-like pharyngeal teeth specialized for crushing hard-bodied prey like native mussels. It resembles the River Redhorse, *M. carinatum,* but has 10 pelvic rays instead of 9 (Rohde et al. 1994). The fish is bronze on the back and sides, and adults are faintly striped on the lower sides. Juveniles have intense red in the caudal fin, which becomes less obvious in adults. Breeding males develop prominent tubercles on the snout, head, and anal and caudal fins (GADNR 1999).

After specimens of a large redhorse collected in Georgia and North Carolina in the 1980s and early 1990s were determined to be the fish described by Cope (1870) as *M. robustum*, major revisions of sucker taxonomy were initiated. Jenkins and Burkhead (1994, in a footnote) applied the name *M. robustum* to the large, rediscovered redhorse and called it Robust Redhorse. Smallfin Redhorse was moved to the newly elevated genus *Scartomyzon* and proposed the common name “Brassy” Jumprock. Its taxonomic status has still not been completely resolved (NatureServe 2024).

With 78 described species in North America (Page et al. 2023), suckers comprise about 8% of the continent’s freshwater ichthyofauna, behind only minnows (Leuciscidae) and perches and darters (Percidae) in number of species (Warren and Burr 2014). The genus *Moxostoma* includes 23 described species (Page et al. 2023), about one third of which are considered imperiled at some level (Jelks et al. 2008; Warren and Burr 2014).

Status

The Robust Redhorse is listed as Endangered in Georgia and North Carolina, the only other states in which it occurs (NatureServe 2024). It is critically imperiled (G1) globally and in all three states (S1) (NatureServe 2024). In July 2024, a law went into effect in South Carolina prohibiting the taking, harming or killing of Robust Redhorse (scstatehouse.gov; accessed 3 August 2024). In the 2000 assessment of southeastern fishes, the Robust Redhorse was considered in danger of extinction throughout all or part of its range (Warren et al. 2000). Over

the past decade, much has been learned about existing populations, and four experimental populations have been stocked. While this progress has reduced the danger of extinction, regional drought and habitat limitations continue to be impediments to reaching the goals of population stability in all parts of its range (S. Lamprecht, pers. obs.). The Robust Redhorse was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of very high concern.

POPULATION SIZE AND DISTRIBUTION

Wild populations of Robust Redhorse are now known to exist in the Ocmulgee and Oconee rivers (Georgia), the Savannah River (Georgia/South Carolina), and the Pee Dee River (North Carolina/South Carolina). In addition, small *stocked populations* have been established in Georgia by introducing Oconee River progeny in the Ocmulgee, Ogeechee, and Broad Rivers; and in South Carolina by introducing Savannah River progeny in the Broad and Wateree Rivers. Mature individuals have been collected and spawning behavior observed in all systems at some point, but detection of natural recruitment into these populations has been limited (SCDNR). Spawning runs of Robust Redhorse remain regularly detectable in the Georgia Broad and South Carolina Broad and Wateree rivers. Field surveys have not observed Robust Redhorse in the Ogeechee River since 2011; however, a recent eDNA survey confirmed their continued presence in that system (Farrae and Darden 2023).

Robust Redhorse population size in the Oconee River was originally estimated as approximately 1,000 to 3,000 adults in an 80 km (50 mi.) section of river. Annual sampling currently suggests that the Oconee population may not be reproducing at levels sufficient to sustain the population. Further, this population is vulnerable to catastrophic events (NatureServe 2024). The latest population estimate for the Oconee River could not be made because the population has decreased to the point where the available detection effort was unable to observe any fish in the spring of 2011 (RRCC 2011).

The Savannah River appears to be supporting a substantial population of Robust Redhorse (RRCC 2004). However, no estimates of the size of the Savannah population have been made to date. Repeated spawning efforts have recaptured adults at an average of about 30%. New individuals continue to be encountered, indicating relatively steady recruitment into the Savannah River population. While the Savannah population has not been studied as extensively as the Oconee and Pee Dee, a decade broodstock collection indicates that it is likely the most stable of the known wild populations (S. Lamprecht, pers. obs.).

In the Yadkin-Pee Dee drainage, Robust Redhorse are only found downstream of Blewett Falls Dam, the most downstream dam on the system. Initial collections were scant, but with the use of telemetry, two spawning shoals were identified, and collection numbers increased to the point where over 20 individuals were actively tracked in 2010 (RRCC 2010). Beginning in 2014 a stocking program was initiated and to date (2023) 67,343 individuals among eight year classes have been stocked across SC and NC portions of the Pee Dee River. In early 2024, SCDNR staff collected seven unmarked (possibly wild) individuals ranging from 285 mm to 540 mm total length from the lower Pee Dee River basin near the confluence of the Great Pee Dee and

Waccamaw Rivers (J. Marsik, SCDNR, pers. comm.). These collections represent the lowermost records of this species in the Pee Dee River basin and may suggest possible downstream dispersal of juveniles as part of the life history of this species. Researchers are currently studying the possible reintroduction of Robust Redhorse in the Tillery reach of the system by looking for eDNA in water samples.

Wirgin et al. (2001) examined mitochondrial DNA (mtDNA) variation in *M. robustum* and concluded that the Oconee/Ocmulgee River and Savannah River populations should be treated as evolutionarily significant units (ESU). These results were confirmed in 2011 by Tanya Darden (RRCC 2011), who also examined a larger Pee Dee population data set and confirmed the preliminary assessment that it too should be considered a distinct ESU (Darden and Tarpey 2014). Both the Pee Dee and Savannah populations show high within-population diversity as well as low levels of inbreeding as compared to the average genetic diversity measured for freshwater fishes, despite relatively low effective population size estimates (RRCC 2011; Darden and Tarpey 2014).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

Robust Redhorse is known only from habitats in mainstream rivers where it has been collected in riffles, runs, and pools. Adults are usually found in association with tree snags, often in deep water near shore. Spawning occurs in course gravel habitats (GADNR 1999). Stocked juvenile Robust Redhorse have been collected in Thurmond Reservoir and in slower Coastal Plain river runs; however, young wild juveniles have remained largely elusive, and little is known about their habitat use. Despite hundreds of full fish assemblage samples conducted by SCDNR on direct tributaries of South Carolina rivers with known Robust Redhorse populations since the early 2000s, this species has never been detected in these tributary habitats. One wild spawn juvenile was collected in Savannah River tidal freshwater. Adults in Georgia's Broad River utilize the downstream reservoir outside of spawning season. These reservoir collections tend to indicate a tolerance of, or a preference for, lentic habitat during a portion of the life cycle (RRCC 2000). Recent telemetry observations in both the Santee River drainage and Georgia's Broad River support the hypothesis that adults select cooler water temperatures during the summer.

CHALLENGES

The Robust Redhorse is susceptible to the same pervasive types of anthropogenic habitat alteration and fragmentation affecting other large riverine catostomids (Cooke et al. 2005), including the construction and operation of dams and impoundments, sedimentation of important foraging and spawning habitats, alteration of hydrologic regimes, and introduction of non-native species. Habitat loss and disruption of spawning migrations resulting from dams and impoundments; predation and competition by introduced non-native species like buffalos, Flathead Catfish and Blue Catfish; and significant deterioration of water quality due to sedimentation and pollution are believed to have contributed to the decline of the Robust Redhorse. Additionally, the limited range of known populations and low rates of recruitment to the adult population represent challenges to the species' future (RRCC 2004).

CONSERVATION ACCOMPLISHMENTS

The Robust Redhorse Conservation Committee (RRCC) was established in 1995 under a Memorandum of Understanding (MOU) between state and federal resource agencies, private industry, and the conservation community to work proactively to recover the population across its historic range. The RRCC was formed in lieu of listing the species under the Endangered Species Act. Partners include 13 signatory members to the MOU, two cooperating members under the MOU, and a variety of university research and resource management facilities as affiliate members.

A plan entitled *Conservation Strategy for the Robust Redhorse*, which provides overall conservation guidance to assure the continued survival of the species, was adopted by the RRCC in 1998 and updated in 2003. It establishes short- and long-term conservation goals, describes the status and distribution of the species, discusses problems facing the species, and presents conservation actions that should be implemented to accomplish short- and long-term goals (RRCC 2004). The recovery goal established by the RRCC is six self-sustaining populations of Robust Redhorse across its former range (Nichols 2003).

Efforts to restore Robust Redhorse to the Santee River drainage began in 2004 with Phase I fingerling stockings in the Broad River above and Below Parr Reservoir. Entering 2011 a total of 50,500 Phase I fingerlings were released in the 2 Broad River restoration sites. The Wateree River site has received 12,601 Phase I fingerlings, 2,400 Phase II juveniles (age 1+), and 400 Phase III juveniles (age 2+). Stocking efforts in these sites are to continue until progeny from 100 parental crossings are produced. To date, mature males and females have been collected and spawning behavior has been observed. Fish of all sizes have been collected, but no wild spawn recruitment has been detected. Telemetry study has shown long distance movement between spawning shoals in the spring and summer residence areas. Telemetry studies on the Pee Dee River have shown that some Robust Redhorse use the South Carolina portion of the river during the summer, fall, and winter, while critical spawning shoals occur in North Carolina.

See the SWAP chapter on SWG grants, particularly those pertaining to the Robust Redhorse.

The Robust Redhorse received legal protection in South Carolina in July 2024, when a law went into effect prohibiting the taking, harming or killing of this species (scstatehouse.gov; accessed 3 August 2024).

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Continue work on habitat preference and utilization for various life stages for the Robust Redhorse.

- Continue refining our understanding of the life history of the Robust Redhorse.
- Maintain the MOU that formed the RRCC and continue working with partners to achieve the goals set forth in the conservation strategy developed by the RRCC.
- Complete the reintroduction of the Robust Redhorse to the Santee River Drainage and confirm natural recruitment.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.

MEASURES OF SUCCESS

Since 2005, work on all of the initial recommendations have been initiated or are nearly completed for Robust Redhorse (RRH). Present occurrence of adult RRH is well defined, as well as habitat preferences of adults, but collection of juveniles continues to be problematic across its range. The genetic work done on RRH has lent insight into existing population health and what to consider as we move forward in efforts to enhance existing populations. The RRCC MOU has been renewed and partners continue to meet and cooperatively address current issues and questions. The importance of RRH has been elevated so that it has been considered in recent FERC relicensing and water flow recommendations that affect critical spawning habitat. South Carolina's Santee drainage reintroduction program is also nearing completion; the ultimate measure of success, natural recruitment, has yet to be observed. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Rosyface Chub is a member of the minnow family (Leuciscidae) and is one of two species of *Hybopsis* in South Carolina, along with Highback Chub (*H. hypsinotus*). Minnows represent the most speciose family of freshwater fishes in North America, with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including six described species of *Hybopsis* (Warren and Burr 2014; Page et al. 2023).

The Rosyface Chub has the typical chub body, somewhat elongate with a long snout, upward-looking eyes, and a small barbel in the corner of its inferior mouth. It resembles a more elongate version of its congener, the Highback Chub. Breeding males can be distinguished from other members of *Hybopsis* by the strong rosy-red coloration that develops on the anterior third of the body. Rosyface Chubs can attain a length of 90 mm (3.50 in.) (Rohde et al. 1994, 2009).

Status

The Rosyface Chub is considered apparently secure globally (G4) (NatureServe 2024); however, there is some concern for their long-term status based on their limited distributions. The Rosyface Chub is considered critically imperiled (S1) in North Carolina largely due to its limited distribution within the State; Georgia has listed the Rosyface Chub as vulnerable to apparently secure (S3S4) while it is ranked vulnerable (S3) in South Carolina (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Rosyface Chub is found in the Altamaha, Savannah, Saluda and extreme upper Edisto drainages of Georgia, North Carolina and South Carolina, predominantly above the fall line. Although it can be locally abundant in appropriate habitat, its distribution is somewhat patchy. In South Carolina, the Rosyface Chub is most common and abundant in the upper Savannah River

basin. This species was observed in 13.7% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Rosyface Chub inhabits runs and pools of small to large streams and small rivers, generally over sand and gravel (Rohde et al. 2009). It spawns in moderately fast riffles and has also been observed aggregating over *Nocomis* nests (Maurakis and Loos 1986; Rohde et al. 2009). The Rosyface Chub primarily consumes aquatic invertebrates but will also feed on terrestrial and aquatic plant matter to a lesser degree (Rybczynski et al. 2008; Rohde et al. 2009). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (100%) in upland small rivers (watershed area 300-2000 km²) of the Savannah River basin and highest average relative abundance (7.6%) in upland large streams (watershed area 100-300 km²) of the same basin.

CHALLENGES

The relatively narrow range of the Rosyface Chub (much of which has been fragmented by large reservoirs) along with its habitat requirements place it at risk of decline from anthropogenic habitat alteration. Challenges to this species are similar to those faced by other aquatic fauna and include point and non-point source pollution, deforestation and loss of riparian corridors, impoundment development, siltation from poor land use practices, and unplanned or poorly planned urban and suburban development. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Rosyface Chub habitat. Approximately 50% of the global range of the Rosyface Chub occurs in South Carolina. Conservation efforts within South Carolina are critical to the global preservation of this species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and

developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Rosyface Chub.
- Identify critical habitats and areas with healthy populations of the Rosyface Chub.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Rosyside Dace
Clinostomus funduloides

Photo: NCFishes.com

Contributors (2013): Kevin Kubach and Mark Scott [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Rosyside Dace belongs to the minnow family (Leuciscidae) and is the only member of the genus *Clinostomus* in South Carolina. Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). Although there are currently only two described species in this genus (Page et al. 2023), variation across the wide range of *C. funduloides* has long been recognized (Deubler 1955; Warren et al. 2000; Tracy et al. 2024). Recently, Weyand and Piller (2019) found *C. funduloides* to be paraphyletic and noted evidence of multiple distinctive lineages likely representing additional unique forms.

Adult Rosyside Dace reach a total length of 56 to 109 mm (2.2 to 4.3 in.) (Rohde et al. 1994, 2009). Overall coloration is olive with a diffuse, dark lateral stripe and usually a red bar or slash behind the opercle. The lower sides of breeding males are bright red. The body is laterally compressed and covered with small scales. The snout is pointed and features a large, oblique mouth (Rohde et al. 2009).

Status

The Rosyside Dace is considered secure (G5) on a global scale and is currently ranked apparently secure (S4) in South Carolina (NatureServe 2024). It is currently stable according to Warren et al. (2000). In Georgia this species is considered apparently secure (S4), while in North Carolina this species is considered secure (S5).

POPULATION SIZE AND DISTRIBUTION

The Rosyside Dace occurs on the Atlantic Slope from the Delaware River drainage, Pennsylvania to the Savannah River drainage, South Carolina and in portions of the upper Tennessee River drainage as well as the upper Ohio River drainage (Rohde et al. 2009). Further resolution of genetically distinctive forms (Weyand and Piller 2019) will probably lead to geographic range revisions involving the species found in South Carolina. In South Carolina, the Rosyside Dace is found in all river basins, primarily in the Piedmont and Blue Ridge, with some records from the inner Coastal Plain. This species was observed in 6.8% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Rosyside Dace is most abundant in flowing pools of clear headwater streams and occasionally larger streams (Rohde et al. 2009). This species is specialized for the cooler, clearer headwater drainages of stream systems and has relatively narrow thermal tolerances (Nelson et al. 2021). Being sight-based drift feeders, the Rosyside Dace requires clear water to feed effectively. Increased turbidity has been shown to be detrimental to the foraging behavior of this species and can negatively affect feeding success even at low levels (Zamor and Grossman 2007). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (28.2%) and average relative abundance (2.2%) in upland small streams (watershed area <15 km^2) of the Santee River basin; it is particularly abundant in higher elevations of the Saluda River basin.

CHALLENGES

Primary threats to the Rosyside Dace include loss of forested land and especially the removal of riparian cover along Piedmont and Blue Ridge streams. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Rosyside Dace habitat. The specialization of this species for higher, cooler headwater drainages places it at heightened risk of local extirpation from anthropogenic habitat alteration (Zamor and Grossman 2007; Nelson et al. 2021) as well as longer-term effects of climatic change on flow and thermal regimes (Grossman et al. 2016; Nelson et al. 2021).

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Sandhills Chub is a member of the minnow family (Leuciscidae) and the most recently described (Snelson and Suttkus 1978) of four species of the genus *Semotilus*, two of which occur in South Carolina (*S. lumbee* and *S. atromaculatus* Creek Chub) (Page et al. 2023). Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and fusiform fishes (Warren and Burr 2014; Page et al. 2023).

Fish in the genus *Semotilus* are large minnows characterized by a robust body and large head. The Sandhills Chub typically ranges from 45−140 mm total length (Phelps 2025; Ramsey 2025) with a maximum reported total length of 240 mm (Rohde et al. 1994). The species appears to be reproductively mature by age-1, and males tend to be larger than mature females (Phelps 2025; Ramsey 2025), which may be a function of the need for males to have a large enough mouth gape to pick up gravel for building pit-ridge nests. There is a very small barbel in a groove above the upper lip near the corner of the mouth. The Sandhills Chub has relatively fine scales, a diffuse black lateral stripe, and a pinkish wash to the body in breeding season. This species can be distinguished from the similar Creek Chub (*S. atromaculatus*) by the absence of a dark spot in the dorsal fin near the anterior base in *S. lumbee* (present in *S. atromaculatus*) and a typical dorsal fin ray count of 9 (8 in *S. atromaculatus*).

Status

Globally, the Sandhills Chub is ranked as vulnerable to apparently secure (G3G4) (NatureServe 2024). It is considered imperiled (S2) in North Carolina and South Carolina, the only two states in which it occurs (NatureServe 2024). The Sandhills Chub was listed as vulnerable in fauna-wide assessments of the southeastern (Warren et al. 2000) and North American (Jelks et al. 2008) freshwater fishes and was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Sandhills Chub occupies a narrow strip of the Sand Hills ecoregion (Griffith et al. 2002) of the inner coastal plain in south-central North Carolina and eastern South Carolina, from the Wateree (Santee) River basin eastward to the Cape Fear River basin (Snelson and Suttkus 1978; Rohde and Arndt 1991; Rohde et al. 2009; Tracy et al. 2020; Tracy et al. 2024). At the time of its description in 1978, the Sandhills Chub was only known from the Pee Dee (including Lynches) and Cape Fear River basins, and its presence in tributaries of the Wateree River (Santee basin) to the west was documented later (Rohde and Arndt 1991). In South Carolina, it is almost wholly restricted to the Sand Hills portions of the Wateree, Lynches, and Pee Dee River drainages. This species was observed in 1.4% of over 900 standardized statewide stream and river assessment samples across South Carolina between 2006 and 2023, but it can be relatively abundant in appropriate habitat within its narrow range (Rohde and Arndt 1991). Populations in the Lynches and Lumber (North Carolina) drainages are strongholds and exhibit higher genetic diversity than those in other drainages (Phelps 2025; Ramsey 2025). Abundance estimates in two representative populations were 218 per km in Aberdeen Creek (Pee Dee basin) and 137 per km in Gum Branch Creek (Cape Fear basin) (Ramsey 2025). Conversely, populations in the Wateree basin in the western portion of its range occur in comparatively low densities (SCDNR data; Rohde and Arndt 1991; Phelps 2025; Ramsey 2025).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Sandhills Chub is almost exclusively associated with small, flowing, often tannin-stained and acidic streams of the Sand Hills ecoregion (Snelson and Suttkus 1978; Rohde and Arndt 1991). Accordingly, in standardized sampling covering streams to small rivers of South Carolina, the Sandhills Chub exhibited its highest frequency of occurrence (14.3%) and average relative abundance (2.9%) in small streams (watershed area 0-15 km^2) of the Sand Hills. It is usually found in streams dominated by sand substrates with some gravel (Rohde and Arndt 1991; Rohde et al. 1994). This species is dependent on relatively cool, flowing, well-oxygenated headwaters with sufficient structure (i.e., wood); higher dissolved oxygen concentrations and greater amounts of cover in the stream section were both positively related to Sandhills Chub presence (Herigan et al. 2023). The Sandhills Chub shares its narrow Sand Hills-specific distribution with the Pinewoods Darter (*Etheostoma mariae*) and, in North Carolina where the latter is still known to occur, these species are often found in the same stream systems (Rohde and Arndt 1991).

Spawning primarily occurs in April and May, with the former month yielding the largest proportion of ripe individuals (Phelps 2025; Ramsey 2025). Males construct a pit-ridge nest characteristic of the genus (Woolcott and Maurakis 1988) using gravel in the 6 mm to 11 mm diameter range (Maurakis et al. 1990). Substrate composition is therefore important, and the amount of gravel in the 6-11 mm size range at the scale of the stream reach was a strong predictor of Sandhills Chub presence (Herigan et al. 2023).

Home range size in the Sandhills Chub is extremely small, with movement generally limited to relatively short stream reaches. In two North Carolina streams, 82% of almost 900 tagged individuals moved less than 200 m from their initial capture section, and only four individuals (<1%) moved distances greater than 1 km (Phelps 2025; Ramsey 2025). This limited movement

has probably contributed to the high degree of genetic structuring observed across populations (Phelps 2025; Ramsey 2025).

CHALLENGES

A narrow range coupled with low mobility and specific habitat and life history requirements in headwater streams render the Sandhills Chub vulnerable to many anthropogenic threats. Its nearly exclusive association with small drainages places it at greater risk of extirpation from a given system due to acute or cumulative disturbances. The small headwater streams occupied by Sandhills Chub can be easily altered or fragmented, and this is compounded by the fact that headwater streams are afforded less regulatory protection than larger streams and rivers. Populations in small stream drainages flowing directly into considerably larger streams or rivers may be at heightened risk of extirpation (Sheldon 1987), since the larger downstream waterbodies could represent a physicochemical or behavioral barrier to emigration and subsequent recolonization, particularly given the low rates of movement exhibited by this species. The few known populations in tributaries of the Wateree (Santee) basin are inherently at higher risk of extirpation from this river basin due to their lower abundance and close proximity to areas of rapid human population growth such as the Columbia-Camden corridor.

Stable hydrology and associated physicochemical regimes are a defining feature of the Sand Hills ecoregion and serve as the template for the life history strategies of many regionally endemic species such as the Sandhills Chub. Even minor alterations to the natural hydrologic, thermal and sediment regimes, such as those typically associated with anthropogenic conversion of natural forested land cover to developed or impervious surfaces, have the potential to disrupt critical life history and ecological processes. Poor agricultural, silvicultural, and road construction practices often lead to stream siltation and non-point source water pollution (Waters 1995). For example, the reduction of natural forest and riparian cover in the watershed would be expected to increase water temperature (decrease dissolved oxygen), reduce wood loading for in-stream habitat and bank cover, and increase fine sediment inputs, all of which would decrease the probability of supporting Sandhills Chub (Marion 2008; Herigan et al. 2023). Unregulated use of motor vehicles in the stream bottoms also results in stream siltation and destruction of fish habitat.

Human-constructed impoundments cause additional impairment of Sandhills Chub habitat. Damming headwater streams to create ponds for golf courses eliminates important lotic habitats; the new lentic environments favor competing and often predatory species such as Largemouth Bass in unnaturally high densities. Impoundments also fragment habitat and can affect dispersal, prevent recolonization of streams after drought or other disturbances, and alter hydrology and sediment transport. Although impoundments are the most visible form of habitat fragmentation, culverts can also function as barriers if they are perched or if water velocity in a culvert prevents movement. The small streams occupied by Sandhills Chub are inherently more likely to be passed under roads by culvert rather than bridge, making full or partial barriers due to culverts a widespread factor affecting dispersal of this species.

CONSERVATION ACCOMPLISHMENTS

The Sandhills Chub has been the focus of two recent State Wildlife Grant investigations by Dr. Derek Crane and his graduate students at Coastal Carolina University since 2019 (Herigan et al. 2023; Phelps 2025; Ramsey 2025):

- 2019-2020: Identification of environmental and biological factors limiting occurrence of the Sandhills Chub (*Semotilus lumbee*) in South Carolina.

- 2022-2025: Conservation planning for a geographically restricted headwater species, the Sandhills Chub.

These investigations have produced important information on Sandhills Chub ecology and habitat requirements, allowing the development and refinement of conservation strategies for this species. Furthermore, this work yielded estimates of abundance, density and survival from two high-integrity populations that can serve as references for the evaluation of other populations.

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the

Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.

- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe additional life history and habitat requirements for the Sandhills Chub.
- Resample known locations to determine the population status of the Sandhills Chub and expand monitoring efforts within the Carolina Sandhills National Wildlife Refuge (NWR) in order to quantify the population within the refuge.
- Protect critical habitats for the Sandhills Chub from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Sandhills Chub.
- Encourage responsible land use planning.

- Consider species needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Santee Chub belongs to the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). It is sister to the Siouan Thinlip Chub (*C. leptocheilus*) of the Pee Dee and Cape Fear River basins (Tracy et al. 2024). Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). The Santee Chub is one of eight species of *Cyprinella* in South Carolina.

Along with the Siouan Thinlip Chub (*C. leptocheilus*) and Thicklip Chub (*C. labrosa*), this species is unique among *Cyprinella* in possessing barbels in the corner of its mouth. These three species furthermore have a different shape than other members of the genus, with a slender, ventrally flattened profile, relatively long snout and inferior mouth. In the Santee and Siouan Thinlip Chubs, the dorsal fin origin is positioned posteriorly to that of the pelvic fin origin, whereas in the Thicklip Chub the dorsal fin origin sits directly over the origin of the pelvic fin (Rohde et al. 2009). The Santee Chub is distinguished from the Siouan Thinlip Chub by the position of the dorsal fin origin modally 2.5 scales posterior to the pelvic fin origin versus modally 1.5 scales posterior to the pelvic fin origin, respectively; mean upper lip width at midpoint modally 3.5% of head length versus modally 2.1% of head length; mean upper lip width at midline modally 4.1% of head length versus modally 2.9% of head length; and mean maxillary barbel length modally 8.0% of head length versus modally 3.5% of head length (Tracy et al. 2024). The Santee Chub can reach a length of 75 mm (3 in.) (Page and Burr 1991). This species exhibits dark cross-hatching on the back and sides; breeding males are silvery with yellow fins and black streaks on the dorsal and caudal fins (Rohde et al. 1994).

Status

The Santee Chub is currently stable (Warren et al. 2000) and apparently secure (G4) throughout its range, though it is ranked vulnerable (S3) in South Carolina and North Carolina (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the

Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Santee Chub is endemic to the Santee River basin of North and South Carolina, primarily in the Piedmont and Blue Ridge foothills (Rohde et al. 1994). It can be locally abundant in appropriate habitat but is typically among the least abundant members of its genus in streams and rivers in which it occurs. This species was observed in 5.3% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Santee Chub inhabits streams to rivers with sand and rocky runs or current-swept pools (Rohde et al. 1994). It is usually more abundant on finer substrate (e.g., sand and fine gravel) than the sympatric Thicklip Chub (*C. labrosa*) (SCDNR unpublished data; Rohde et al. 2009), resulting in some degree of habitat segregation with *C. zanema* in more uniformly sandy runs and *C. labrosa* in rockier areas. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (55.6%) in upland small rivers (watershed area 300-2000 km²) of the Santee River basin and highest average relative abundance (2.4%) in upland large streams (watershed area 100-300 km²) of the Santee River basin.

CHALLENGES

Although the Santee Chub can be locally abundant in appropriate habitat of Piedmont streams, its limited distribution is cause for concern. The Santee Chub, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Santee Chub habitat. One of the fastest-growing areas of human population pressure and land development in the United States, the Interstate 85 corridor between Greenville, South Carolina and Charlotte, North Carolina, runs directly through the range of this species. The vast majority of its populations occur on private (unprotected) lands. Approximately 75% of the global range of the Santee Chub occurs in South Carolina; conservation efforts within the state are critical to the preservation of this species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including

statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
  We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the

critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Satinfin Shiner belongs to the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America (about 27% of the continental fauna) with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). The Satinfin Shiner is one of eight described plus one undescribed (as of 2024) species of *Cyprinella* in South Carolina.

Fishes of the genus *Cyprinella* are characterized by large, vertical, diamond shaped scales and a dark blotch on the dorsal fin. The Satinfin Shiner is extremely similar to the Greenfin Shiner (*C. chloristia*), which was once considered its subspecies (Rohde et al. 2009), but the former usually has 9 anal fin rays whereas the latter typically has 8. The dorsal fin of the Satinfin Shiner exhibits black speckles on all membranes with a distinct black blotch on its rear half (Rohde et al. 1994). Breeding males appear gray-blue with yellow fins (Rohde et al. 1994). Adults range in size from 47 to 110 mm (1.9 to 4.3 in.) (Rohde et al. 1994).

Status

Globally, the Satinfin Shiner is considered secure (G5) (NatureServe 2024). The Satinfin Shiner is currently considered vulnerable (S3) in South Carolina (NatureServe 2024). In North Carolina this species is considered to be secure (S5). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Satinfin Shiner is found on the Atlantic slope from the Hudson River and southern Lake Ontario drainages in New York south to the Pee Dee River drainage in North and South Carolina (Page and Burr 1991). In South Carolina, the southern fringe of its global range, the Satinfin Shiner is restricted to tributary streams of the upper Pee Dee River drainage in the Slate Belt and Sandhills Ecoregions (SCDNR, unpublished data), with a notable population in Thompson

Creek. This species was observed in 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Satinfin Shiner occupies pools and runs of creeks and small to medium rivers with substrate ranging from sand to gravel and rubble. Occasionally, this species is found in headwaters and tidal portions of some large rivers elsewhere in its range. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (2.9%) and average relative abundance (0.05%) in upland large streams (watershed area 100-300 km²) of the Santee River basin.

As with other non-barbeled *Cyprinella* species, the Satinfin Shiner is a crevice spawner, depositing eggs in crevices of logs and rocks in a territory defended by the male over an extended spring-summer breeding period (Gale and Buynak 1978; Rohde et al 1994; Rohde et al. 2009). Eggs are attached to branches, stumps and logs and may be deposited in cracks in rocks, in crevices under loose submerged bark, between exposed tree roots, and/or under flat rocks (NatureServe 2024). Due to the limited habitat available for this species in South Carolina if it is to be maintained as part of South Carolina's fauna, then it is essential that the habitat requirements for these fishes be better understood, and actions taken to protect and preserve appropriate sites for the survival of this species.

CHALLENGES

This species is vulnerable in South Carolina due to its very limited distribution but is currently stable throughout much of its range. The Satinfin Shiner, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. The breeding behavior of the non-barbeled *Cyprinella* makes this group particularly vulnerable to impacts from both suspended and deposited sediment. Because the breeding process is dependent on visual cues (extended display and territorial defense period) as well as clean crevices for egg deposition and larval development, suspended sediment (increased turbidity) and deposited sediment has been shown to delay or inhibit spawning success in fishes of this genus (Hubbs and Echelle 1972; Burkhead and Jelks 2001; Warren and Burr 2014). Furthermore, the introduction and establishment of the highly invasive Red Shiner (*Cyprinella lutrensis*) in the North Carolina portion of the Pee Dee River basin (Poulos et al. 2012; Glotzbecker et al. 2016; Tracy et al. 2020; Tracy et al. 2024) represents a potential threat to native *Cyprinella*, including the Satinfin Shiner. *C. lutrensis* has been shown to impact native *Cyprinella* through competition and hybridization (Walters et al. 2008; Ward et al. 2012), both of which can be exacerbated with additional stressors such as elevated turbidity resulting from alteration of natural land cover (Glotzbecker et al. 2015) and broader influences of climate change (Poulos and Chernoff 2014). The limited distribution of the Satinfin Shiner in South Carolina—the southern fringe of its global range—makes it particularly susceptible to

extirpation from the state should the Red Shiner expand downstream into the South Carolina waters of the Pee Dee basin.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Satinfin Shiner.
- Survey Thompson Creek and surrounding areas in Chesterfield County to determine the status of the Satinfin Shiner as this stream likely houses the strongest populations of this species and may have been severely impacted by the drought of 2002. Protect these areas, once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Savannah Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). The Savannah Darter is sister to the Christmas Darter (*E. hopkinsi*) and closely related to the form of the Christmas Darter occurring in the Savannah River basin, the "Hanukkah" Darter (*E. binotatum*) (Near et al. 2011).

The Savannah Darter is characterized by a broad dark stripe on its side and a red marginal or submarginal band on its first dorsal fin. The dorsum is pale. This colorful darter also displays alternating green and orange bars on its lower side as well as orange on its belly. Savannah Darters reach a length of 74 mm (2.9 in.) (Rohde et al. 1994).

Status

Globally, the Savannah Darter is considered apparently secure (G4), but it is considered vulnerable in South Carolina (S3) and imperiled (S2) in Georgia (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Savannah Darter is only found in the mid to lower Savannah River basin of Georgia and South Carolina and the mid to upper Edisto and Combahee River drainages in South Carolina. It is restricted to the mid to upper elevations of the coastal plain, predominantly occurring in the Southeastern Plains ecoregion where topography supports flowing streams and rivers. In appropriate habitat of the Sand Hills and Atlantic Southern Loam Plains, it occurs regularly and

can be somewhat abundant. This species was observed in 4.5% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Savannah Darter inhabits clear or tannin-stained creeks and small rivers with steady current and sand or gravel substrates (Rohde et al. 2009). It is generally found in or near aquatic vegetation or woody debris (Layman 1993; Rohde et al. 1994). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (34.5%) and average relative abundance (1.7%) in large streams (watershed area 100-300 km^2) of the Sand Hills.

CHALLENGES

Although the Savannah Darter is currently considered stable (Warren et al. 2000), its limited distribution is cause for concern. Of the Savannah Darter's global range, 75% occurs in South Carolina. Loss of habitat in South Carolina from development, point and non-point source pollution, and poor land management practices would threaten its global existence. This species is dependent on the habitat heterogeneity supported by intact watershed forest cover and riparian floodplains and wetlands, which supply woody material and maintain channel morphology and substrate composition encouraging the growth of aquatic vegetation (Layman 1993; Marion 2008). Destruction of forest cover and especially the alteration or draining of forested riparian wetlands and floodplains represents a principal threat to the Savannah Darter. Channelization of streams for agricultural drainage further alters flow regimes and reduces the habitat complexity required by this species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage

SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

    - Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements for the Savannah Darter.
- Conduct genetic assessments to determine appropriate taxonomy for the Savannah Darter.
- Protect critical habitats for the Savannah Darter from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Savannah Darter.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Sawcheek Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). This species is a member of the subgenus *Hololepis*, which is also represented in South Carolina by the Swamp Darter (*E. fusiforme*) and Carolina Darter (*E. collis*) (Rohde et al. 2009).

Adult Sawcheek Darters range in size from 40 to 68 mm total length (1.6 to 2.7 in.) (Rohde et al. 2009). Overall coloration is tan with dark mottling on the side and a greenish venter. It has a highly arched and incomplete lateral line and a serrated edge on its preopercle. Two vertically aligned dark spots, usually outlined in orange or red, are present at the base of the caudal fin. The cheek, opercle, breast, and belly are fully scaled (Rohde et al. 1994, 2009).

Status

The Sawcheek Darter is considered secure (G5) on a global scale (NatureServe 2024) and currently stable according to Warren et al. (2000). It has received varying degrees of state status including imperiled (S2) in Georgia, vulnerable (S3) in Virginia, secure (S5) in North Carolina, and apparently secure (S4) in South Carolina (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The Sawcheek Darter is distributed primarily on the Atlantic coastal plain from the Chowan River basin of southeastern Virginia to the Altamaha River basin, Georgia (Rohde et al. 2009). In South Carolina, it is found across all river basins, primarily in the coastal plain and occasionally in the outer Piedmont. This species was observed in 5.7% of over 900 standardized statewide stream and river assessment samples across South Carolina between 2006 and 2023. It is typically not abundant; where collected, the mean sample catch was 3.1 individuals, and the highest two sample catches were 21 and 11 (SCDNR data).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Sawcheek Darter typically occur in small to moderate Coastal Plain streams with mud, sand, and organic substrates, often in association with flow and aquatic vegetation (Hoover and Killgore 1999; Rohde et al. 2009). In South Carolina, this species is predominantly found in streams of the inner coastal plain characterized by stable baseflow; in standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (19.1%) and average relative abundance (0.2%) in medium streams (watershed area 15-100 km^2) of the Sand Hills ecoregion. Spawning occurs in March and April (Kuehne and Barbour 1983; Rohde et al. 2009).

CHALLENGES

Although it has a relatively wide range across South Carolina, the Sawcheek Darter generally occurs in low abundance where it is found. Primary threats to the Sawcheek Darter include loss of forested land and especially the removal of riparian cover along coastal plain streams. Mature forest and riparian vegetation are important sources of large woody debris in coastal plain streams which provides critical habitat for many endemic southern Atlantic coastal plain species including the Sawcheek Darter (Marion 2008). In addition to providing direct habitat, wood is important in creating and maintaining overall habitat heterogeneity and stability of stream channels. Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use

and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.

- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.

- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species and others. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Seagreen Darter

Etheostoma thalassinum

Photo: NCFishes.com

Contributor (2005): Gene Hayes and Jason Bettinger [SCDNR]
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Seagreen Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). It is sister to the Turquoise Darter (*E. inscriptum*) of the Altamaha, Savannah and Edisto River basins (Richards 1966; Near et al. 2011).

The Seagreen Darter is a moderate-sized darter ranging in adult length from 66 to 78 mm (2.6 to 3.1 in.) (Rohde et al. 1994). This species has seven to eight dark brown saddles and a similar number of small dark brown blotches on the sides, the posterior three or four of which usually form vertical bars (Tracy et al. 2024). The first dorsal fin has a red edge with a dusky black base and the second dorsal fin is reddish-orange. Pelvic and anal fins are blue (Rohde et al. 1994). Breeding males are brilliantly colored and develop tubercles on the mid-ventral scales just anterior to the anus and also on the caudal peduncle (Kuehne and Barbour 1983).

Status

The Seagreen Darter is listed as stable throughout its range (Warren et al. 2000) and apparently secure (G4) globally but considered vulnerable (S3) in South Carolina and North Carolina, the only two states in which it occurs (NatureServe 2024). North Carolina also designates the Seagreen Darter as State Significantly Rare (Tracy et al. 2020). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Seagreen Darter is restricted to the Santee River drainage of the Carolinas. In South Carolina, it is predominantly an upland fish and sees its highest abundance in swift-flowing streams and rivers, but it also occurs in lower numbers in scattered localities on the inner coastal

plain of the Congaree and Wateree drainages where topography supports steady flow. In high-gradient streams and rivers with continuous suitable habitat it can be moderately abundant, but due to the siltation of many Piedmont streams and the localized nature of appropriate coarse riffles in lower-gradient Piedmont streams, it is often limited in abundance. This species was observed in 10.9% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

In the Piedmont and Blue Ridge portions of its range, the Seagreen Darter occurs in streams to large rivers in higher-velocity areas with coarse substrates ranging from gravel to cobble and bedrock (Page 1983; Kuehne and Barbour 1983; Rohde et al. 2009). Where it occurs (in lower abundance) in the inner coastal plain, the streams are characterized by steady flow over sand and fine gravel (SCDNR data, unpublished). Life history characteristics are not well known but are presumably similar to those of the sister Turquoise Darter (*E. inscriptum*). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (44.4%) and average relative abundance (1.8%) in upland small rivers (watershed area 300-2000 km²) of the Santee River basin.

CHALLENGES

Although the Seagreen Darter is currently considered stable, conservation efforts within South Carolina are critical to their global conservation. More than half the global range of the Seagreen Darter occurs in South Carolina. Within the State, destruction of stream riffle habitat caused by land development, deforestation, loss of riparian cover, siltation, and hydrologic alterations like channelization and impoundments could jeopardize these species. The distribution of this species overlaps with three of the most populated and rapidly growing metropolitan areas of South Carolina—Greenville-Spartanburg, Rock Hill-Charlotte, and Columbia—placing it in the path of unprecedented anthropogenic habitat alteration. Inner coastal plain populations of Seagreen Darters in particular, with lower abundance, may be especially vulnerable to extirpation due to their proximity to Columbia. Further, in extreme headwaters of their range, Seagreen Darters may be adversely affected by Brown and Rainbow Trout introductions.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning

the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of Seagreen Darters.
- Study the potential predator/prey relationship between darters (Turquoise and Seagreen Darters) and introduced trout (Brown and Rainbow Trout) and the impact of this relationship on the native darters.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Siouan Thinlip Chub
Cyprinella leptocheilus

Photo: NCFishes.com

Contributor (2005): Jason Bettinger (SCDNR)
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Siouan Thinlip Chub is a recently described (Tracy et al. 2024) member of the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). The earliest recognized specimens date from the early 1960s in North Carolina, and this species is sister to the Santee Chub (*C. zanema*) of the Santee River basin (Tracy et al. 2020; Tracy et al. 2024). Tracy et al. (2024) detected genetic distinctiveness between *C. leptocheilus* in the Pee Dee and Cape Fear basins and recommended recognition of these clades as evolutionarily significant units. Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). There are eight additional species of *Cyprinella* in South Carolina.

Along with the Santee Chub (*C. zanema*) and Thicklip Chub (*C. labrosa*), this species is unique among *Cyprinella* in possessing barbels in the corner of its mouth (Tracy et al. 2024). These three species furthermore have a different shape than other members of the genus, with a slender, ventrally flattened profile, relatively long snout and inferior mouth. In the Siouan Thinlip Chub and Santee Chubs, the dorsal fin origin is positioned posteriorly to that of the pelvic fin origin, whereas in the Thicklip Chub the dorsal fin origin sits directly over the origin of the pelvic fin (Rohde et al. 2009; Tracy et al. 2024). The Siouan Thinlip Chub is distinguished from the Santee Chub by the position of the dorsal fin origin modally 1.5 scales posterior to the pelvic fin origin versus modally 2.5 scales posterior to the pelvic fin origin, respectively; mean upper lip width at midpoint modally 2.1% of head length versus modally 3.5% of head length; mean upper lip width at midline modally 2.9% of head length versus modally 4.1% of head length; and mean maxillary barbel length modally 3.5% of head length versus modally 8.0% of head length (Tracy et al. 2024). A light yellow-green stripe is present above the dark lateral stripe. Siouan Thinlip Chubs attain sizes similar to Santee Chubs, about 75 mm (3 in.).

Status

The Siouan Thinlip Chub is listed as imperiled (G2Q) globally and imperiled to critically imperiled (S1S2) in South Carolina (NatureServe 2024). It is also considered a species of Special Concern in North Carolina and is considered imperiled (S2) there (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of high concern.

POPULATION SIZE AND DISTRIBUTION

The Siouan Thinlip Chub is endemic to the Carolinas, occurring primarily on the inner coastal plain of the Cape Fear River and Pee Dee River basins. In South Carolina, it is known from scattered localities in the Lumber, Little Pee Dee, Great Pee Dee, and Lynches drainages (Rohde et al. 2009; Tracy et al. 2024).

Due to its small range and infrequent occurrence, Siouan Thinlip Chub population size and trends are not well known. It is not commonly encountered within its known range (F. Rohde, pers. comm.) and, when detected, is generally among the least abundant species in the fish community. This species was observed in 0.4% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Siouan Thinlip Chub inhabits small to large rivers of the inner coastal plain over sand and gravel substrate (Rohde et al. 2009). It occurs in some typical flowing blackwater rivers as well as rivers exhibiting transitional characteristics between those of the Piedmont and Coastal Plain. Although its occurrence in deeper river sections is difficult to infer due to challenges of effectively sampling these habitats, the Siouan Thinlip Chub has been observed in association with schools of mixed leuciscids on inside river bends over sand and gravel in shallow to intermediate depths (SCDNR unpublished data). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (15.4%) and average relative abundance (0.8%) in small rivers (watershed area 300-2000 km^2) of the Sand Hills in the Lynches and Pee Dee basins. The Siouan Thinlip Chub probably spawns in mid to late summer (Rohde et al. 2009).

CHALLENGES

The Siouan Thinlip Chub is threatened by the same anthropogenic disturbances that challenge all aquatic fauna. However, due to its limited distribution, it is especially vulnerable to development as the Sandhills ecoregion of South Carolina is under constant development pressure. Habitat modifications in this region that impact the Siouan Thinlip Chub include agriculture, residential development, and tourism. Damming headwater streams to create ponds for golf courses eliminates important lotic habitats; the new lentic environments favor competing—and often predatory—species such as Bluegill and Largemouth Bass. Poor agricultural, silvicultural, and road construction practices often lead to stream siltation and non-point source water pollution (Waters 1995). Unregulated use of motor vehicles in stream bottoms also results in stream siltation and destruction of fish habitat. The elusiveness of this species also represents a

fundamental challenge in its conservation, confounding efforts to monitor its status and habitat requirements.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT’s second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting’s pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.

- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

    - Marion, C.A., M.C. Scott, and K.M. Kubach. 2015. Multiscale environmental influences on fish assemblage structure of South Atlantic coastal plain streams. Transactions of the American Fisheries Society. 144(5):1040-1057.

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements for Siouan Thinlip Chub.
- Protect critical habitats for Siouan Thinlip Chub from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat for Siouan Thinlip Chub.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame fish species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are

implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Snail Bullhead is a member of the family Ictaluridae. The ictalurids, with approximately 51 species, represent the largest family of fishes indigenous to only North America (Warren et al. 2020; Page et al. 2023). The genus *Ameiurus* contains the moderately-sized (reaching only a few pounds) catfish collectively known as the "bullheads." Snail Bullheads have a large, flat head, a decurved snout profile, uniformly colored maxillary barbel, short rounded anal fin, emarginate tail and a large dusky blotch at the base of the dorsal fin. Snail Bullheads vary greatly in color and pattern, but in general they have a brown or yellow-green back, mottled sides of the same colors, and a white belly. In their natural habitats (rivers and streams), Snail Bullheads typically reach maximum adult sizes of 294 mm (11.4 in.) (Rohde et al. 1994); however, in impounded river reaches and reservoirs, they reach substantially greater sizes (443 mm or 17.6 in.) (SCDNR unpublished data).

Status

The Snail Bullhead is apparently secure (G4) over its range; however, in a recent assessment of southeastern fishes, this species was considered vulnerable to imperilment (V) (Warren et al. 2000; Jelks et al. 2008). It is considered vulnerable to apparently secure (S3S4) in South Carolina (NatureServe 2024). The Snail Bullhead is considered at least vulnerable to imperilment in 3 of the 6 states where it occurs. It is considered imperiled (S2) in Virginia, vulnerable (S3) to imperilment in Alabama, and apparently secure (S4) in Florida, Georgia and North Carolina (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Snail Bullheads occur along the Atlantic Slope from the Dan River system in Virginia and North Carolina south to the Altamaha River system in Georgia and the Saint Johns River drainage in Florida (NatureServe 2024). They also occur in Gulf Slope drainages of the Apalachicola River system in Georgia, Alabama, and Florida and in the upper Coosa River system in northern Georgia (Page and Burr 1991).

The Snail Bullhead is found in all of South Carolina's river basins and ecoregions, although it is most widespread and abundant in the uplands. Snail Bullheads appear to be relatively stable in South Carolina streams; however, their fate in the larger rivers is uncertain due to the presence of the non-native Flathead Catfish and Blue Catfish. They are common to abundant in the upper Santee basin but decreasing trends have been noted in many coastal rivers like the Edisto River and lower Savannah River following the introduction of Flathead Catfish (C. Thomason, SCDNR, pers. comm.). The largest populations of Snail Bullhead are probably located in the Broad River system; however, both the Flathead Catfish and Blue Catfish have been documented in the system in recent decades, and their impact has yet to be determined. This species was observed in 11.7% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Snail Bullhead is found in rocky riffles, shoals, runs, and pools in streams and rivers. (Jenkins and Burkhead 1994; Rohde et al. 1994; NatureServe 2024). It has also been found in small streams and rivers in the Blue Ridge (Rohde et al. 2009). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (83.3%) in small upland rivers (watershed area 300-2000 km²) of the Savannah River basin and highest average relative abundance (3.0%) in upland small rivers (watershed area 300-2000 km²) of the Santee River basin.

CHALLENGES

The Snail Bullhead is adversely affected by the same myriad of challenges plaguing all aquatic species such as sedimentation, hydrologic modification, impoundments, non-point source pollution, and development. Other threats to the Snail Bullhead include loss of forested land and especially the removal of riparian cover along upland streams. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Additionally, this species is threatened by the introduction of non-native ictalurids like the Flathead Catfish and Blue Catfish; both non-native species displace and prey on the smaller bullheads (Guire et al. 1984; Ashley and Buff 1986; Quinn 1988; Bart et al. 1994).

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment (2006-2011) data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. DESCRIPTION

Taxonomy and Basic Description

The Striped Bass is a member of the family Moronidae, which contains four North American species that are known as the temperate basses (Jenkins and Burkhead 1994; Page et al. 2023). The Striped Bass, commonly called "rockfish" or "lineside," has a compressed, moderately deep body covered with ctenoid scales. Striped Bass have an olive-green back, a silvery flank with several thin, dark lines and silvery-white belly. Striped Bass are large, robust fish that attain adult sizes of up to 198 cm (78 in.), but most individuals in freshwater systems are much smaller, measuring less than 99 cm (39 in.).

Status

Although the Striped Bass is currently considered stable (Warren et al. 2000) and secure (G5) overall across its native range, it is considered critically imperiled (S1) in South Carolina (NatureServe 2024). Although the species currently appears stable, there are populations of concern in South Carolina. South Carolina is home to small reproductively isolated populations of Striped Bass that exhibit minimal anadromy and are generally restricted to their natal coastal rivers (Bulak et al. 2004). It is those small, unique populations that warrant conservation concern in South Carolina.

POPULATION SIZE AND DISTRIBUTION

The Striped Bass's native range includes coastal rivers on the Atlantic Slope from the St. Lawrence River, Canada, to the St. Johns River, Florida, and in Gulf Slope drainages from western Florida to Lake Pontchartrain, Louisiana (NatureServe 2024). The Striped Bass has been introduced into rivers and reservoirs throughout the United States as it provides a valuable recreational fishery. The populations of conservation concern within South Carolina inhabit coastal rivers in the Lower Coastal Plain including the Savannah River, New River, Combahee River, Ashepoo River, Edisto River, Santee-Cooper Rivers, Black River, Lynches River, Great Pee Dee River, Little Pee Dee River and Waccamaw River.

Striped Bass population trends within the coastal rivers are not well known. However, based on anecdotal evidence it appears that the coastal Striped Bass populations have declined. Coastal Striped Bass populations appear to be relatively small. A recent study of the Combahee River estimated the population of Striped Bass greater than 30 cm (12 in.) to be only 406 individuals (Bulak et al. 2004). This species was observed in only 0.6% of over 900 standardized statewide stream and small river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

Striped Bass inhabit medium to large rivers; they are also found in impoundments where they have been introduced but are often unable to complete their life cycle. They prefer to occupy areas with clean, sandy bottoms with fine gravel and rock (NatureServe 2004). Adult Striped Bass have a thermal tolerance of 6 to 27°C (43-81°F) (Merriman 1941) but seek temperatures between 18 to 25°C (64-77°F) when available (Coutant and Carroll 1980; Crance 1984). During spawning, Striped Bass occupy shallow rocky and gravely areas with strong, turbulent water flow. Striped Bass eggs are semi-buoyant; they drift and sink slowly requiring moderate current to keep the eggs from settling to the bottom and dying before they are hatched in 1 to 3 days (Scruggs 1955, Etnier and Starnes 1993). Hassler et al. (1981) observed that optimum water temperatures for successful Striped Bass egg hatching and survival in North Carolina was 17 to 18°C (63-64°F).

CHALLENGES

The major challenges to South Carolina's coastal Striped Bass populations include siltation, increased river water temperatures, oxygen depletion associated with nutrient enrichment, hydrologic modification, and over-exploitation. Clearing forests and riparian areas along coastal rivers and their tributaries has led to increased siltation and potentially warmer water temperatures. Increased water withdrawals for agricultural and municipal purposes may also pose a threat to habitat quality and quantity by reducing river flows and potentially increasing water temperatures. Warmer water temperatures may decrease the amount of summertime refuge habitat for Striped Bass and negatively impact reproduction. In the Combahee and Edisto rivers, Striped Bass used upstream areas with greater riparian overstory and associated cooler water temperatures as summertime thermal refuges (Bjorgo et al. 2000). Dams negatively impact Striped Bass populations by disrupting migrations and altering thermal and hydrologic regimes. The presence of impoundments along the Savannah and Pee Dee Rivers may partially account for limited reproduction in those systems. Additionally, stocking non-endemic Striped Bass into coastal rivers may compromise the genetic integrity of these small, isolated populations (Bulak et al. 2004). Escapement of hybrid Striped Bass into coastal systems containing reproducing populations of Striped Bass may also pose a threat to the genetic integrity of those populations.

CONSERVATION ACCOMPLISHMENTS

Striped Bass fishing regulations on coastal river systems were implemented in 2012 to reduced harvest and summer mortality of Striped Bass due to angling. The 2012 regulations made it unlawful to take, attempt to take, or to possess Striped Bass from the State's coastal river

systems from June 1st to September 30th, decreasing the potential for angling-related summer mortality. In 2018, those regulations were amended and made it unlawful to take, attempt to take, or to possess Striped Bass from June 16th to September 30th. During the remainder of the year, Striped Bass must be at least 66 cm (26 in.) in length, protecting female Striped Bass from harvest prior to spawning. Hybrid Striped Bass are not stocked in the Santee-Cooper, Pee Dee, Ashepoo, Combahee or Edisto drainages in order to protect those spawning stocks. The genetic integrity of small isolated Striped Bass populations is protected thanks to the current South Carolina Department of Natural Resources (SCDNR) stocking policy which allows only endemic stocks to be used to augment small coastal river Striped Bass populations. Spawning flows for Striped Bass have been identified for several hydroelectric facilities in South Carolina that are currently in the relicensing process.

The genetic structure of Striped Bass populations within South Carolina's major coastal rivers has been evaluated to determine genetic diversity within and among populations to guide future efforts to restore and/or enhance coastal Striped Bass populations (Anderson et al. 2014). Restoration stocking of Striped Bass was conducted for eight years (2006 – 2014) in the Ashley River (SCSWG 2014). While the effort did not successfully restore Striped Bass to the Ashley River, methods were developed for stocking Striped Bass into coastal systems and stocked fish survived to adulthood, demonstrating that stocking may be a viable tool to maintain coastal river populations.

Two efforts were conducted to determine if habitat (i.e., temperature and dissolved oxygen) were causal factors for limiting or extirpating the Striped Bass population from the Ashely River. Johnson (2015) validated the existing Striped Bass bioenergetics model (Hartman and Brandt 1995) for use in a southeastern river and used it to evaluate Striped Bass Habitat quality in the Ashley River. The study emphasized the importance of summer-time thermal refuges in upstream portions of the river and demonstrated the potential for the Ashely River to support a self-sustaining Striped Bass population; however, additional perturbances (e.g., increased water temperatures or decreased dissolved oxygen) to the system could have serious consequences to available suitable habitat and the sustainability of the population. The effects of temperature and hypoxia on the metabolic performance of a southern stock of juvenile Striped Bass were also evaluated (Anweiler et al. 2019). The two studies demonstrated how bioenergetic approaches could be used to assess habitat suitability in coastal rivers and used as a tool to select and prioritize appropriate restoration habitats.

The Pee Dee River population has undergone a population assessment in recent years including genetic genotyping, adult telemetry tracking, juvenile telemetry tracking, and stocking augmentation. Through genetic assessment, the population was determined to include wild spawned fish, SCDNR stocked fish and NCWRC stocked fish from upriver reservoirs. A telemetry study of adult Striped Bass determined spawning areas, summer refugia, and resting areas (Doll and Marsik 2023). A juvenile telemetry study of stocked Phase II fish was conducted to determine movement patterns and identify the best stocking locations. Since 2019, nearly 150,000 Phase II Striped Bass have been stocked over four year classes, using Santee-Cooper Striped Bass progeny, into the Great Pee Dee River. A standardized electrofishing study design has been implemented to determine hatchery contribution as well as population trends.

In 2019, a study was initiated to document the seasonal movements of adult Striped Bass in the Edisto River, assess the genetic structure of the Striped Bass population, and identify summer-time thermal refuges. Between 2019 and 2023, 28 adult Striped Bass were implanted with acoustic transmitters and fin clips for genetic analysis were collected from 161 individuals. Annually adult Striped Bass follow similar seasonal patterns occupying the downstream tidally influenced portion of the river during cool weather months (October to March) and the upper reaches of the mainstem and the forks of the river during warm weather months (April to September). The vast majority (98%) of the population is comprised of naturally spawned Edisto "strain" Striped Bass.

In 2023, a study (SWG F22AF03676) was initiated to quantify the effect of mean daily flow on summertime water temperatures in the Edisto River, model summertime water temperature under current and future climate and water withdrawal scenarios and determine if thermal tolerances of SWAP fishes (e.g., Striped Bass) are exceeded.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.

- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Describe life history and habitat requirements of the Striped Bass.
- Identify critical habitats and areas with healthy populations of the Striped Bass. Protect these areas, once identified.
- Identify and monitor key Striped Bass habitats like thermal refuges and spawning sites.
- Assess Striped Bass reproductive potential in the coastal rivers.
- Continue to monitor genetic stock structure of Striped Bass in coastal rivers.
- Determine reasons for lack of Striped Bass recruitment in coastal populations.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices (BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider species needs when participating in the environmental permit review process.
- Augment coastal Striped Bass populations with endemic strains, as needed.
- Use hatchery practices that will either maintain or enhance effective population size in a particular drainage.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for these species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of these fish could assist in determining the effectiveness of those measures. An increase in coastal Striped Bass populations within the State would also indicate that restoration and habitat protections were successful. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Swallowtail Shiner belongs to the minnow family (Leuciscidae) and was recently moved to the genus *Miniellus* from the polyphyletic *Notropis* (Stout et al. 2022 and sources therein; Page et al. 2023), joining the reclassified Whitemouth Shiner (*M. alborus*) as the only *Miniellus* in South Carolina. Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including 21 recognized species of *Miniellus* (Warren and Burr 2014; Page et al. 2023).

Adult Swallowtail Shiners range from 46 to 78 mm in total length (1.8 to 3.1 in.) (Rohde et al. 2009). The overall coloration is a somewhat translucent straw-yellow with a dark lateral stripe extending onto but not encircling the snout. It has a predorsal stripe, a dash of black pigment at the base of the dorsal fin and two light dashes along the back, just anterior and posterior to the dorsal fin. The breast is usually unscaled (Rohde et al. 2009). This species can be distinguished from the Whitemouth Shiner by the presence in Swallowtail of a predorsal stripe, a black stripe not completely encircling the snout, and moderate pigmentation on the upper lip (absent in Whitemouth).

Status

The Swallowtail Shiner is considered secure (G5) on a global scale (NatureServe 2024) and is currently stable according to Warren et al. (2000). It is listed as vulnerable (S3) in South Carolina, imperiled (S2) in New York, and critically imperiled (S1) in West Virginia. Other states within its range list it as secure (S5), including North Carolina and Virginia, or apparently secure (S4) as in Delaware, Maryland, New Jersey, and Pennsylvania (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Swallowtail Shiner is distributed along the Atlantic Slope from the Delaware and Susquehanna River basins in New York to the Santee River basin in South Carolina (Rohde et al. 2009). In South Carolina, it is found in the Pee Dee and Santee River basins primarily in the Piedmont, with fewer records from the inner coastal plain. Although it can be locally abundant in certain areas such as the upper Catawba and Lynches River drainages, it is patchy across much of its range in South Carolina. This species was observed in 6.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Swallowtail Shiner occurs in sandy pools of streams and small rivers (Jenkins and Burkhead 1994; Rohde et al. 2009). In standardized sampling covering streams to small rivers of South Carolina, this species exhibited its highest frequency of occurrence (34.3%) in upland large streams (watershed area 100-300 km^2) of the Santee River basin and average relative abundance (6.8%) in upland small rivers (watershed area 300-2000 km^2) of the Santee River basin. It spawns from May to July in moderate current over sand or in the nests of sunfish or other minnows (Jenkins and Burkhead 1994; Warren and Burr 2014).

CHALLENGES

The Swallowtail Shiner is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody cover in upland streams, which contributes to beneficial habitat diversity and channel stability. Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Swallowtail Shiner habitat.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion and “ecobasin” (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning

the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Swampfish is one of nine known species of cavefishes (Amblyopsidae) (Page et al. 2023), and the lone representative in South Carolina (Rohde et al. 2009). Although taxonomically a cavefish, the Swampfish is a strictly epigean (surface water-dwelling) member of the family and is placed in its own genus, *Chologaster* (Warren and Burr 2020; Page et al. 2023). The cavefishes are considered sister to the Pirate Perches (Aphredoderidae) (Betancur-R et al. 2017).

Adult Swampfish are small, ranging in total length from 23 to 68 mm (0.9 to 2.7 in.) (Rohde et al. 2009). This is one of the only pigmented members of the cavefish family (Warren and Burr 2020). The Swampfish has a very unique appearance: coloration contrasts sharply from brown dorsally to creamy white–yellow ventrally, with 3 dark longitudinal stripes on each side. The scales are cycloid and are absent from the head. It is dorso-ventrally compressed anteriorly and laterally compressed posteriorly. It has very small eyes, a supraterminal mouth, and lacks pelvic fins. The caudal fin is clear along its base and black in its center. In adults, the anus is located in a jugular position and is usually covered by the branchiostegal membranes. Short rows of neuromasts—small protruding papillae—are present on the head, body, and caudal fin (Rohde et al. 2009).

Status

The Swampfish is considered secure (G5) on a global scale and vulnerable (S3) in South Carolina (NatureServe 2024). The species in currently listed as imperiled to vulnerable (S2S3) in Georgia (NatureServe 2024). Otherwise, it is currently stable according to Warren et al. (2000). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Swampfish occurs along the southern Atlantic coastal plain from the Chickahominy River, Virginia to the Altamaha River, Georgia (Warren et al. 2000; Rohde et al. 2009). It is found across the coastal plain of South Carolina in all river basins. Although it may be locally common

in some locations, it is not widely encountered due in part to its nocturnal behavior and the heavily vegetated habitats in which it resides (Rohde et al. 1994). It can be categorized as a species that is widespread but not abundant (as detected by most standardized electrofishing methods, largely because it occurs in complex habitats and heavy cover). This species was observed in 3.4% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Swampfish occurs primarily in calm, acidic blackwater swamps, sloughs and streams in association with organic matter and aquatic vegetation (Rohde et al. 2009). Accordingly, it possesses various physiological and behavioral adaptations for these settings, including nocturnal activity and generally sedentary behavior with low metabolic rates (Warren and Burr 2020). Aquatic vegetation and complex structure are important as diurnal cover for light and predator avoidance (Warren and Burr 2020). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (30.8%) and average relative abundance (0.4%) in small rivers (watershed area 300-2000 km^2) of the outer coastal plain.

CHALLENGES

Primary threats to the Swampfish include loss of forested land and especially the removal of riparian cover along Coastal Plain streams. Fish assemblage integrity of coastal plain streams increases with natural land cover, whereas integrity decreases as the amount of agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in Coastal Plain streams, which provides critical habitat for many endemic Southern Atlantic Coastal Plain species including the Swampfish (Marion 2008). Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of naturally stagnant lowland swamps and streams into channelized, shallow drainage ditches with consistently high current velocities represents a principal threat to Swampfish habitat.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). These estimates for the first time provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Tennessee Shiner belongs to the minnow family (Leuciscidae) and was recently moved to the resurrected genus *Paranotropis* from the polyphyletic *Notropis* (Stout et al. 2022 and sources therein), joining the reclassified Mirror Shiner (*P. spectrunculus*) as the only members of this genus in South Carolina (Page et al. 2023). Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including eight recognized species of *Paranotropis* (Warren and Burr 2014; Page et al. 2023).

The Tennessee Shiner is slender with a prominent midlateral stripe and a lateral line set off by dashes terminating in a small rectangular spot at the base of the caudal fin. During the breeding season, the bodies and fins of males take on a red hue and they display a lime green stripe on their upper side. Adult Tennessee Shiners range in length from 43 to 82 mm (1.7 to 3.2 in.) (Rohde et al. 1994).

Status

The Tennessee Shiner is listed globally as currently stable (Warren et al. 2000), secure (G5), and is considered vulnerable (S3) in South Carolina (NatureServe 2024). It is also considered vulnerable (S3) in Georgia and critically imperiled in Alabama (S1) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Overall, the Tennessee Shiner primarily occurs in upland drainages in the Tennessee, Cumberland and Green River basins of Alabama, Georgia, Kentucky, North Carolina, and Tennessee, as well as small portions of the upper Savannah, Linville (Santee), and New River basins (Rohde et al. 2009). In South Carolina, it is only known from several locations in the upper Savannah River basin, with the bulk of its occurrences coming from the Chattooga River (Rohde et al. 2009). Its presence in the upper Savannah and Linville basins of the Atlantic Slope is probably a result of stream capture with the Tennessee basin (Ramsey 1965; Ross 1970; Rohde et al. 2009; Tracy et al. 2020), similar to other taxa in this volume with predominantly Mississippi drainage distributions.

Information on population size and status is limited for this species. Based on samples of the South Carolina/Georgia section of the Chattooga River over the past several decades, the abundance of Tennessee Shiner is very low compared with most other leuciscids in the river; usually only one or two are collected in a typical community sample. Its congener the Mirror Shiner is considerably more abundant in the Chattooga River. On a statewide scale, this species was observed in only 0.1% of over 900 standardized statewide stream and river assessment samples across South Carolina between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Tennessee Shiner inhabits the mid-water areas of riffles, runs and pools adjacent to moderate and swift currents in streams to medium rivers (Jenkins and Burkhead 1994; Rohde et al. 2009). This species spawns in May to June and has been observed using the nests of stonerollers (*Campostoma* spp.) and River Chubs (Etnier and Starnes 1993; Rohde et al. 2009), but it is also known to spawn in shallow gravel runs without nests (Jenkins and Burkhead 1994).

In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (0.1%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin.

CHALLENGES

While the Tennessee Shiner is currently stable throughout the majority of its range, its limited distribution and apparently low abundance in South Carolina make it vulnerable to imperilment within the state. Although much of the Chattooga River drainage is officially designated as wilderness area and therefore protected from development, other anthropogenic actions such as the introduction of non-native species (both aquatic and terrestrial) or long-term environmental change represent potential threats to this species. For example, non-native organisms such as the hemlock woolly adelgid (*Adelges tsugae*) or other tree pathogens could cause widespread loss of major forest constituent tree species and therefore alter the natural thermal and other ecological regimes to which aquatic fauna have adapted. As with other freshwater fishes, anthropogenic landscape alteration can result in cumulative degradation of dependent aquatic ecosystems.

CONSERVATION ACCOMPLISHMENTS

The core area of Tennessee Shiner abundance is protected by the Wild and Scenic Chattooga River.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Tennessee Shiner.
- Identify critical habitats and areas with healthy populations of the Tennessee Shiner and protect these areas once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Thicklip Chub belongs to the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). It is closely related to the sister pair of Santee Chub (*C. zanema*) and Siouan Thinlip Chub (*C. leptocheilus*) (Tracy et al. 2024). Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). The Thicklip Chub is one of eight described plus one undescribed (as of 2024) species of *Cyprinella* in South Carolina.

Along with the Santee Chub (*C. zanema*) and Siouan Thinlip Chub (*C. leptocheilus*), this species is unique among *Cyprinella* in possessing barbels in the corner of its mouth. These three species furthermore have a different shape than other members of the genus, with a slender, ventrally flattened profile, relatively long snout and inferior mouth. In the Thicklip Chub, the dorsal fin origin is positioned directly over the pelvic fin origin, whereas in the Santee and Siouan Thinlip Chubs the dorsal fin origin sits posterior to that of the pelvic fins (Rohde et al. 2009). The back of the fish is marked with prominent cross-hatching and ranges in color from dark olive (juveniles and females) to steel blue (breeding males). All fins have cream-colored edges; males develop straw to red colored fins during the breeding season. Adults range in length from 46 to 75 mm (1.8 to 3 in.) (Rohde et al. 1994).

Status

The Thicklip Chub is considered apparently secure (G4); however, there is some concern for their long-term status based on their limited distributions (NatureServe 2024). In South Carolina, the Thicklip Chub is considered imperiled to vulnerable (S2S3), is considered vulnerable (S3) in North Carolina, and possibly extirpated (SH) in Virginia (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Thicklip Chub is largely restricted to the Santee and Pee Dee River basins of the Carolinas; however, there was one record for the Thicklip Chub in the Pee Dee drainage of Virginia (Jenkins and Burkhead 1994). In South Carolina, the Thicklip Chub is known from the Broad and Saluda drainages of the Santee River system above the Fall Line. In North Carolina, it is found both in the upper Pee Dee and upper Santee drainages. It can be locally abundant in appropriate habitat but is typically among the least abundant members of its genus in streams and rivers in which it occurs. This species was observed in 1.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Thicklip Chub is found in cool- to warmwater streams and rivers, generally in riffles and runs with sand, gravel and rock bottoms (Page and Burr 1991; Jenkins and Burkhead 1994; Rohde et al. 2009). It usually inhabits coarser substrate (e.g., gravel to cobble) than the sympatric Santee Chub (*C. zanema*) (SCDNR unpublished data), resulting in some degree of habitat segregation with *C. labrosa* in rockier areas and *C. zanema* in more uniformly sandy runs (Rohde et al. 2009). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (0.5%) in upland small rivers (watershed area 300-2000 km^2) of the Santee River basin.

CHALLENGES

The Thicklip Chub, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Thicklip Chub habitat. The apparent preference of this species for coarser substrate than that occupied by the sympatric Santee Chub may suggest it is more sensitive to runoff and increased fine sediment loading in streams. One of the fastest-growing areas of human population pressure and land development in the United States, the Interstate 85 corridor between Greenville, South Carolina and Charlotte, North Carolina, runs directly through the range of this species. The vast majority of its populations occur on private (unprotected) lands. Approximately 50% of the global range of the Thicklip Chub occurs in South Carolina; conservation efforts within the state are critical to the preservation of this species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Thicklip Chub.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a

significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Turquoise Darter

Etheostoma inscriptum

Photo: NCFishes.com

Contributor (2005): Gene Hayes and Jason Bettinger [SCDNR]
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Turquoise Darter is a member of the perch and darter family (Percidae), an extremely diverse group of predominantly small, bottom-dwelling fishes currently represented by 224 described species comprising more than 20% of the North American freshwater ichthyofauna (Page 1983; Kuehne and Barbour 1983; Near et al. 2011; Page et al. 2023). With 138 described species, *Etheostoma* is the most diverse genus of North American freshwater fishes (Page et al. 2023). It is sister to the Seagreen Darter (*Etheostoma thalassinum*) of the Santee River basin (Richards 1966; Near et al. 2011).

The Turquoise Darter is a moderate-sized darter, ranging in adult length from 66 to 78 mm (2.6 to 3.1 inches) (Rohde et al. 1994). Adults of both sexes have 5 to 6 dark dorsal saddles and 6 blotches on the side (Kuehne and Barbour 1983). The male Turquoise Darter is brown with several horizontal rows of small red spots, whereas the sides of the female are yellow-brown with brown saddles and blotches. Breeding males take on a pinkish body color with dark green bars on the side. The lower portion of the head becomes blue, as do the pelvic fins, anal fins, and outer edges of the caudal fin. The dorsal fin of the male becomes blue-green with a red upper edge during the spawning period (Rohde et al. 1994).

Status

Globally, the Turquoise Darter is listed as apparently secure (G4) (NatureServe 2024). The Turquoise Darter is considered imperiled to vulnerable (S2S3) in South Carolina and apparently secure (S4) in Georgia, but is a fish of special concern in North Carolina, where it is considered critically imperiled (S1) (NatureServe 2024) due to its very restricted range in that state. In an assessment of Southeastern fishes, the Turquoise Darter was considered currently stable (Warren et al. 2000). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The Turquoise Darter is native to the Altamaha, Savannah and Edisto River basins of the southern Atlantic slope. In South Carolina, it is predominantly an upland fish and sees its highest abundance in swift-flowing streams and rivers, but it also occurs in lower numbers in scattered localities on the inner coastal plain of the Savannah and Edisto River basins where topography supports steady flow. In high-gradient streams and rivers with continuous suitable habitat it can be moderately abundant, but due to the siltation of many Piedmont streams and the localized nature of appropriate coarse riffles in lower-gradient Piedmont streams, it is often limited in abundance. This species was observed in 4.5% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

In the Piedmont and Blue Ridge portions of its range, the Turquoise Darter occurs in streams to large rivers and almost exclusively in swift riffle habitats with coarse substrates ranging from gravel to cobble and bedrock (Page 1983; Kuehne and Barbour 1983; Rohde et al. 2009; K. Lusk and B. Peoples, unpublished data). In an Inner Piedmont stream during spring-summer, Turquoise Darter density was highest in depths of 5-20 cm, velocities of 55-65 cm per second, and substrate of boulder/bedrock (DeLong 1991). Where it occurs (in lower abundance) in the inner coastal plain, the streams are characterized by steady flow over sand and fine gravel (SCDNR data). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (50%) and average relative abundance (3.3%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin. Spawning occurs from late March to early June with a peak in April (Richards 1966; Irwin 2009). Following the first spawn of a reintroduced Turquoise Darter population in the upper Savannah River basin, juveniles were found exclusively downstream of and on finer (gravel) substrate than the adults (Kubach 2003), suggesting age-specific differences in habitat use as well as probable downstream drift of pelagic larvae as a dispersal method, which has been observed in other darters (Rakes 1999; Muller 2000). Other aspects of its biology are not well studied but are probably similar to those of the related and wider-ranging Greenside Darter, *E. blennioides*.

CHALLENGES

Although the Turquoise Darter is currently considered stable, conservation efforts within South Carolina are critical to its global conservation. Approximately one-third of the global distribution of Turquoise Darter occurs in South Carolina. Within the state, destruction of stream riffle habitat caused by land development, deforestation, loss of riparian cover, siltation, and hydrologic alterations like channelization and impoundments could jeopardize this species. Much of its preferred larger, fluvial habitat in the upper Savannah River basin has already been lost to major reservoirs collectively spanning hundreds of thousands of acres. The patchy and limited distributions of remaining intact habitats and populations are vulnerable to habitat alteration. Coastal plain populations of the Turquoise Darter are of concern due to increased development pressures in that region and smaller darter population sizes. Further, in extreme headwaters of their range, Turquoise Darters may be adversely affected by Brown and Rainbow Trout introductions.

CONSERVATION ACCOMPLISHMENTS

Populations of Turquoise Darters occurring in Howard Creek are protected through land purchase and/or conservation easements. A successful reintroduction of Turquoise Darters was conducted on Six Mile Creek in 2003.

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and "ecobasin" (ecoregion x river basin). These estimates, for the first time, provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of Turquoise Darters.
- Study the potential predator/prey relationship between darters (Turquoise and Seagreen Darters) and introduced trout (Brown and Rainbow Trout) and the impact of this relationship on the native darters.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The V-lip Redhorse is a member of the sucker family (Catostomidae), which is represented by 78 described species in North America (Page et al. 2023). Suckers comprise about 8% of the continent's freshwater ichthyofauna, behind only minnows (Leuciscidae) and perches and darters (Percidae) in number of species (Warren and Burr 2014). The genus *Moxostoma* includes 23 described species (Page et al. 2023), about one third of which are considered imperiled at some level (Jelks et al. 2008; Warren and Burr 2014).

This family is characterized by soft-rayed fins, a mouth located on the underside of the head, thick, fleshy, distensible lips, and paired fins attached low on the body (Rohde et al. 1994). Adult V-lip Redhorse range in total length from 252 to 420 mm (10 to 16.5 in.) (Rohde et al. 2009). The V-lip Redhorse is elongate and slender, with a tan-olive back and silver to gold or brassy sides with dark scale bases. Lips are papillose, and the lower lip has a deeply V-shaped posterior margin. The dorsal fin is concave and usually has 12 or 13 rays. Caudal and anal fins may have faint reddish edges, and paired fins are orange or pale red (Jenkins and Burkhead 1994).

Status

The V-lip Redhorse is currently considered stable (Warren et al. 2000) and apparently secure (G4) (NatureServe 2024). However, there is some concern about the long-term outlook for the species due to declines and other factors and is considered vulnerable in South Carolina (S3) (NatureServe 2024). Though it may be uncommon in certain areas like within South Carolina, it is not considered rare and is listed as apparently secure (S4) in both North Carolina and Virginia (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The V-lip Redhorse occurs on the Atlantic slope from the Roanoke–Chowan basin in Virginia to the Santee River basin in South Carolina (Rohde et al. 2009). In South Carolina, the species is

only known from the Broad and Saluda River drainages of the Santee River basin (Rohde et al. 2009), where it is uncommon. Despite being known from many localities in the upper Catawba River basin in North Carolina (Tracy et al. 2020; 2024) and most of the other Piedmont drainages of the Santee basin in South Carolina, the V-lip Redhorse has not been observed in the Catawba-Wateree basin in South Carolina; this apparent absence may represent extirpation or occurrence in very low densities. This species was observed in 1.4% of over 900 standardized statewide stream and river assessment samples throughout South Carolina between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The V-lip Redhorse inhabits rocky runs and silty to firm-bottomed pools within warm, medium-sized streams to large rivers of moderate or gentle gradient (Jenkins and Burkhead 1994; Rohde et al. 2009). Juveniles have been collected in the lower reaches of larger streams that join the rivers supporting its primary populations. This species is a benthic feeder and has been observed feeding in slow current, gravel-bottomed areas (NatureServe 2024). In standardized sampling covering streams to small rivers in South Carolina, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (0.03%) in upland small rivers (watershed area 300-2000 km^2) of the Santee River basin.

CHALLENGES

The V-lip Redhorse has a very limited distribution in South Carolina; any major disturbances or cumulative impacts to these rivers could have a substantial influence on its populations. This species may experience impacts from non-native catfish species such as Blue and Flathead Catfish that likely prey on juvenile and adult redhorses (Guire et al. 1984; Bart et al. 1994), both of which are expanding in the Santee River basin. The V-lip Redhorse is susceptible to the same pervasive types of anthropogenic habitat alteration and fragmentation affecting other large riverine catostomids (Cooke et al. 2005), including the construction and operation of dams and impoundments, sedimentation of important foraging and spawning habitats, alteration of hydrologic regimes, and introduction of non-native species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion and “ecobasin” (ecoregion x river basin). These estimates for the first time provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and

developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the V-lip Redhorse.
- Identify critical habitats and areas with healthy populations of V-lip Redhorse, and protect these areas once identified.
- Investigate the existence of the V-lip Redhorse in the Pee Dee River.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Warpaint Shiner

Coccotis coccogenis

Photo: NCFishes.com

Contributor (2005): Jason Bettinger (SCDNR)
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The Warpaint Shiner is a member of the minnow family (Leuciscidae) and was recently moved to the resurrected genus *Coccotis* from its former classification in *Luxilus* (Stout et al. 2022 and sources therein; Page et al. 2023). It is the only species of *Coccotis* in South Carolina, and its only current North American congener is the Bandfin Shiner, *C. zonistius*. Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023).

Fishes within the genus *Coccotis*, like those of *Luxilus*, are characterized by deep, strongly compressed bodies and large lateral scales which are much higher than wide (Jenkins and Burkhead 1994; Rohde et al. 1994). Warpaint Shiners range in length from 76 to 120 mm (3.0 to 4.7 in) (Rohde et al. 2009). This attractive species displays a dark submarginal band in the dorsal and caudal fins and a prominent red slash on the opercle behind the eye. Breeding males display red on the upper lip and snout (Rohde et al. 1994).

Status

Globally, this species is considered currently stable (Warren et al. 2000) and secure (G5) but is considered vulnerable (S3) in South Carolina (NatureServe 2024). Along with South Carolina, Georgia and Virginia consider the Warpaint Shiner to be vulnerable (S3) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The presence of the Warpaint Shiner in the Savannah River of the southern Atlantic slope is likely due to a stream capture from the Tennessee River, similar to other taxa in this volume with predominantly Mississippi drainage distributions (Ramsey 1965; Ross 1970; Rohde et al. 2009). In South Carolina, the Warpaint Shiner is restricted to upland drainages in the Chattooga and Seneca River systems in the upper Savannah River drainage. Outside of South Carolina, the Warpaint Shiner occurs in upland drainages in the upper Tennessee River drainage of western Virginia, western North Carolina, eastern and southern Tennessee, northern Georgia and

northern Alabama. This species was observed in 0.7% of over 900 standardized statewide stream and river assessment samples in South Carolina between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Warpaint Shiner inhabits clear coolwater streams and rivers with moderate to high gradients (Jenkins and Burkhead 1994) and gravel and rubble substrates. It is often observed spawning over mounds built by nest-building *Nocomis* species in late May through mid-July (Rohde et al. 2009). This species is generally found in the slower moving areas associated with pools, slow runs, and riffle margins. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (1.5%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin.

CHALLENGES

Although the Warpaint Shiner is currently stable throughout the majority of its range, its limited distribution in South Carolina makes it vulnerable to imperilment within the state. It is especially vulnerable to development within the Chattooga and Seneca River systems. The major challenges to this species include loss of forested land and especially the removal of riparian cover along upland streams. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Warpaint Shiner habitat. The habitat requirements of the Warpaint Shiner for colder and higher-gradient streams and the limited availability of this habitat in South Carolina also make it susceptible to competition from non-native species such as introduced trout (Elkins and Grossman 2014; Elkins et al. 2018). Although the Warpaint Shiner appears to be secure where it overlaps with introduced trout in South Carolina streams that exhibit high habitat quality on protected lands (SCDNR unpublished data), such competition could represent a greater threat in streams in which anthropogenic habitat alteration places additional stresses on native species.

CONSERVATION ACCOMPLISHMENTS

South Carolina Stream Assessment data have facilitated the calculation of standardized abundance (density) estimates for this species at multiple spatial strata including statewide, river basin, level-IV ecoregion, and “ecobasin” (ecoregion x river basin). For the first time, these estimates provide an objective measure of current population status that will serve as a baseline for following future population trends and gauging the effectiveness of conservation actions.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina’s freshwater habitats and understand the relationships between aquatic resource integrity and a

rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify levels and spatial distributions of critical habitat factors to sustain the species in geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements of the Warpaint Shiner.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Western Blacknose Dace is a member of the minnow family (Leuciscidae) and one of six currently recognized North American species of the genus *Rhinichthys* (Page et al. 2023), two of which occur in South Carolina (*R. obtusus* and *R. cataractae* Longnose Dace). Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023).

Genetic and morphological variation across the large range of the Blacknose Dace in eastern North America (all of which were formerly known as *R. atratulus*) has long been recognized and varying proposed subspecific and/or specific geographic delineations have arisen (Etnier and Starnes 1993 and sources therein; Jenkins and Burkhead 1994; Nelson et al. 2004; Kraczkowski and Chernoff 2014). Most recently, a genetic analysis by Kraczkowski and Chernoff (2014), in alignment with previous distributional works (Boschung 1992; Jenkins and Burkhead 1994; Rohde et al. 2009; Straight et al. 2009), supported the occurrence of *R. atratulus* (Blacknose Dace) in Atlantic drainages from Nova Scotia south to and including the Roanoke River basin as well as southeastern Lake Ontario drainages, whereas *R. obtusus* was determined to occur in the St. Lawrence and Great Lakes basins (except southeastern Lake Ontario tributaries), upper Mississippi basin, southern Atlantic basins from the James to the Savannah (i.e., in South Carolina, including the upper Savannah and Santee basins), and portions of the Mobile River basin. The zoogeographic dynamics responsible for the distribution of *R. obtusus* in the upper portions of southern Atlantic basins (e.g., potential capture of adjacent Tennessee/Ohio drainages) warrant additional investigation (Kraczkowski and Chernoff 2014).

Adult Western Blacknose Dace range in length from 44 to 100 mm (1.7 to 3.9 in.) (Rohde et al. 1994, 2009). The species has small scales, a frenum, a subterminal mouth with a small barbel in each corner, a moderate-sized head, small eyes, a moderate-sized mouth and fleshy lips. The breast and belly are fully scaled. There is a black lateral stripe extending from the snout through the eye to the caudal area, separating a brownish back from a whitish belly (Jenkins and Burkhead 1994).

Status

The Blacknose Dace is considered currently stable within its range (Warren et al. 2000) and globally secure (G5) (NatureServe 2024). The Blacknose Dace is considered imperiled (S2) in South Carolina primarily on the basis of its extremely limited range and available habitat in the state. In surrounding states including more of its range, the species is listed as vulnerable to secure (S3S5) in Georgia and secure (G5) in North Carolina (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

Based on the most recent analysis (Kraczkowski and Chernoff 2014), the Western Blacknose Dace occurs in the St. Lawrence and Great Lakes basins (except southeastern Lake Ontario tributaries), upper Mississippi basin, southern Atlantic basins from the James to the Savannah (i.e., in South Carolina, including the upper Savannah and Santee basins), and portions of the Mobile River basin. In South Carolina, Blacknose Dace are found in the upper Savannah and Saluda River drainages, almost exclusively in the Blue Ridge ecoregion. This species was observed in 0.3% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

Blacknose Dace are common throughout their range (Page and Burr 1991; Rohde et al. 1994; Etnier and Starnes 1993). Healthy populations are known to occur in Howard Creek (Savannah drainage), Matthews Creek and Big Falls Creek (Saluda drainage). Blacknose Dace also occur in lower abundance in the Chattooga (where it is considerably lower in abundance than the congeneric Longnose Dace, *R. cataractae*), Whitewater, Eastatoee, Middle Saluda, and South Saluda Rivers (SCDNR unpublished data).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Western Blacknose Dace occurs in small to medium coldwater streams and rivers with slow to rapid current and a diverse substrate of sand, gravel, and rock (Rohde et al. 1994). Observations of this species indicate seasonal colonization of headwaters of small intermittent and perennial streams (Goettel et al 2015) and a tendency to move upstream in lotic systems (Trail et al. 1983). In South Carolina, the Western Blacknose Dace is one of few species known to occur sympatrically with native Brook Trout in small headwater streams of the Blue Ridge (SCDNR unpublished data). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (3.0%) and average relative abundance (2.7%) in upland small streams (watershed area 0-15 km^2) of the Savannah River basin.

CHALLENGES

While the Blacknose Dace is currently stable throughout the majority of its range, its limited distribution in South Carolina makes it vulnerable to imperilment within the state. Although much of its range in the Blue Ridge of South Carolina is officially designated as wilderness area and therefore protected from development, other anthropogenic actions such as the introduction of non-native species (both aquatic and terrestrial) or long-term environmental change represent potential threats to this species. For example, non-native organisms such as the hemlock woolly

adelgid (*Adelges tsugae*) or other tree pathogens could cause widespread loss of major forest constituent tree species and therefore alter the natural thermal and other ecological regimes to which aquatic fauna have adapted. As with other freshwater fishes, anthropogenic landscape alteration such as development, deforestation, loss of riparian cover, siltation, and impoundments can result in cumulative degradation of dependent aquatic ecosystems. The occurrence of Western Blacknose Dace in predominantly smaller and shorter headwater streams in South Carolina places it in a position vulnerable to extirpation from such streams due to acute disturbances.

CONSERVATION ACCOMPLISHMENTS

Populations of Blacknose Dace found in Matthews Creek, Big Falls Creek, and Howard Creek have been protected through fee simple land purchases and/or conservation easements in those areas.

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.

- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify
- levels and spatial distributions of critical habitat factors to sustain the species in
- geographic areas of interest.
- Use South Carolina Stream Assessment decision-support GIS modeling tools to identify
- priority regions and watersheds at greatest risk of decline in stream integrity.
- Describe life history and habitat requirements for the Blacknose Dace.
- Identify streams with healthy populations and intact critical habitat in the upper Savannah River drainage, and Saluda River System for Blacknose Dace. Protect these areas, once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop other educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.

- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for these species. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

White Catfish

Ameiurus catus

Photo: NCFishes.com

Contributor (2005): Forrest Sessions, Scott Lamprecht, and Jason Bettinger [SCDNR]
Reviewed and Edited (2013): Mark Scott, Kevin Kubach, M. Troy Cribb, and Andrew Gelder [SCDNR]
Reviewed and Edited (2024): Kevin Kubach, Andrew Gelder, Rachel Moore, Clint Burton, Andrew Peel, and Mark Scott [SCDNR]

DESCRIPTION

Taxonomy and Basic Description

The White Catfish is one of 51 recognized species comprising the family Ictaluridae (Page et al. 2023; Warren and Burr 2020). It is within the genus *Ameiurus*, which contains medium-sized catfish often referred to as "bullheads." Of the seven species of *Ameiurus*, five occur in South Carolina. This genus is characterized by a lack of scales, four pairs of barbels, one stout spine supporting dorsal and pectoral fins, an upper jaw protruding over the lower, cardiform teeth on jaws, and an adipose fin (Jenkins and Burkhead 1994). The White Catfish is bluish-gray to olive above and white on the belly with unmarked sides. The tail is slightly forked with rounded tips. Maximum length is 620 mm (24.4 in.), making them among the largest of the *Ameiurus* bullhead species (Rohde et al. 2009); however, White Catfish are typically less than 500 mm (20 in.) long. The anal fin is convex with a ray count ranging between 19 and 23.

Status

Overall, the White Catfish is currently considered to be stable (Warren et al. 2000) and common as well as widespread and secure (G5) (NatureServe 2024). It is considered vulnerable to apparently secure (S3S4) in South Carolina and vulnerable (S3) in Alabama (NatureServe 2024). Populations have greatly declined in the Neuse River, Cape Fear River, Pee Dee River (W. Starnes, pers. comm.) and Edisto River (W. McCord, pers. comm.) since the introductions of Flathead Catfish and Blue Catfish. This declining trend has also been observed in other small coastal plain rivers of South Carolina that were former strongholds for the White Catfish (C. Thomason, pers. comm.).

POPULATION SIZE AND DISTRIBUTION

The White Catfish is native to the major Atlantic Slope drainages from Delaware to Florida as well as the eastern Gulf Slope in Alabama, Florida and Georgia. This species has been observed in all of South Carolina's river basins and ecoregions (Rohde et al. 2009; Nature Serve 2024). White Catfish populations in North Carolina and South Carolina coastal rivers have declined

since the introduction of non-native Blue Catfish and Flathead Catfish, (*Ictalurus furcatus* and *Pylodictis olivaris*, respectively) (W. Starnes, pers. comm.; SCDNR unpublished data). This species was observed in 1.3% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

White Catfish primarily inhabit small to large rivers in freshwater and brackish water habitats, venturing into the lower reaches of tidally influenced rivers (Jenkins and Burkhead 1994, Rohde et al. 2009). This species also shows a tolerance for reservoirs, probably owing to its occurrence in large, deep river sections among its native habitats. It spawns in early summer, with both parents exhibiting parental care until the young hatch (Rohde et al. 1994). These catfish are relatively long-lived, reaching a maximum of 14 years (Rohde et al. 1994; Jenkins and Burkhead 1994). White Catfish feed on plants, insects, and other fish. In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (15.4%) and average relative abundance (0.8%) in small rivers (watershed area 300-2000 km^2) of the coastal plain.

CHALLENGES

This species is threatened by the introduction of non-native ictalurids like the Flathead Catfish and the Blue Catfish; both of these non-native species displace and prey on the smaller bullheads (Guire et al. 1984; Ashley and Buff 1986; Quinn 1988; Bart et al. 1994). Predation by and competition with introduced Flathead Catfish and Blue Catfish may negatively affect abundance of the White Catfish and limit its distributions in portions of its range. Other threats to the White Catfish include loss of forested land and especially the removal of riparian cover. Fish assemblage integrity increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in coastal plain streams, which provides critical habitat for many native southern Atlantic coastal plain species including the White Catfish (Marion et al. 2015). Land development, siltation, and hydrologic alterations such as channelization and construction of impoundments also threaten this species. The conversion of naturally stagnant lowland swamps and streams into channelized, shallow drainage ditches with consistently high current velocities represents a principal threat to White Catfish habitat.

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Control exotic catfish species, like Blue and Flathead Catfish, through eradication efforts and by educating landowners, fishermen, and the general public to the discontents of stocking non-native species.
- Describe life history and habitat requirements of the White Catfish.
- Identify critical habitats and areas with healthy populations of the White Catfish; protect these areas, once identified.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Whitemouth Shiner belongs to the minnow family (Leuciscidae) and was recently moved to the genus *Miniellus* from the polyphyletic *Notropis* (Stout et al. 2022 and sources therein; Page et al. 2023), joining the reclassified Swallowtail Shiner (*M. procne*) as the only *Miniellus* in South Carolina. Minnows represent the most speciose family of freshwater fishes in North America (about 27% of the continental fauna), with at least 323 described taxa of predominantly small (<150 mm) and slender fishes including 21 recognized species of *Miniellus* (Warren and Burr 2014; Page et al. 2023).

Adult Whitemouth Shiners range from 36 to 61 mm in total length (1.4 to 2.2 in.) (Rohde et al. 2009). Its straw-colored upper half and white lower half are bisected by a thin, dark, jagged-edged lateral stripe terminating in a small, triangular caudal spot (Rohde et al. 1994). This species can be distinguished from the Swallowtail Shiner by the absence in Whitemouth of a predorsal stripe, a black stripe completely encircling the snout, and lack of pigmentation on the upper lip (present in Swallowtail) (Rohde et al. 2009).

Status

The Whitemouth Shiner is considered apparently secure globally (G4) (NatureServe 2024). Its status, however, does vary from apparently secure to critically imperiled as one moves across its range. In South Carolina, the status of the Whitemouth Shiner is imperiled to vulnerable (S2S3) (NatureServe 2024). This species was selected as a Regional Species of Greatest Conservation Need in the Southeastern Association of Fish and Wildlife Agencies regional effort (Rice et al. 2019), receiving a designation of moderate concern.

POPULATION SIZE AND DISTRIBUTION

The native range of the Whitemouth Shiner includes the Chowan, Roanoke, Cape Fear, and Pee Dee basins in Virginia, North Carolina and South Carolina (Jenkins and Burkhead 1994). It is believed to have been extirpated from the Chowan basin (Jenkins and Burkhead 1994) and is apparently absent from intervening Tar and Neuse drainages (Jenkins and Burkhead 1994;

NatureServe 2004). This species has also been collected in the Catawba River system of the Santee basin in North Carolina, presumably as a result of introduction (Hocutt et al. 1986; Jenkins and Burkhead 1994; Tracy et al. 2020; Tracy et al. 2024).

The Whitemouth Shiner occurs predominantly on the outer Piedmont, where it is fairly common in some drainages (Tracy et al. 2020; Tracy et al. 2024). In South Carolina, it is only known from Thompson Creek and its confluence with the Pee Dee River (Rohde et al. 2009); these localities represent the southern edge of the global range of this species. This species was observed in 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Whitemouth Shiner occurs in streams and small rivers that typically exhibit riffle-pool sequences with sand, rubble and bedrock (Rohde et al. 2009; NatureServe 2024). Like its congener the Swallowtail Shiner (*M. procne*), this species presumably spawns in spring to early summer over sand or in the nests of sunfish or other minnows (Jenkins and Burkhead 1994; Warren and Burr 2014). In standardized sampling covering streams to small rivers of South Carolina, this species exhibited its highest frequency of occurrence (2.9%) and average relative abundance (0.4%) in upland large streams (watershed area 100-300 km²) of the Pee Dee River basin.

CHALLENGES

The occurrence of the Whitemouth Shiner in only one stream system in South Carolina, and on the southern fringe of its global range, makes it vulnerable to decline in the state. Cumulative or acute disturbances to Thompson Creek could cause extirpation of this species from South Carolina. Challenges to this species are similar to those of other aquatic fauna and include point and non-point source pollution, deforestation, and loss of riparian corridors, impoundment development, channelization and siltation from poor land use practices, and unplanned or poorly planned urban and suburban development. Fish assemblage integrity of upland streams increases with natural land cover, whereas integrity decreases as the amount of developed and agricultural land increases (SCDNR 2023). Mature forest and riparian vegetation are important sources of large woody debris in upland streams, which contributes to beneficial habitat diversity and channel stability. The conversion of upland streams into channelized ditches with little in-stream habitat represents a principal threat to Whitemouth Shiner habitat. Because of its limited distribution, it is also vulnerable to habitat losses due to anthropogenic influences such as water withdrawals or environmental disturbances such as drought.

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning

the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.

- Compilation of information and photographs for the development of nongame fish description web pages currently in development.
- Collaboration with SC Education Television in the filming and production of informative nature programs highlighting the diversity and status of South Carolina's aquatic fauna

CONSERVATION RECOMMENDATIONS

- Survey Thompson Creek and surrounding areas in Chesterfield County to determine the status of the Whitemouth Shiner as this stream likely houses the strongest populations of this species and may have been severely impacted by the drought of 2002. Protect these areas, once identified.
- Describe life history and habitat requirements of the Whitemouth Shiner
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

DESCRIPTION

Taxonomy and Basic Description

The Whitetail Shiner belongs to the minnow family (Leuciscidae), the most speciose family of freshwater fishes in North America with at least 323 described taxa of predominantly small (<150 mm) and slender fishes (Warren and Burr 2014; Page et al. 2023). Following the recent revision of the formerly large genus *Notropis* (Stout et al. 2022), *Cyprinella* is currently the most diverse genus of North American minnows, with 29 described species (Page et al. 2023). The Whitetail Shiner is one of eight described plus one undescribed (as of 2024) species of *Cyprinella* in South Carolina.

Members of the genus *Cyprinella* are distinguished from other leuciscids by their large, vertically-elongated, diamond-shaped scales and a black blotch in the dorsal fin (Rohde et al. 1994). As with the other *Cyprinella* species, the Whitetail Shiner is a crevice spawner (Jenkins and Burkhead 1994). Whitetail Shiners have moderately deep and compressed bodies. Two large creamy white spots at the base of the caudal fin separate the Whitetail Shiner from other similar *Cyprinella* species (Rohde et al. 1994). During the breeding season, males often display a red tint to the pectoral, dorsal, and caudal fins (Rohde et al. 2009). Adults range in size from 44 to 150 mm (1.7 to 5.9 in.) (Rohde et al. 1994).

Status

Globally, this species is currently considered to be stable (Warren et al. 2000) and secure (G5). The Whitetail Shiner is considered vulnerable (S3) in South Carolina, apparently secure (S4) in North Carolina, and Georgia has the species listed between vulnerable and apparently secure (S3S4) (NatureServe 2024).

POPULATION SIZE AND DISTRIBUTION

The presence of the Whitetail Shiner in the upper Savannah River basin of the southern Atlantic slope is likely due to a stream capture from the Tennessee River basin, similar to other taxa in this volume with predominantly Mississippi drainage distributions (Ramsey 1965; Ross 1970; Rohde et al. 2009). In South Carolina, this species occurs only in the Chattooga and Seneca River systems of the upper Savannah River drainage. Interestingly, in the Chattooga River it

appears to be absent upstream of Big Bend Falls. This species was observed in 0.1% of over 900 standardized statewide stream and river assessment samples between 2006 and 2023.

The Whitetail Shiner occurs in upland drainages both east and west of the former Mississippi Embayment. It occurs in the Cumberland and Tennessee drainages of Virginia, Kentucky, North Carolina, Tennessee, Georgia, Alabama, and Mississippi. It also occurs in the upper Santee drainage in North Carolina. West of the Mississippi River, the Whitetail Shiner occurs in the St. Frances and White River drainages of Missouri and Arkansas (Page and Burr 1991).

HABITAT OR NATURAL COMMUNITY REQUIREMENTS

The Whitetail Shiner inhabits clear, coolwater streams and rivers with moderate to high gradients (Jenkins and Burkhead 1994) and gravel and rubble substrates. This species is common in deep pools near riffles and is often associated with large boulders and rocky banks (Mayden 1989). In standardized sampling covering streams to small rivers, this species exhibited its highest frequency of occurrence (16.7%) and average relative abundance (1.1%) in upland small rivers (watershed area 300-2000 km^2) of the Savannah River basin. As with other non-barbeled *Cyprinella* species, the Whitetail Shiner is a crevice spawner, depositing eggs in crevices of logs and rocks in a territory defended by the male over an extended spring-summer breeding period (Gale and Buynak 1978; Rohde et al 1994; Rohde et al. 2009).

CHALLENGES

Although the Whitetail Shiner is currently stable throughout the majority of its range, its limited distribution in South Carolina makes it vulnerable to imperilment within the State. The Whitetail Shiner, like many other specialized stream fishes, is susceptible to an array of acute and cumulative impacts from anthropogenic alterations to the watershed, riparian zone and streams and rivers directly. These include deforestation and conversion of natural land cover for development and agriculture with resulting sedimentation and non-point source pollution, hydrologic alterations, and habitat fragmentation from dams and reservoirs. The breeding behavior of the non-barbeled *Cyprinella* makes this group particularly vulnerable to impacts from both suspended and deposited sediment. Because the breeding process is dependent on visual cues (extended display and territorial defense period) as well as clean crevices for egg deposition and larval development, suspended sediment (increased turbidity) and deposited sediment has been shown to delay or inhibit spawning success in fishes of this genus (Hubbs and Echelle 1972; Burkhead and Jelks 2001; Warren and Burr 2014).

CONSERVATION ACCOMPLISHMENTS

Following and building upon the dataset amassed from the South Carolina Stream Assessment study (2006-2011), additional standardized river and stream assessment efforts have enhanced the ability to assess the status of freshwater fishes across the majority of South Carolina's freshwater habitats and understand the relationships between aquatic resource integrity and a rapidly changing landscape. The dataset now includes over 1,000 standardized samples spanning the past 20 years, providing the framework for modeling impacts to aquatic ecosystems and developing conservation tools aimed at preserving or restoring species status to former levels and

mitigating future impacts on them. Aquatic resource conservation products and efforts completed or initiated since the previous SWAP include:

- The development and revision (C-SWG collaboration with North Carolina) of a web-based Aquatic Planning Tool (APT). This tool will allow practitioners to better manage SGCNs by providing predictive maps of the effects of proposed future development and restoration. The APT will have two primary functions, the first being an application to visualize current occurrence probabilities of SGCNs and their relationships with land use and climate across the Carolinas. The APT's second function will be an interactive online tool allowing users to explore predicted impacts of future land management and climate scenarios on SGCNs at any stream segment in the Carolinas. This tool will be used by numerous and diverse conservation practitioners to guide future SGCN prioritization and surveys, restoration and reintroduction, and 'smart' city development to prevent the worst impacts of urbanization on freshwater fish SGCNs.
- Development of the first fish-based biotic index covering all freshwater stream regions in the state. The index provides a measure of stream biological (fish assemblage) integrity based on the relative abundance of region-specific and basin-specific indicator species. Current uses involve incorporating the index with fish vouchering and reporting into the Office of Environmental Permitting's pipeline for wetland mitigation in an effort to assess success of mitigation and restoration projects.
- We conduct analysis of stream integrity based on the biotic index versus the watershed land use categories in an effort to determine thresholds of land-use-based disturbance and how fish communities respond.
- Provide collaborative input to the Office of Environmental Programs review of projects and permitting.
- Review fish collection permits for validity and ethics in regard to species and number of fish taken and the proposed purpose therein.
- We work closely with Aquatic Information Staff to promote awareness of SC aquatic resources and biodiversity.
- We collaborate with university researchers and graduate students to analyze relationships between aquatic species and environmental change.
- We produced eleven publications and manuscripts analyzing South Carolina stream and river resource response to environmental gradients and disturbances:

CONSERVATION RECOMMENDATIONS

- Describe life history and habitat requirements of the Whitetail Shiner.
- Identify critical habitats and areas with healthy populations of the Whitetail Shiner and protect these areas, once identified.
- Conduct targeted surveys of the Seneca River Basin to assess the existence or extirpation of the Whitetail Shiner. Surveys should be concentrated on the Toxaway River and the tributaries of Lake Jocassee. Once identified, these areas should be protected.
- Protect critical habitats from future development and further habitat degradation by following Best Management Practices(BMPs) and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Continue to develop educational materials in order to raise public awareness of nongame species and their ecological importance to the natural history of South Carolina's aquatic habitats.
- Educate motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.

MEASURES OF SUCCESS

Determining the distribution, life history, habitat needs, and Southeastern population structure and trends would represent a measure of success for this species. Methods that protect water quality are also likely to protect this species. In the event that more protective BMPs are implemented, population studies of this fish could assist in determining the effectiveness of those measures. Successful conservation of South Carolina's native aquatic species is best accomplished proactively by maintaining natural land cover, which supports aquatic habitat integrity and dependent species assemblages. For example, achieving the foremost goal of the Southeastern Aquatic Resource Partnership's 2008 Southeast Aquatic Habitat Plan that 85% of lands within 30 m (100 ft.) of streams or rivers be maintained in natural vegetation would be a significant measure of success. Maintenance or recovery of natural land cover levels above the critical thresholds identified quantitatively using aquatic conservation planning tool modeling applications represents a foremost, highly-defensible measure of success in supporting species of greatest conservation need. At the species level, an indicator of effective conservation implementation could include a stable or increasing distribution and/or abundance relative to current levels as measured by statewide assessment data.

Altamaha Arcmussel

Alasmidonta arcula (Lea, 1838)

Contributor (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Morgan Kern (SCDNR)

Figure 1. Image of *Alasmidonta arcula* courtesy of the North Carolina State Museum of Natural Sciences, Jamie Smith, and Dr. Art Bogan. The NCSM catalog number of the specimen photographed is 56179.

DESCRIPTION

Taxonomy and Basic Description

Like many other freshwater mussel species in South Carolina, taxonomy in the genus *Alasmidonta* is still under revision. A recent study of the genus performed by Whelan et al. (2023) maintained *Alasmidonta arcula* as a separate species due to conflicting results. Future studies using additional nuclear models may support synonymy of *Alasmidonta arcula*, *Alasmidonta undulata*, and *Alasmidonta triangulata* (Whelan et al. 2023).

The Altamaha Arcmussel is a small-shelled mussel that can grow to around 3 inches in length (Figure 1). The umbo, or beak, is high above the hinge line near the center of the shell. The umbo or beak cavity is relatively shallow. The posterior ridge is sharp and straight. Pseudocardinal teeth are present. Lateral teeth are reduced or absent in the left valve. The outer surface is generally smooth except on the posterior slope which can have defined ridges corresponding with growth lines. The shell is inflated with a rounded anterior end and ventral margin with a truncated posterior end. The shell is considered triangular in shape. The coloration is brown to greenish-yellow with green rays, becoming darker in mature individuals. The nacre, inner shell surface, is bluish-white or white. (Johnson 1970; Wisniewski 2018).

As with many of our native freshwater mussels, Altamaha Arcmussel can be misidentified as other South Carolina species. The height of the umbo/beak and the severity of the posterior ridge will distinguish it from most forms of Triangle Floater (*Alasmidonta undulata*) which has lateral teeth that are absent or vestigial, and the more compressed Carolina Slabshell (*Elliptio congaraea*).

Status

NatureServe (2024) lists the current global status for the Altamaha Arcmussel as imperiled (G2). In South Carolina it is critically imperiled (S1) and in Georgia it is vulnerable (S3).

This species has been a candidate for listing as Threatened or Endangered under the endangered species act since the publishing of the Partial 90-Day Finding on a Petition to List 404 Species in the Southeastern United States as Endangered or Threatened with Critical Habitat in 2011 to the federal register (USFWS 2011). No species status assessment has been completed to determine the need to list this species.

POPULATION SIZE AND DISTRIBUTION

The Altamaha Arcmussel is an endemic species to Georgia in the Altamaha, Ocmulgee, Oconee, Ogeechee

and the Savannah River Basins. This species has only been found in the Savannah River and attached Thurmond Lake in South Carolina (Figure 2). Altamaha Arcmussel was once thought to be restricted to the Altamaha River system in Georgia (Johnson 1970). Now it is known from several rivers of the Altamaha River system in Georgia, including the Ocmulgee, Little Ocmulgee, Ohoopee, and Altamaha Rivers to the Ogeechee and Savannah River which is the border for Georgia and South Carolina. It was found in the Savannah River downstream of Augusta in 2006 (NatureServe 2024). Live individuals have been identified in the lower Savannah River as recently as 2011 (personal communication, Morgan Wolf USFWS). Individuals have also been found in Thurmond Lake (Clarks Hill Lake in GA) in 2007 and the lower Ogeechee River as recently as 2018 in surveys performed by Georgia DNR (Wisniewski 2018).

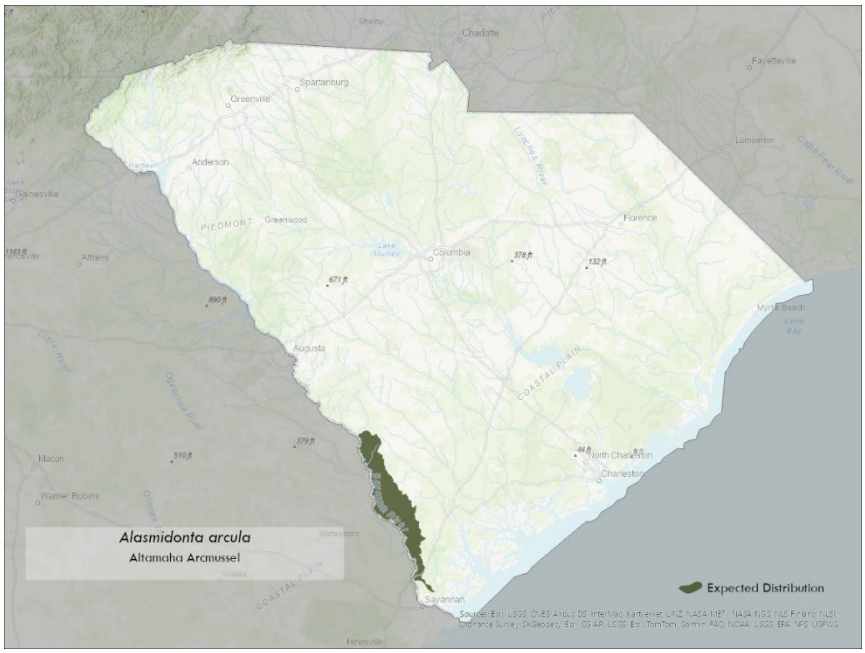

Figure 2. Expected distribution of *Alasmidonta arcula* based on reported observations at a HUC 10 watershed level and designated ecoregion.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Altamaha Archmussel is typically found in sloughs, oxbows, or depositional areas in large creeks, large rivers and reservoirs with silt, mud, and/or sand substrates. This species is often found in shallow areas near the water's edge and occasionally in pools with coarse sand and gravel from 6-9ft in depth in Georgia (Wisniewski 2018).

In South Carolina, the Altamaha Arcmussel has only been found in the Savannah River and connected lakes, and not in the surveyed tributaries in the Savannah Basin. No targeted efforts to survey this species in South Carolina have been made. Reported hosts include Eastern Mosquitofish (*Gambusia holbrooki*), Robust Redhorse (*Moxostoma robustum*), and Striped Jumprock (*Moxostoma rupiscartes*). More host fish research is needed for this species as both Robust Redhorse and Striped Jumprock showed low metamorphosis percentages in lab testing (Johnson et al. 2012). Testing of Eastern Mosquitofish reported only numbers of juveniles recovered and did not report transformation success; the life history of this surface-dwelling fish is unlikely to put them in contact with Altamaha Arcmussel in the wild (O'Brien 2002).

Johnson et al. (2012) report collecting gravid females in November at a temperature of 16°C. The reproductive cycle, brooding behavior, and glochidia release of *A. arcula* are understudied and attention is needed. Like other species in the Anodontini tribe, glochidia of the Altamaha Arcmussel are hooked and triangular, images can be seen in Johnson et al. (2012).

CHALLENGES

As it has only been documented in South Carolina recently, little is known about the habitat preferences, abundance, and population range of the Altamaha Arcmussel in South Carolina. Without opening its shell, Altamaha Arcmussel can resemble some forms of the Triangle Floater and may be misidentified during surveys. The Altamaha Arcmussel appears rare in South Carolina, but little work has been done to survey the Savannah River and non-wadable habitat in the larger Savannah Basin where this species can be found. Little is known about the reproductive and brooding behaviors of *A. arcula* and wild host fish(es) are unknown.

Like other freshwater mussels, the Altamaha Arcmussel is sensitive to changes in water quality, habitat, and access to host fish(es), although the degree of sensitivity to these changes is understudied. The host fish(es) for the Altamaha Arcmussel are unknown, but like other freshwater mussels, the Altamaha Arcmussel must have adequate access to species-specific hosts and relies on host fish(es) for reproduction and distribution. Maintaining stream connectivity for host fish(es) is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments for the species currently.

CONSERVATION RECOMMENDATIONS

- Conduct surveys to document the extent of distribution and population size and range of the Altamaha Arcmussel.
- Complete comprehensive, range-wide genetic analysis to determine the validity of the species alongside other species in the genus *Alasmidonta*.
- Determine habitats that are critical for this species in South Carolina.
- Perform host fish trials to determine natural hosts for native populations.
- Study interactions of laboratory host fish(es) in the wild.
- Conserve populations of host fish(es) to insure reproduction of the Altamaha Arcmussel in the wild.
- Protect critical habitats for the Altamaha Arcmussel from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Altamaha Arcmussel.
- Consider this species' needs when participating in the environmental permit review process.
- Encourage responsible land use planning.
- Work to improve minimum flows and restoration of more natural hydrologic regimes in the Savannah River.
- Research the reproductive and brooding behavior of the species.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Altamaha Arcmussel to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Completion of targeted surveys in areas of historic occupancy and similar habitat types in the Savannah Basin.
- Determine the host fish(es) and complete surveys in suitable habitat for host fish(es).
- Collection of genetic swabs of Altamaha Arcmussel and Triangle Floater to ensure successful identification of species range and distribution.

- Work to reduce or halt further disturbance to the habitat and natural hydrology of the Savannah River.
- Determine the effects of channel modification, such as dams, on the Altamaha Arcmussel.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determination of environmental and toxicological tolerances and endpoints.

Triangle Floater

Alasmidonta undulata (Say, 1817)

Contributor (2005): Jennifer Price (SCDNR)
Reviewed and Edited (2012): William Poly (SCDNR)
Reviewed and Edited (2024): Ericah Beason and Morgan Kern (SCDNR)

Figure 1. Image of *Alasmidonta undulata* photographed by Briana Cairco, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

Like many other freshwater mussel species in South Carolina, taxonomy in the genus *Alasmidonta* is still under revision. A recent study of the genus performed by Whelan et al. (2023) maintained *Alasmidonta undulata* as a separate species due to conflicting results. Future studies using additional nuclear models may support synonymy of *Alasmidonta arcula*, *Alasmidonta undulata*, and *Alasmidonta triangulata* (Whelan et al. 2023). Clarke (1981) notes that although there are morphological differences, the beak sculpturing, posterior slope sculpturing, and relative height are too irregular to suggest *A. undulata* and *A. triangulata* are separate species. Additionally, internal anatomy and glochidia of northern and southern populations were compared and no differences attributable to genetic divergence were evident (Clarke 1981). More studies are needed to determine the validity of *A. arcula*, *A. undulata*, and *A. triangulata*.

The Triangle Floater (Figure 1) is a small-shelled mussel that can grow to around 3 inches in length (Bogan and Alderman 2004, 2008). The umbo or beak is prominent and raised above the hingline (Figure 1). A posterior ridge is present and distinct. The Triangle Floater has prominent, triangular shaped pseudocardinal teeth, but lacks lateral teeth. The exterior shell surface is smooth and shiny, yellowish/greenish with broad green or blackish rays, becoming black with age. The shell has strong ridges that run parallel with the growth lines. The shell of the Triangle Floater is subtriangular to ovate. The shell is thicker at the anterior end than at the posterior. The interior shell surface is white but includes salmon pink or red anteriorly and becomes iridescent posteriorly (Bogan and Alderman 2004, 2008; Nedeau 2008; Clarke 1981).

As with many of our native freshwater mussels, Triangle Floater can be easily misidentified especially when the individual is still living. They can closely resemble the sister species, the Altamaha Arcmussel. The shell of the Triangle floater has varying morphology, the subtriangular morphology closely resembles Altamaha Arcmussel, but lacks lateral teeth.

Status

The current global status for the Triangle Floater is apparently secure (G4) due to the wide range of this species (NatureServe 2024). In North Carolina and Virginia, it is ranked as vulnerable (S3) and in West Virginia it is ranked as critically imperiled (S1). It is ranked as critically imperiled (S1?) in South Carolina with a conservation priority ranking of data deficient because of insufficient data collection and targeted surveys. Most reported observations of the species are from surveys in the Savannah River which were completed by Georgia. The Savannah River, and other non-wadeable streams and reservoirs have historically not been thoroughly surveyed by South Carolina state partners.

POPULATION SIZE AND DISTRIBUTION

The range of the Triangle Floater extends from the St. Lawrence River Basin in Ontario and Quebec to the Ogeechee Basin in Florida (Bogan and Alderman 2004, 2008). Throughout its range it is found in a variety of habitat types from small creeks to large rivers and lakes, with sand, fine gravel, sandy mud, or silt as a substrate. It is found in the Neuse River Basin, Tar River Basin, Roanoke River Basin, Chowan River Basin, and PeeDee Basin in North Carolina and has not been reported in Georgia. In South Carolina, a shell of Triangle Floater was found in Turkey Creek in a 2005 survey conducted by Alderman Environmental. A live specimen was found in the Savannah River in 2006 by Tim Savidge in Jasper County. The Triangle Floater has not been reported in South Carolina since 2006. Expected distribution of the species can be seen in Figure 2. Bogan and Alderman (2004, 2008) identify the Santee-Cooper drainage as part of the Triangle Floater's historic range. Targeted survey efforts for this species in South Carolina have not occurred.

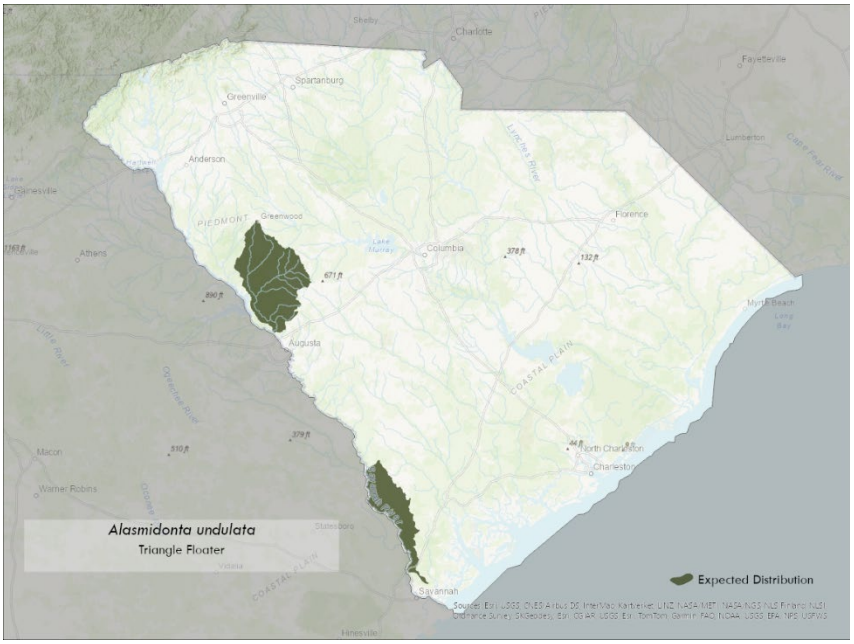

Figure 2. Expected distribution of *Alasmidonta undulata* based on reported observations at a HUC 8 watershed level and designated ecoregion.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The Triangle floater is reported to show little habitat preference in North Carolina being collected from silt/sand in slower waters, gravel/sand in riffles and runs, and crevices in bedrock (NCWRC 2024). Historically, it was reported to be common in sections of moderate flow in small rivers and headwater streams (Bogan and Alderman 2004). Ortmann (1919) and Clarke (1981) note that the species is not typically found in large waters and prefers smaller, headwater streams or outlet streams just below lakes. Host fish trials have occurred in the grey literature for this species from the work of Barry Wicklow and Tom Watters' lab at Ohio State. Blacknose Dace, Slimy Sculpin, Common Shiner, Central Stoneroller, Rosyface Shiner, Northern Hogsucker, Pumpkinseed, Largemouth Bass, Fantail Darter, Fallfish, and Longnose Dace produced animals (Fichtel and Smith 1995; Watters 1999; Maine 2000; Nedeau et al. 2000). No metamorphosis percentage was reported on the fish species tested.

Clarke (1981) noted gravid females being collected from August-October; however, glochidia from the gravid female collected in August possessed short, blunt stylets and soft, pliable microstylets which was likely due to being immature. Ortmann (1912) described the breeding season being from July until June of the following year. Of the specimens found, he reported animals found in July having eggs and animals (only 2) found in June having mature glochidia. North Carolina reports only finding gravid females during cooler months of the year (NCWRC

2024). Ortmann (1912) describes the outer demibranchs of female *A. undulata* being pale yellow when containing eggs and brownish when containing glochidia. The reproductive cycle, brooding behavior, and glochidia release of *A. undulata* are understudied and attention is needed. Like other species in the Anodontini tribe, glochidia of the Triangle Floater are hooked and triangular; images can be seen in Clarke (1981).

CHALLENGES

Without opening its shell, Triangle Floater can resemble some forms of the Altamaha Arcmussel. and may be misidentified during surveys. Unsettled taxonomy also makes determining short- and long-term population trends difficult. The Triangle Floater appears rare in South Carolina, but little work has been done to survey the Savannah River and non-wadable habitats in the larger Savannah, PeeDee and Santee-Cooper basin where this species may be found.

Like other freshwater mussels, the Triangle Floater is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. The Triangle Floater must have adequate access to species-specific hosts, like other native freshwater mussel species, and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

There are no significant conservation accomplishments for the species currently.

CONSERVATION RECCOMENDATIONS

- Conduct additional surveys in reservoirs in the Pee Dee Basin, Savannah Basin, and Santee-Cooper collecting genetic swabs to determine Triangle Floater presence and abundance in this state.
- Complete comprehensive, range-wide genetic analysis to determine the validity of the species alongside other species in the genus *Alasmidonta*.
- Explore the need to determine special concern status for the Triangle Floater based on survey results.
- Protect critical habitats for the Triangle Floater from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Triangle Floater.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Work to improve minimum flows and restoration of more natural hydrologic regimes in river systems with suitable habitat for Triangle Floater.
- Perform host fish trials to determine natural hosts for native populations.
- Research the reproductive and brooding behavior of the species.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Triangle Floater to various point and non-point sources of pollution and land use impacts.

MEASURES OF SUCCESS

- Completion of targeted surveys in areas of historic occupancy and similar habitat types in the PeeDee Basin, Savannah Basin, and Santee-Cooper.
- Collection of genetic swabs of Triangle Floater and Altamaha Arcmussel to ensure successful identification of species range and distribution.
- Work to reduce or halt further disturbance to the habitat and natural hydrology in river systems with suitable habitat for Triangle Floater.
- Perform outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Determine the effects of channel modification, such as dams, on the Triangle Floater
- Determination of environmental and toxicological tolerances and endpoints.

Brook Floater

Alasmidonta varicosa
(Lamark, 1819)

Figure 1. Image of hatchery produced *Alasmidonta varicosa* photographed by Briana Carico, SCDNR.

DESCRIPTION

Taxonomy and Basic Description

The Brook Floater (Figure 1 and Figure 2) is a small mussel that rarely exceeds 3 inches in length. The Brook Floater has a series of corrugations (or raised ridges) along the upper posterior slope, perpendicular to the growth lines. These corrugations may be difficult to see on young, eroded, stained individuals or mussels that are covered with algae. The pseudocardinal teeth are poorly developed and lateral teeth are absent. The outer surface is generally smooth except on the posterior slope; the anterior margin is abruptly curved, the ventral margin long, and shells are gently concave centrally. The color of the shell is yellowish, greenish, turquoise, or covered with dark greenish rays in juveniles. The outer surface becomes brownish with rays partially obscured or almost black in some adults. The shell of the Brook Floater is oblong, long, and rhomboid. The inner shell surface is whitish or bluish-white often with salmon, pink or purple in the beak cavity. Maximum shell length for this species is 70 mm (2.8 in.) (Bogan and Alderman 2004, 2008; Nedeau 2008).

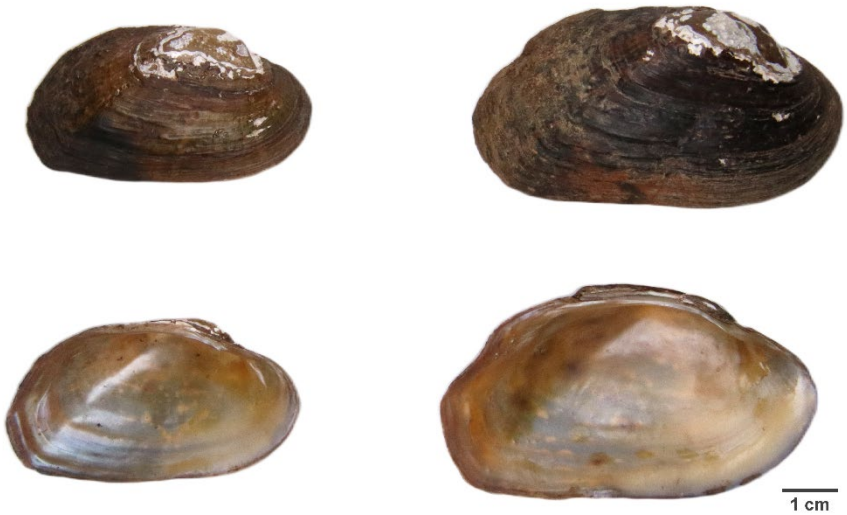

Figure 2. Image of wild *Alasmidonta varicosa* photographed by Briana Cairco, SCDNR.

Brook Floaters are distinct but can be confused with Creeper (*Strophitus undulata*) which has a similar shape with poorly developed pseudocardinal teeth. Creeper mussels lack corrugations and are boxier in appearance.

Status

The current global status for the Brook Floater is vulnerable (G3); it is ranked critically imperiled to imperiled (S1S2) in South Carolina (NatureServe 2024). This species has been a candidate for listing as Threatened or Endangered under the endangered species act since the publishing of the Partial 90-Day Finding on a Petition to List 404 Species in the Southeastern United States as Endangered or Threatened with Critical Habitat in 2011 to the federal register. A species status assessment was completed and a finding of not warranted for listing as endangered or threatened was published to the federal register in 2019 (USFWS 2019).

POPULATION SIZE AND DISTRIBUTION

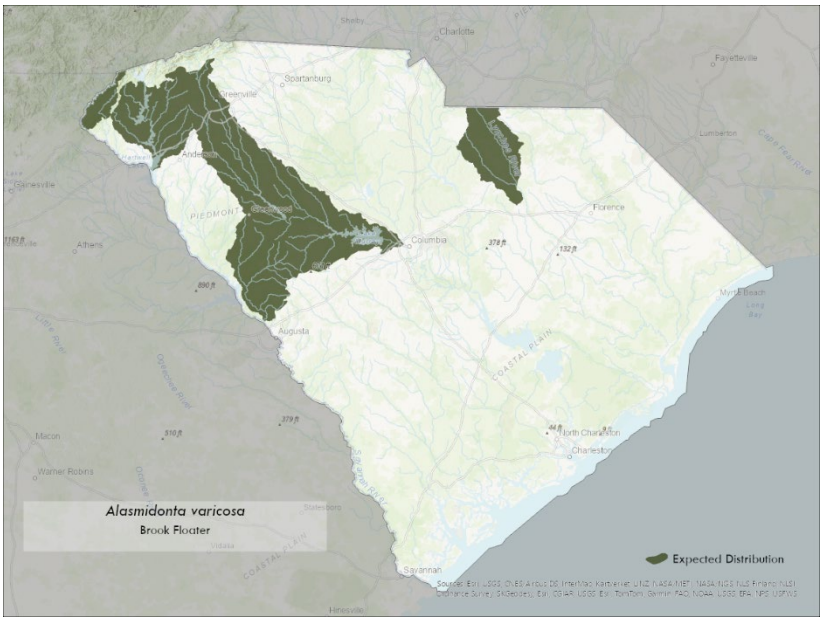

Figure 2. Expected distribution of *Alasmidonta varicosa* based on reported observations at a HUC 8 level and designated ecoregion.

The Brook Floater is found along the East Coast from eastern Canada to the Savannah River basin in South Carolina and Georgia. In South Carolina, it also occurs in Flat Creek and the Lynches River; however, this species is becoming increasingly rare in this system (Figure 2). No live animals were found in the Lynches during recent surveys. In the Savannah basin it is found in several streams in the Steven's Creek watershed but is often rare, with only one or two animals recovered at a site. While the historic range in the Savannah basin included more of the piedmont and blue ridge regions in South Carolina, recent surveys were unable to locate living animals in the upper Savannah basin outside of the Chattooga River. The Brook Floater population in the Chattooga River on the South Carolina/Georgia state line is possibly the second largest on the Atlantic Slope and appears stable.

HABITAT AND NATURAL COMMUNITY REQUIREMENTS

The main population of Brook Floater in South Carolina is found in the Chattooga River that borders South Carolina and Georgia. The Chattooga is a high relief stream where Brook Floater can be found among boulders in sand or along the banks. In smaller streams Brook Floater has been found in riffles in mixed cobble or boulders in South Carolina. In the North Atlantic slope, this species inhabits streams and rivers of varying sizes, but ones that usually have low to moderate flow velocities and stable substrates. While absent from reservoirs or lakes, this species may inhabit the upstream end of small impoundments created by run-of-river dams.

In South Carolina, gravid females have been collected in February and March. Reported hosts include Golden Shiner, Longnose Dace, Margined Madtom, Yellow Perch, Slimy Sculpin, Pumpkinseed, Blacknose Dace, Tessellated Darter, and Bluegill. No studies have confirmed how well laboratory results relate to the availability of hosts or parasitism under natural conditions. (Schulz and Marbain 1998; Fichtel and Smith 1995; Nedeau 2008).

CHALLENGES

While a strong population of Brook Floater exists in the Chattooga River with habitat on US Forest Service owned land, we have seen a recent reduction in populations in the Pee Dee and lower Savannah Basin.

Like other freshwater mussels, the Brook Floater is sensitive to changes in water quality, habitat, and access to host fishes, although the degree of sensitivity to these changes is understudied. Like other freshwater mussels, the Brook Floater must have adequate access to species-specific hosts and relies on host fishes for reproduction and distribution. Maintaining stream connectivity for host fishes is important to allow

distribution of juveniles and gene flow between populations. Environmental stressors that lead to degradation of water quality, habitat, and stream connectivity include development, agriculture, and incompatible forestry management; additionally, systemic changes that have negative effects include climate change, invasive species, and dams and barriers (USFWS 2021).

In South Carolina, practices such as mining, clearcutting for timber production, and recreational vehicle use in streams are observed to result in degradation of habitat. Preservation of a riparian buffer is needed for the continued existence of suitable habitat for most native freshwater mussels. A riparian buffer is the land area adjoining a stream, lake or wetland characterized by a cover of naturally occurring vegetation consisting of trees, shrubs, grasses, and forbs where development is restricted or prohibited.

CONSERVATION ACCOMPLISHMENTS

The Brook Floater is a species of federal concern and has been included in a petition for listing as a Federally Threatened or Endangered species (USFWS 2011). As such, the US Fish and Wildlife Service may conduct a status survey to determine its range and abundance to evaluate its status as a potential candidate for federal listing.

Propagation of this species using brood stock collected from the Chattooga River has been attempted in South Carolina resulting in 12 animals being stocked into Turkey Creek in October 2019. SCDNR completed propagation of the species in 2023 and examined a 21.6% metamorphosis success on Bluegill fish.

South Carolina has partnered with other states in the species range to aid in the conservation of Brook Floater in the Competitive State Wildlife Grants Grant: Advancing Conservation and Restoration of Brook Floater and Associated Freshwater Mussels.

CONSERVATION RECOMMENDATIONS

- Continue monitoring populations of Brook Floater in South Carolina.
- Continue conducting genetic investigations, particularly to compare Brook Floater populations in the Lynches River and Steven's Creek Basins if possible.
- Protect Brook Floater habitat, critical for their survival from future development and further habitat degradation by following best management practices and protecting and purchasing riparian areas, especially those portions along Flat Creek in the Lynches River drainage.
- Conserve populations of host fish to insure propagation of the Brook Floater in the wild.
- Consider propagation efforts to augment declining populations.
- Promote land stewardship practices through educational programs both within critical habitats with healthy populations and in other areas that contain available habitat for the Brook Floater.
- Encourage responsible land use planning.
- Consider this species' needs when participating in the environmental permit review process.
- Educate off-road motor vehicle operators of the negative effects of crossing streams at multiple locations and using stream bottoms as trails.
- Conduct further research to determine the degree of sensitivity of the Brook Floater to various point and non-point sources of pollution and land use impacts.
- Study interactions of laboratory host fishes in the wild.

MEASURES OF SUCCESS

- Protecting land and maintaining healthy riparian habitat adjacent to streams with populations of Brook Floaters will indicate some success.
- Outreach to relevant landowners about the importance of freshwater mussels and their habitats.
- Development of species-specific restoration plan based on the results of routine monitoring and the implementation of that plan for augmentation.

- Monitoring of wild populations of the species that show stabilization or an increase in the size of South Carolina's populations of the Brook Floater.
- Determine the effects of channel modification, such as dams, on the Brook Floater.
- Determination of environmental and toxicological tolerances and endpoints.
